*These clinical signs may occur concomitantly in the same patient. The collective term used to describe these signs is "pseudopancreatitis."

Significant hyperlipidemia characterized by lipemic serum and hypertriglyceridemia has been observed as an incidental finding in fasted adult dogs and cats. The absence of clinical signs at the time of presentation does not justify ignoring the significance of the lipemia. Because of the risks associated with hypertriglyceridemia, patients that behave normally but have persistent lipemia should be managed in the same manner as

Figure 28-4. Lipemia retinalis in a cat with hyperlipidemia. Note the white, milky appearance of the retinal blood vessels.

Box 28-1. Handling Lipemic Samples.

Submission of lipemic blood to a commercial laboratory necessitates knowing how the sample will be processed. Because of the interference induced by lipemia, some laboratories will simply reject lipemic samples. Many laboratories, however, will attempt to clear lipemic serum (by removing chylomicrons) before performing any biochemical assays. Unfortunately, there is neither a standardized method for clearing lipemic serum nor do commercial laboratories consistently report whether or not an attempt was made to clear the sample. For veterinarians, however, knowledge of the fact that a lipemic sample was cleared before determining the triglyceride concentration is critical in making reasonable interpretations. Although clearing a lipemic sample eliminates interference associated with chylomicrons, it effectively eliminates a critical element of clinical information (i.e., that the patient is hypertriglyceridemic).

Ideally, two aliquots of a serum sample from a lipemic patient should be submitted simultaneously. One sample, if effectively cleared, can be used to perform routine biochemical testing, including triglyceride levels. Determining triglyceride concentrations in the second, lipemic (uncleared) sample documents the true extent of triglyceride excess, serves as an important baseline value for assessing response to therapy and can, when compared to the triglyceride value in the cleared sample, characterize the nature of the hyperlipidemia.

those presenting with clinical signs.

Hyperchylomicronemia is confirmed in fasted dogs with lipemic serum, hypertriglyceridemia (in uncleared serum) greater than 500 mg/dl and a positive chylomicron test. Clinical signs are not prerequisite for diagnosis nor for recommending therapeutic intervention. However, therapy in dogs that do not have associated signs is generally reserved for those having fasting hypertriglyceridemia on two consecutive samples two to four weeks apart.

Chylomicrons will normally appear in the serum of dogs and cats within 30 minutes to one hour after ingestion of a meal containing fat. This finding is associated with a transient (i.e., six to 12 hours) increase in serum triglycerides after which triglyceride levels rapidly return to baseline values. Physiologic hyperlipidemia is easily excluded from consideration if the patient is known to have fasted throughout the 12-hour period before blood collection. In normal, postprandial animals, serum turbidity is associated with a modest elevation of serum triglycerides (from 150 to 400 mg/dl) that typically returns to normal within 10 hours.

Lipoprotein Electrophoresis

Lipoprotein electrophoresis (LPE) has been used as a means of characterizing abnormalities in lipid metabolism (Ford, 1993; Armstrong and Ford, 1989; Whitney, 1992). The value of LPE has been in question in human medicine for several years and is justifiably questioned in veterinary medicine. Compared to the quantitative assays currently available, LPE appears to have limited value in the clinical evaluation of lipid disorders in dogs and cats.

The Chylomicron Test

Knowing that the patient has fasting lipemia provides immediate evidence of hypertriglyceridemia. The lipid disorder may be further characterized by performing a simple, in-hospital test for the presence of chylomicrons. The lipemic serum, separated from red cells, is refrigerated and allowed to stand undisturbed for six to 12 hours. Chylomicrons, if present, will float to the surface of the sample forming an opaque "cream layer" over a clear infranatant (**Figure 28-5**). This finding suggests a disorder of chylomicron metabolism, the most common form of hyperlipidemia in dogs. If the sample remains turbid, but doesn't form a cream layer, retention of very low-density lipoproteins (VLDL), rather than chylomicrons, is suggested. This finding also suggests that the hyperlipidemia is secondary to an underlying disorder. In some dogs, particularly poorly regulated diabetics, a cream layer may form over turbid, lipemic serum suggesting retention of chylomicrons and VLDL (Armstrong and Ford, 1989; Chapman, 1980).

Risk Factors

Familial (primary) hyperchylomicronemia in cats has been reported as an autosomal recessive trait limited to certain lines of cats. The trait is thought to be present in mixed-breed cats throughout much of the world; therefore, clinically affected cats appear sporadically. Certain dog breeds, most notably

miniature schnauzers, are also at increased risk of clinical illness associated with hypertriglyceridemia characterized by the inability to degrade chylomicrons. Though not definitively proven, familial traits are thought to cause these disorders. Results of a limited survey of healthy adult dogs suggested that primary hypercholesterolemia might occur within some families of Doberman pinschers, rottweilers,[a] Shetland sheepdogs (Sato et al, 2000), rough collies (Jeusette et al, 2004) and briards (Watson et al, 1993).

Secondary risk factors (i.e., particularly endocrine disorders, certain drugs and possibly certain diets leading to hyperlipidemia) are known to occur but have not been well studied. For example, profound fasting hypertriglyceridemia occurs inconsistently in dogs with unregulated diabetes mellitus. Clinical signs associated with excess triglyceride concentrations typically include vomiting, diarrhea and abdominal discomfort. Approximately 30% of untreated hypothyroid dogs and from 25 to 30% of untreated dogs with pituitary-dependent hyperadrenocorticism have excess serum cholesterol concentrations. However, the relationship between clinical signs, if any, and the hyperlipidemia has not been established.

Obesity is known to cause abnormalities of lipid metabolism in people. Experimentally induced chronic obesity in otherwise normal dogs fed a complete and balanced maintenance food resulted in significantly higher concentrations of cholesterol in total plasma (+41%) and in VLDL (+125%), HDL (+45%) and low-density lipoprotein (LDL) (+58%) fractions and significantly higher concentrations of triglycerides in total plasma (+75%) and in the VLDL (+118%). When switched to a low-energy, high-fiber diet that resulted in overall decreased energy intake, plasma lipid values decreased (Jeusette et al, 2005).

In some animals, drugs are known to either decrease lipoprotein degradation or increase lipoprotein production, thereby causing hyperlipidemia. For example, dogs receiving long-term phenobarbital therapy for regulation of idiopathic epilepsy may develop hypercholesterolemia. The clinical significance is unknown and may, in fact, be related to thyroid-hormone production or activity. Cats receiving megestrol acetate may secondarily develop diabetes mellitus, which may culminate in altered lipoprotein lipase activity and hyperchylomicronemia.

Etiopathogenesis

Normal Lipid Metabolism

LIPOPROTEINS

Cholesterol and triglycerides are hydrophobic molecules; therefore, they cannot circulate in the aqueous milieu of blood without being incorporated into complex, spherical macromolecules called lipoproteins (Brown and Goldstein, 1987; Chapman, 1980; Schaefer and Levy, 1985; Weinberg, 1987; Watson and Barrie, 1993). The water-soluble outer coat of the lipoprotein is comprised of phospholipids, nonesterified (free) cholesterol and several unique proteins called apolipoproteins (**Figure 28-6**). Cholesterol, in the form of cholesterol esters, and triglycerides are carried within the nonpolar core of spherical lipoprotein macromolecules. Abnormally high concentra-

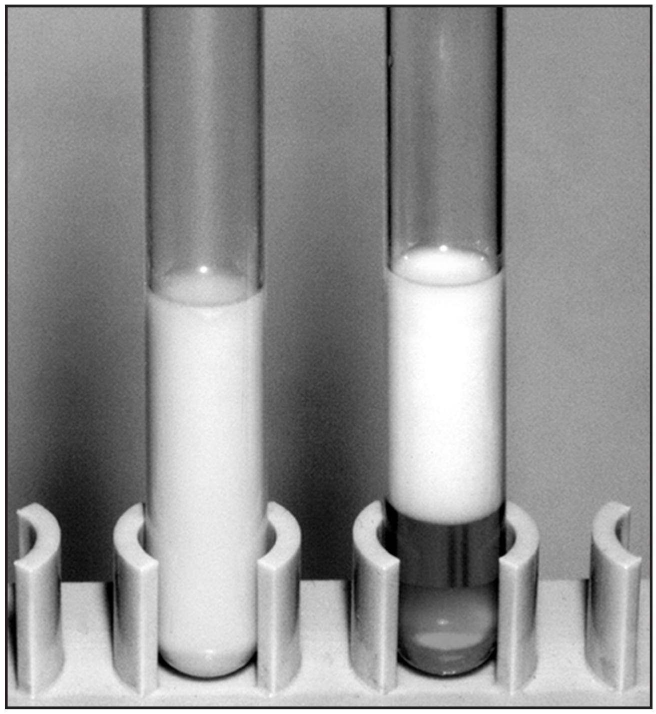

Figure 28-5. The positive chylomicron test. The lactescent serum in both tubes was obtained from a dog with hypertriglyceridemia. The sample on the left is the serum immediately after separation from the red blood cells whereas the sample on the right was allowed to stand undisturbed for 10 hours. The so-called "cream layer" is comprised of triglyceride-rich chylomicrons. (Reprinted with permission from Ford RB. Canine hyperlipidemia. In: Ettinger SJ, Feldman EC, eds. Textbook of Veterinary Internal Medicine, 4th ed. Philadelphia, PA: WB Saunders Co, 1995; 1417.)

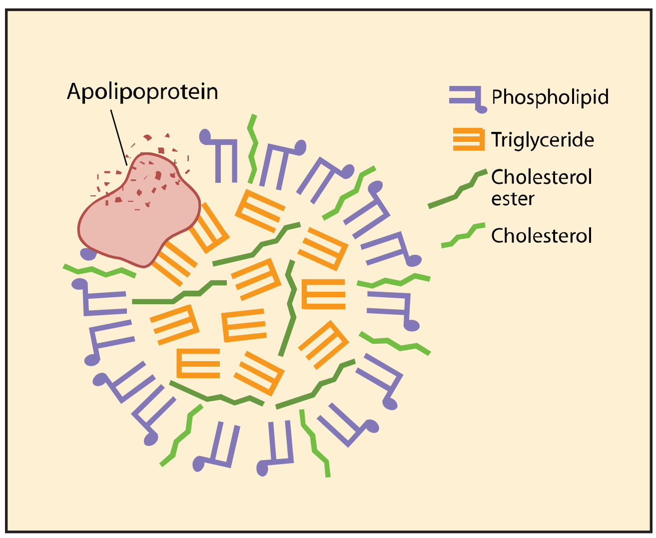

Figure 28-6. Diagram illustrating the composition and structure of lipoproteins. Cholesterol and triglycerides comprise much of the lipoprotein core and are present in varying proportions. (Adapted from Brody T, ed. Nutritional Biochemistry. New York, NY: Academic Press Inc, 1994; 276.)

tions of cholesterol or triglycerides, as measured in routine biochemical assays, actually reflect increased synthesis or decreased degradation of lipoproteins.

APOLIPOPROTEINS

It is well recognized that the apolipoproteins (commonly referred to as apoproteins), contained within the outer coat of lipoproteins, bind to specific enzymes or transport proteins on cell membranes (Brown and Goldstein, 1987; Chapman, 1980; Naito, 1986). Thus, they are responsible for directing the lipoprotein to various sites of metabolism. Several apoproteins have been recognized in dogs and cats. Abnormalities or deficiencies in specific apoproteins are likely to be responsible for altered lipoprotein metabolism that culminates in hyperlipidemia.

Apoprotein C-II (also called apo C-II) (**Figure 28-6**) activates lipoprotein lipase and is very much involved in triglyceride metabolism during the postprandial period. An inherited deficiency in apo C-II is one of the proposed mechanisms responsible for hyperchylomicronemia in dogs.

Classes of Lipoproteins

Four major lipoprotein classes in dogs and cats can be separated by preparative nonionic precipitation and ultracentrifugation: 1) chylomicrons, 2) VLDL, 3) LDL and 4) HDL (Mahley et al, 1974; Armstrong and Ford, 1989; Barrie et al, 1993). A comprehensive lipoprotein profile consists of determining the concentration (mg/dl) of triglycerides and cholesterol in each lipoprotein class. Through lipoprotein profiling, it is possible to categorize hyperlipidemic patients according to lipoprotein phenotype, facilitate diagnosis of primary and secondary lipid disorders and even prescribe therapy. Unfortunately, uniform standards for performing lipoprotein profiles are not commercially available. Alternatively, laboratory determinations of total cholesterol and triglycerides are routinely available and can be used to make good diagnostic and therapeutic decisions.

CHYLOMICRONS

The largest and least dense lipoprotein particles are chylomicrons. These large, triglyceride-rich lipoprotein complexes transport dietary fat (triglycerides) from the small intestine via the lymphatics and general circulation to various sites of metabolism. Appearing in plasma within one hour after consumption of a fat-containing meal, chylomicrons can be visually confirmed as turbid or cloudy serum, a finding that corresponds to a transient (i.e., six to 12 hours postprandial), physiologic hypertriglyceridemia. A cream layer comprised of chylomicrons may form over a clear infranatant if serum is allowed to stand undisturbed for six to 10 hours.

In dogs, and probably cats, only about 10% of the lipid contained in chylomicrons is cholesterol (cholesterol ester). After a meal, hypertriglyceridemia is associated with transient increases in serum cholesterol that may exceed the normal reference range.

Chylomicrons transport fat to the capillaries of adipose tissue and skeletal muscle where they are exposed to the enzyme lipoprotein lipase. The enzyme, once activated by apo C-II, hydrolyzes triglycerides into glycerol and free fatty acids. What remains of the chylomicron is a remnant particle, rich in cholesteryl esters, that subsequently delivers cholesterol to the liver (Schaefer and Levy, 1985; Weinberg, 1987; Gotto, 1988; Eckel, 1989). Chylomicron hydrolysis is normally complete within six to 12 hours following a meal, after which the plasma will again become clear. Fasting hyperchylomicronemia is an abnormal condition resulting from decreased clearance of chylomicrons in the circulation. It is recognized in dogs, cats and people. Although clinical manifestations recognized in dogs are quite different from those in cats, hyperchylomicronemia is the most common lipid disorder recognized in companion animals.

VERY LOW-DENSITY LIPOPROTEINS

Produced in the liver and containing a predominance of triglycerides, VLDL are transported to tissue capillaries where they are catabolized by lipoprotein lipase in the same manner as chylomicrons (Brown and Goldstein, 1987; Eckel, 1989). Retention of VLDL, and the resulting hypertriglyceridemia, occurs frequently in dogs with insulin-dependent diabetes mellitus. Although serum turbidity is manifest in the fasted patient, a cream layer will not separate when the sample is left undisturbed, even when refrigerated.

LOW-DENSITY LIPOPROTEINS

Like VLDL, LDL is responsible for transporting endogenously synthesized lipids (especially cholesterol) from the liver to target tissues. Subsequent to the hydrolysis of VLDL and the removal of triglycerides from its core, a short-lived intermediate-density lipoprotein is ultimately processed by hepatic lipase to form LDL. Delivery of LDL to peripheral tissues is facilitated by the interaction of the structural protein of LDL with a specific receptor, called the LDL receptor. In people, approximately 70% of total cholesterol is carried within LDL, which is sometimes referred to as the atherogenic lipoprotein (Mahley et al, 1974). However, most cholesterol in dogs and cats is carried on HDL.

HIGH-DENSITY LIPOPROTEINS

Newly formed HDL, secreted by the liver and the intestine, binds with unesterified cholesterol released from peripheral tissues during normal cellular turnover (Brown and Goldstein, 1987; Barrie et al, 1993; Gotto, 1988; Eckel, 1989). The conversion process from nascent HDL to mature, spherical HDL particles is mediated by the enzyme lecithin-cholesterol acyltransferase (LCAT) (Brown and Goldstein, 1987; Gotto, 1988). As members of the antiatherogenic lipoprotein family, HDL is recognized for its ability to remove excess cholesterol from tissues and transport it to the liver.

A number of subgroups of HDL have been recognized in people (HDL_2 and HDL_3) (Brown and Goldstein, 1987) and dogs (HDL_1 and HDL_2) (Mahley et al, 1974; Rogers et al, 1975, 1975a). In both dogs and cats, a large HDL molecule (HDL_1) is formed as HDL acquires free cholesterol and expands under the influence of LCAT. However, the actual role of HDL subgroups in predicting or diagnosing disease in ani-

mals has not been defined. Because commercial laboratories do not routinely isolate HDL subgroups, subgroup analyses in veterinary medicine have not been found to have immediate application in clinical practice.

Classification of Hyperlipidemic States

Hyperlipidemic states can be classified as postprandial, familial or acquired. Familial hyperlipidemia, also called primary hyperlipidemia, refers to those defects in lipoprotein metabolism that are known or suspected to be inherited. Fasting lipemia is frequently recognized in miniature schnauzers and is possibly linked to a familial defect in chylomicron metabolism. Feline hyperchylomicronemia is the only hyperlipidemic state proven to be familial (Jones and Watson, 1995; Jones et al, 1983; Jones, 1993, 1995).

Acquired hyperlipidemia, also called secondary hyperlipidemia, refers to an excess concentration of lipid in blood resulting from an underlying disease in which normal lipoprotein metabolism is markedly altered. Several endocrine diseases alter lipid metabolism leading to secondary hyperlipidemia. For example, insulin-deficient states alter carbohydrate and lipid metabolism. Animals with insulin-dependent diabetes mellitus may have either hypertriglyceridemia or hypercholesterolemia. Hyperadrenocorticism, renal disease and hypothyroidism are variably associated with secondary hyperlipidemia (Ford, 1996; DeBowes, 1987; Whitney, 1992; Barrie et al, 1993; Rogers, 1977; Zerbe, 1986).

In clinical practice, it is not unusual to encounter a patient with both primary and secondary hyperlipidemia. A miniature schnauzer presented with diabetes mellitus is likely to have extreme elevations in serum triglycerides and lactescent serum. From the clinician's perspective, hyperlipidemia, whether primary or secondary, can be associated with undesirable clinical effects. The ability to recognize the signs associated with hyperlipidemia and to make appropriate dietary or therapeutic recommendations becomes fundamental to the management of these cases.

Postprandial Hyperlipidemia

Triglycerides are the predominant dietary fat in pet food. Subsequent to consuming a meal, dogs and cats will experience transient, physiologic hyperlipidemia characterized by increased triglyceride concentration (circulating chylomicrons) and, depending on the amount of fat consumed, serum turbidity (lipemia). However, postprandial hyperlipidemia does not necessarily imply that a disorder of lipid or lipoprotein metabolism exists. In normal dogs and cats, postprandial hyperlipidemia normally persists from six to 12 hours after a meal. Even when a high-fat food is consumed, serum triglyceride levels are not expected to exceed 500 mg/dl in normal animals. In dogs and cats, hyperlipidemia associated with serum triglyceride levels greater than 1,000 mg/dl, whether fasted or not, is likely to result from an underlying disorder of lipid metabolism (Ford, 1996). Because chylomicrons carry only a fraction of circulating cholesterol, consumption of a meal has little impact on cholesterol during the six- to 12-hour postprandial period.

Postprandial hyperlipidemia, although physiologic, must be distinguished from intrinsic causes (primary or secondary). Confirming that a hyperlipidemic patient has fasted for 10 to 12 hours before collection of blood effectively excludes a recent meal as the cause for increased blood lipids and, therefore, justifies further evaluation in an attempt to determine the source of the hyperlipidemic state.

Canine Familial Hyperchylomicronemia

Hypertriglyceridemia, particularly that associated with retention of chylomicrons, is the most prevalent lipid disorder recognized in dogs and cats and is associated with the greatest health risk (Ford, 1993, 1995). In dogs, the precise mechanism has not been elucidated; however, this disorder of lipoprotein metabolism is believed to be caused by either the lack of lipoprotein lipase activity or the absence of apo C-II (Brown and Goldstein, 1987; Schaefer and Levy, 1985; Gotto, 1988; Zerbe, 1986). Several reports have been published suggesting that miniature schnauzers are predisposed to primary or familial hyperlipidemia (Ford, 1993, 1995, 1996; Rogers et al, 1975; Rogers, 1975a). Although it is not definitively known that hyperlipidemia is an inherited disorder of miniature schnauzers, there appears to be a higher than expected prevalence of hypertriglyceridemia in the breed (Ford, 1993).[a] Several other purebred and mixed-breed dogs have been identified as having fasting hyperchylomicronemia with significant clinical illness, but have no detectable underlying disease.

Canine Idiopathic Hypercholesterolemia

Results of a limited survey of healthy, adult dogs suggested that primary hypercholesterolemia might occur within some families of Doberman pinschers and rottweilers (Armstrong and Ford, 1989). A relationship between the presence of peripheral corneal dystrophy, regarded by some ophthalmologists as containing cholesterol, and excess serum cholesterol concentration (>300 mg/dl) is of noteworthy interest. Lipoprotein profiles of affected dogs demonstrate elevations of LDL-cholesterol.[a] To date, no studies have demonstrated whether or not administration of cholesterol lowering drugs (e.g., fibrates, statins) would either decrease the cholesterol concentration of hypercholesterolemic dogs or cause regression of the corneal dystrophy. Dietary management with a low-fat veterinary therapeutic food was successful in treatment of bilateral lipid keratopathy in one dog (Linton et al, 1994). In a family of rough collies, treatment with a low-fat, energy-restricted food had no effect on serum total cholesterol or corneal lipidosis. The addition of short-chain fructooligosaccharides resulted in regression of corneal lipidosis, but had a variable and transient effect on total serum cholesterol (Jeusette et al, 2004).

Occasionally, extreme elevations of cholesterol will be discovered incidentally in healthy, adult dogs with normal triglyceride values. The clinician is justified in evaluating the patient for evidence of an underlying disorder, such as diabetes mellitus or hyperadrenocorticism. However, in some dogs, hypercholesterolemia cannot be explained. Unless clear evidence of underlying disease exists, treatment specifically intended to lower serum cholesterol does not appear warranted.

Table 28-2. Key nutritional factors for hyperlipidemia.

Disorder	Factor	Dietary recommendations
Hyperlipidemia	Triglycerides	Feed a food that reduces serum triglycerides Restrict dietary fat (<12% dry matter [DM]) Feed a food that reduces serum triglycerides and binds cholesterol and bile acids Increase dietary fiber: Dogs: ≥10% DM Cats: ≥7% DM Add lipid-reducing drugs (fibrates) if dietary management alone is unsuccessful in controlling hyperlipidemia

Feline Inherited Hyperchylomicronemia

A primary, genetic disorder of young cats was found to alter chylomicron metabolism (Jones et al, 1983). Cats that had inherited this disorder developed a form of hyperlipidemia similar to that reported to occur in miniature schnauzers.

Secondary Disorders of Lipid Metabolism

Considering the prevalence of metabolic diseases that affect lipid metabolism, it is possible that secondary hyperlipidemia affects more animals than primary hyperlipidemia. Several endocrine diseases, as well as renal and hepatic diseases, variably alter lipoprotein metabolism resulting in either hypertriglyceridemia or hypercholesterolemia.

DIABETES MELLITUS

Hyperlipidemia secondary to diabetes mellitus in dogs and cats may be characterized by hypertriglyceridemia and moderate hypercholesterolemia (Ford, 1996; Armstrong and Ford, 1989; Barrie et al, 1993). In insulin-deficient states, clearance of chylomicrons is impaired due to insufficient activation of lipoprotein lipase in vascular endothelial cells by insulin (Brown and Goldstein, 1987). Examination of lipid profiles of diabetic dogs reveals lipemia, an increase in chylomicrons and VLDL and a corresponding increase in triglyceride concentration. In some diabetic dogs, excess serum cholesterol concentrations will be present independent of hypertriglyceridemia. In one study, diabetic dogs did not have cholesterol levels significantly different from those of a control population (Barrie et al, 1993). LDL-cholesterol, on the other hand, was increased presumably as a result of increased LDL synthesis. The clinical significance of this finding is unknown.

Although a relationship between the quality of glucose regulation and serum triglyceride levels has been recognized in people, it is unknown whether a similar relationship exists in dogs and cats. Lipemia retinalis in dogs and cutaneous xanthomatosis in cats are associated clinical findings that may be apparent among insulin-dependent diabetics, particularly those with severe hypertriglyceridemia. The hyperlipidemia associated with diabetes mellitus usually improves or resolves as glycemic control is achieved.

Diabetic dogs with excess serum triglyceride concentrations appear to be at risk for developing acute pancreatitis or pseudopancreatitis. Dietary fat restriction can be expected to lower the serum triglyceride concentration and may facilitate glycemic regulation in dogs receiving insulin.

PROTEIN-LOSING NEPHROPATHY

Hyperlipidemia, characterized by increased serum cholesterol or triglyceride levels, may be detected in patients with proteinuria due to glomerulonephritis or amyloidosis. An inverse relationship between elevated blood lipids/lipoproteins and decreased plasma albumin concentration has been reported to occur in patients with nephrotic syndrome. The actual pathogenesis whereby the hyperlipidemia develops is complex and appears to be due to a combination of factors involving altered metabolism of lipoproteins (Bernard, 1982). Hypercholesterolemia occurs inconsistently in dogs with heavy proteinuria. The lipoprotein profile of dogs and cats with nephrotic syndrome has not yet been characterized. The influence of hyperlipidemia on morbidity and mortality in nephrotic syndrome is unknown.

HYPERADRENOCORTICISM

Hypercholesterolemia has been recognized in dogs with hyperadrenocorticism (Cushing's syndrome) without concomitant diabetes mellitus (Armstrong and Ford, 1989; DeBowes, 1987; Barrie et al, 1993). Affected dogs have clear serum, increased plasma cholesterol and LDL-cholesterol levels, but no discrete clinical signs specifically attributable to excess cholesterol. In a limited study of adult dogs confirmed to have hyperadrenocorticism, only 30% were hypercholesterolemic.[a] There appears to be little diagnostic value to performing lipid determinations in dogs suspected of having endogenous cortisol excess. However, monitoring changes in a given patient's cholesterol profile may have prognostic value in dogs undergoing treatment.

HYPOTHYROIDISM

Hypercholesterolemia is present in up to two-thirds of hypothyroid dogs and is believed to result from impaired LDL clearance from the general circulation. It has been suggested that an absolute triiodothyronine deficiency may lead to an increased hepatic cholesterol pool. In turn, LDL-receptor activity is down regulated preventing excess sterol accumulation in the liver (Barrie et al, 1993). Atherosclerotic-type arterial lesions have occasionally been reported (DeBowes, 1987). This finding has led to the suggestion that cholesterol be included in an initial diagnostic screening for hypothyroidism. However, superior laboratory tests are available for evaluating thyroid disease in cats and dogs and should be considered before serum cholesterol evaluation. Therapy should be directed towards correcting the thyroid-hormone deficiency. Although hypothyroid people may experience decreased cholesterol levels after thyroid-replacement therapy is started, there is no apparent value in monitoring cholesterol in affected dogs.

Key Nutritional Factors

Fat

Chylomicrons are exclusively of dietary origin; therefore, the amount and type of dietary fat is of primary importance. Foods containing less than 12% dry matter (DM) fat are most commonly recommended (**Table 28-2**).

Marine fish oils are rich in omega-3 (n-3) fatty acids, which effectively decrease production of triglyceride-rich VLDL. Marine fish oils have been recommended as the first line of medical treatment for idiopathic hypertriglyceridemia in dogs. Suggested doses range from 10 to 30 mg/kg to 200 mg/kg body weight. Experience with marine fish oils is limited and most reported successes are based on anecdotal reports.

Fiber

Many low-fat foods also have increased levels of dietary fiber. The contribution of fiber in low-fat foods and fiber's ability to reduce serum lipids is unclear. At this time, no studies have been done in animals to evaluate the effects of dietary fiber type or amount on reducing serum triglyceride levels. Multiple studies in people have shown that dietary fiber, regardless of type or amount, has no significant effect on serum triglyceride levels. Increasing dietary fiber, however, can lower serum cholesterol levels. Furthermore, primarily soluble fibers of differing types have been evaluated. Psyllium, oat bran, guar gum and pectin are a few that effectively reduce cholesterol in people. Reports have shown cholesterol reductions with fiber range from 3 to 10%, depending on fiber type and amount (Hunninghake et al, 1994; Anderson et al, 2000). In some studies, the amount of dietary fiber was high and patient compliance may have been reduced due to increased gastrointestinal side effects (i.e., diarrhea, flatulence, abdominal distention).

Several mechanisms have been suggested for the cholesterol-reducing effects of soluble fiber. Fiber binds dietary cholesterol in the intestine thereby reducing absorption and binds bile acids in the intestine resulting in increased gastrointestinal excretion and increased cholesterol usage to synthesize more bile acids (Marlett, 1997). Some investigators suggest that the cholesterol-lowering effect is due to the substitution of dietary fiber for higher fat content foods (Swain et al, 1990). Studies with prebiotic fibers have shown similar cholesterol-reducing effects (Maki et al, 2003; Behall et al, 2004). Similar effects may occur in animals. Short-chain fructooligosaccharides are reportedly effective in reducing serum cholesterol concentrations and treating corneal lipidosis (Diez et al, 2000); however, when used to treat long-term corneal lipidosis in a rough collie dog the serum cholesterol-lowering effects were transient although the corneal lipidosis resolved (Jeusette, 2004).

Several low-fat veterinary therapeutic foods that have been used successfully to treat hyperlipemic dogs and cats also include increased levels of dietary fiber. The effect of fiber in low-fat foods on further reduction of serum lipids is unclear. However, responses of hyperlipemic patients to dietary intervention with low-fat, high-fiber foods have been positive, including significant decreases in serum triglycerides (**Case 28-1**) (Jeusette et al, 2005; Linton et al, 1994; Rogers et al, 1975). Therefore, based on the lipid-lowering effects observed clinically when commercial low-fat, high-fiber foods have been used, including knowledge of the fiber content of these foods, fiber levels of at least 10% DM are recommended for dogs and at least 7% are recommended for cats.

FEEDING PLAN

Assess and Select the Food

Long-term dietary management of dogs and cats with lipemia caused by primary hypertriglyceridemia is indicated only after secondary causes of hypertriglyceridemia have been ruled out. Food is the single most important element in managing primary hyperlipidemia, particularly in hypertriglyceridemic patients. **Tables 28-3** and **28-4** list commercially available foods marketed for the management of primary hyperlipidemia for dogs and cats, respectively, and compare their key nutritional

Table 28-4. Selected commercial foods used in cats with hyperlipidemia compared to recommended levels of key nutritional factors.*

*From manufacturers' published information; all values expressed on a dry matter basis unless otherwise stated.
**Energy density values are listed on an as fed basis and are useful for determining the amount to feed (the amount to feed = the daily energy requirement ÷ the energy density [kcal/cup or can]); cup = 8-oz. measuring cup. To convert to kJ, multiply kcal by 4.184.

factor content with the recommended levels of key nutritional factors (**Table 28-2**). The patient's current food should be compared to the foods in **Tables 28-3** and **28-4** and a new food selected if the key nutritional factors in the patient's current food do not closely match the levels recommended in the tables. Selection of a new food should be made on the basis of the closest match to the recommended key nutritional factors.

The approach to treating any patient with secondary hypertriglyceridemia includes managing the underlying disease; an appropriate response to the medication should include resolution of the lipemia. Concurrent disorders may also influence the key nutritional factors and lead to other food and feeding method choices. Depending on their underlying disease, dogs and cats with secondary hyperlipidemia may benefit from foods listed in **Tables 28-3** and **28-4**. However, there may be other nutritional factors to consider in some diseases, for example, key nutritional factors important for patients with protein-losing nephropathy should also be considered when making food selections (Chapter 37).

Assess and Determine the Feeding Method

The method of feeding is often not altered in the nutritional management of lipid disorders. If a new food is fed, the amount to feed can be determined from the product label or other supporting materials. The food dosage may need to be changed if the fat level in the food is reduced, because the caloric density of the new food will probably differ from that of the previous food (i.e., the caloric density will usually be lower). The patient's body condition score (BCS) and body weight should be recorded before initiating dietary management because these become important parameters to monitor during reassessment. If body weight and BCS are optimal initially, the dosage of the new food should reflect the amount of energy (kcal or kJ) consumed by the animal previously.

Dogs and cats with hyperlipidemia due to diabetes mellitus may benefit from a feeding protocol that matches their insulin therapy (Chapter 29). Good compliance is necessary for effective clinical nutrition. Enabling compliance includes limiting access to other foods and knowing who feeds the animal. If the dog or cat comes from a household with multiple pets, access to other pets' food should be denied.

MEDICAL MANAGEMENT OF SECONDARY HYPERLIPIDEMIC STATES

Hyperlipidemic states associated with a primary underlying disorder (e.g., diabetes mellitus or hyperadrenocorticism) can cause clinical signs in dogs and cats indistinguishable from those caused by primary hyperlipidemic states. Accurate diagnosis and treatment of the underlying disorder should resolve the hyperlipidemia and any associated signs. However, dietary therapy as outlined above should still be implemented. Dogs and cats with clinical signs associated with persistent hyperlipidemia, whether primary or secondary, should benefit from appropriate dietary therapy (**Tables 28-3** and **28-4**) as long as optimal weight is maintained.

REASSESSMENT

The effect of dietary therapy on hyperlipidemic patients is best determined three to four weeks after the feeding plan is initiated. Reassessment includes reviewing the client's assessment of the patient's response, documenting body weight and condition and evaluating the extent outward manifestations (i.e., ocular or cutaneous lesions) have resolved. Laboratory assessment involves: 1) collecting a blood sample from a fasted animal (10 to 12 hours), 2) evaluating the appearance of the serum for lipemia, 3) determining the triglyceride level in uncleared serum and 4) performing a chylomicron test. The veterinary health care team should assess the client's compliance with the outlined feeding plan. Feeding high-fat snacks and treats and access to other pet foods, even infrequently, can markedly increase circulating triglyceride levels in affected patients.

The goals of dietary therapy are to achieve: 1) a clear serum sample, 2) a total triglyceride concentration less than 500 mg/dl, 3) a negative chylomicron test, and, most importantly 4) amelioration or elimination of clinical signs. Amelioration or elimination of clinical signs can be expected within two weeks (dogs with pseudopancreatitis) to as long as three months (cats with cutaneous xanthomata) after initiation of appropriate dietary therapy.

Most dogs and cats with primary hyperlipidemia will experience a marked reduction in serum triglyceride and cholesterol concentrations if appropriate dietary management is employed

Box 28-2. Medical Management of Primary Hyperlipidemia.

Although dietary therapy is recommended as the initial means of managing primary hypertriglyceridemia, up to 10% of dogs with idiopathic hyperlipidemia are unresponsive to dietary fat restriction and may require pharmacologic supplementation. A variety of medical treatments for reducing lipid levels in dogs and cats have been recommended. However, the efficacy and pharmacokinetics of these treatments in animals have not been well researched. Furthermore, cost, dosage and toxicity are factors that must be considered when recommending long-term drug therapy to manage primary hyperlipidemic states.

FIBRATES

Gemfibrozil is the most commonly recommended drug to lower serum triglyceride levels in dogs and cats when dietary management fails. The drug is administered to dogs at doses ranging from 200 mg/day, orally, to 150 to 300 mg every 12 hours. The dosage of gemfibrozil for cats is 7.5 to 10 mg/kg body weight every 12 hours. Side effects in cats and dogs appear to be minimal; however, reports have suggested a long-term cancer risk associated with its use in people.

DIETARY SUPPLEMENTS

Massive doses of nicotinic acid (niacin) have also been recommended for reducing serum cholesterol concentrations in people and thereby reducing the risk of coronary artery disease. There is no known value in using nicotinic acid to manage primary hyperlipidemic states in dogs and cats.

Dietary supplementation with aged garlic extract has beneficial effects on the lipid profile and blood pressure of moderately hypercholesterolemic human patients. The effect of garlic extracts on hyperlipidemic animals has not been investigated.

STATINS

The 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors, commonly referred to as "statins," effectively reduce hepatic cholesterol synthesis and enhance excretion of LDL-cholesterol from the circulation. Because of their ability to reduce the risk of coronary artery disease, the HMG CoA reductase inhibitors are the preferred class of drug prescribed to manage hypercholesterolemia in people. Although these drugs are generally well tolerated by dogs, the actual therapeutic advantage associated with lowering circulating levels of LDL-cholesterol is unknown. Dogs and cats normally have very low levels of LDL-cholesterol. Specific dosages for dogs and cats have not been reported.

CHOLESTEROL ABSORPTION INHIBITORS

Drugs such as ezetimibe inhibit dietary cholesterol and bile acid cholesterol uptake in the intestine and have been an effective tool for reducing serum cholesterol levels. In people, the use of statin drugs markedly reduces cholesterol production; however, there is a resultant increase in cholesterol uptake from the gastrointestinal tract. Similar compensatory mechanisms have been demonstrated in dogs. Combining statins with drugs that selectively inhibit cholesterol uptake from the digestive tract is more effective than statins alone at lowering serum cholesterol concentrations. Safety and similar synergistic effects have been shown in normal dogs. The application and dosages of these combination drugs in clinical patients have not been evaluated. Because these drugs (especially statins) can have serious side effects, their use is currently not recommended.

BILE ACID SEQUESTRANTS

The bile acid sequestrants, categorized as ion exchange resins, effectively reduce serum cholesterol concentrations through their ability to reduce enterohepatic circulation of bile salts and enhance cholesterol excretion. Cholestyramine has been recommended for dogs with persistent idiopathic hypercholesterolemia at dosages of 1 to 2 g every 12 hours. However, the associated side effects, principally gastrointestinal discomfort and diarrhea, combined with the fact that actually reducing serum cholesterol levels may not resolve clinical signs, limits the clinical value of these drugs.

The Bibliography for **Box 28-2** can be found at www.markmorris.org.

and rigorously followed. A reasonably acceptable goal is slight serum turbidity, a triglyceride concentration less than 1,000 mg/dl and an incomplete cream layer at the top of the sample.

Unless weight loss is desired, the patient's body weight and BCS should be the same as it was before the feeding plan was initiated.

For reasons currently unknown, some patients remain profoundly hyperlipidemic despite excellent owner compliance in feeding an appropriate food. However, these animals should continue to receive the appropriate low-fat food; human table food should not be fed. The patient should be reassessed in one to two months. If a demonstrable reduction in fasting serum triglyceride concentrations still hasn't occurred, drug therapy should be added to the dietary therapy. Drug therapy for patients with primary hypertriglyceridemia has included clofibrate, niacin, gemfibrozil and dietary supplementation with omega-3 fatty acids from fish oils (**Box 28-2**) (Logas et al, 1991; Levy, 1988; Schaefer, 1988; Watson, 1996).

Patients that lose a significant amount of weight (more than 1% of body weight per week) should receive gradually increasing amounts of the recommended food until desired weight can be maintained. In these cases, caloric intake may be inadequate.

CASE 28-1

Episodic Diarrhea in a Mixed-Breed Dog

Richard B. Ford, DVM, Dipl. ACVIM (Internal Medicine)
School of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina, USA

Patient Assessment

A seven-year-old, female, mixed-breed dog was initially examined for a four-month history of episodic diarrhea accompanied by lethargy and a decreased appetite. The owner reported that the frequency of the episodes had gradually increased to once weekly over the last two months. Clinical signs would spontaneously resolve within 24 to 48 hours.

The initial physical examination revealed an active, alert dog. Abdominal palpation was unremarkable and well tolerated. The dog weighed 11.8 kg and appeared thin (body condition score 2/5) although the owner had not reported weight loss.

A presumptive diagnosis of dietary intolerance was made and empiric treatment with a veterinary therapeutic food for management of gastrointestinal (GI) disease was initiated. Ten days later the dog was examined for significant lethargy and abdominal discomfort. The owner indicated that the dog had eaten nothing during the past 24 hours but did drink water. Soft feces were noted occasionally. Abdominal palpation was associated with discomfort; however, the source of the abdominal pain could not be localized.

Results of an abdominal radiograph, urinalysis and fecal flotation for intestinal parasites were normal. Blood collected for analysis was profoundly lipemic and moderately hemolyzed. Test results were obtained from a commercial laboratory on the following day. Results of a complete blood count were normal. Abnormal serum biochemistry profile results included hypocalcemia (8.5 mg/dl, normal 9.2 to 11.2). Serum cholesterol (278 mg/dl) and triglyceride (96 mg/dl) concentrations were normal.

Assess the Food and Feeding Method

The dog was normally fed a combination of dry and moist commercial grocery store brand foods with occasional snacks. The food was offered once daily. The dog's diet had been consistent for several years until the change 10 days ago to a moist veterinary therapeutic food (Prescription Diet i/d Canine[a]) designed for the management of GI disorders.

Questions

1. Why is the serum triglyceride concentration normal in a patient with lipemia?
2. What is the tentative diagnosis in this patient?
3. What is an appropriate feeding plan (food and feeding method) for this dog?

Answers and Discussion

1. In an attempt to avoid lipid interference with other biochemical assays, many commercial laboratories will use ultracentrifugation to clear chylomicrons before performing any tests on a lipemic serum sample. This process removes excess triglycerides before testing. Thus, the triglyceride concentration reported by the laboratory may be normal. Simply observing a lipemic sample in a fasted (six to 12 hours) animal is sufficient clinical evidence to document hypertriglyceridemia. The low serum calcium concentration was probably an artifact due to interference from the lipemia.
2. The predominant cause of hyperlipidemia in dogs is excess concentrations of triglyceride-rich chylomicrons. Thus, canine hyperchylomicronemia (hypertriglyceridemia) is the most likely diagnosis, after the clinician has observed the serum sample and confirmed the presence of lipemia (i.e., a cream layer denoting hyperchylomicronemia) or measured triglyceride levels (i.e., levels exceeding 500 mg/dl). Fasting lipemia can be a significant clinical problem associated with episodic diarrhea, inappetence, abdominal discomfort and occasional vomiting. The collective term to describe this syndrome is "pseudopancreatitis." The rapid worsening of clinical signs justifies expanding the differential diagnosis to include pancreatitis, hypoadrenocorticism, neoplasia and primary intestinal disease (e.g., inflammatory bowel disease, etc.). Additional endocrine testing may be indicated to rule out secondary causes of hyperlipidemia.
3. For any patient with fasting hyperlipidemia, regardless of the cause, food with a fat content less than 12% dry matter is recommended. Foods designed for empiric management of GI disorders often have a fat content that exceeds this recommendation. Multiple small meals rather than one large meal per day may be helpful in patients with GI signs.

Progress Notes

After fasting hypertriglyceridemia (hyperchylomicronemia) was confirmed, the initial treatment prescribed was limited to dietary intervention with low-fat, high-fiber food. Prescription Diet w/d Canine[a] dry was recommended because of its palatability, low-fat content (approximately 9.0% dry matter [DM]) and high-fiber level (17.6% DM). The owner was advised that: 1) dietary manage-

ment is the most reasonable, economical means of controlling this potentially serious condition, 2) dietary fat restriction would be a life-long requirement, if treatment were successful and 3) even a single high-fat meal (e.g., eating from the trash) could acutely exacerbate clinical signs and cause pancreatitis.

The patient was reexamined after consuming the veterinary therapeutic food for three weeks to assess dietary compliance and serum triglyceride levels. A fasting (overnight) blood sample was collected. The serum triglyceride (uncleared) concentration was determined and compared to that obtained during the initial examination (**Table 1**).

Results suggested excellent dietary control of the hyperlipidemic state and good dietary compliance. Specific drug intervention was deemed unnecessary at the time the patient was rechecked. However, the owner was advised that although the risk of serious illness (pancreatitis) had been markedly reduced, follow-up examinations twice yearly, including fasting triglyceride measurements, would be a prudent course to follow.

INTRODUCTION

The interactions of carbohydrate and lipid metabolism and their control by hormones comprise the basis for metabolic homeostasis in health and disease. Diagnosing and treating these disorders requires a working knowledge of cellular changes and the role of hormones in controlling nutrient flux. This chapter covers the nutritional aspects of diabetes mellitus, hyperthyroidism and hypothyroidism.

DIABETES MELLITUS

Diabetes mellitus describes an alteration in cellular transport and metabolism of glucose, lipids and amino acids wherein insulin-dependent tissues (e.g., skeletal and cardiac muscle, adipose tissue) either never receive the signal or fail to properly interpret the signal. Altered metabolism results in either an absolute or relative deficit in insulin secretion by pancreatic beta cells as perceived by insulin-dependent cells in the periphery of the body. Causative pathophysiologic mechanisms include: 1) insufficient insulin release from the pancreas (e.g., glucose toxicity, beta-cell degeneration or islet amyloid deposition), 2) decreased number of functional insulin receptors (down regulation) and 3) problems with transduction of the insulin signal following binding of insulin to insulin receptors (**Table 29-1**) (Feldman and Nelson, 2004, 2004a).

Classification

In people, diabetes mellitus is usually classified as: 1) type I, 2) type II, 3) secondary (type S), 4) impaired glucose tolerance (e.g., gestational diabetes) (type IGT) and 5) previous abnormality of glucose tolerance (type PrevAGT) based on the pathophysiologic mechanisms and pathogenic alterations affecting beta cells (Stogdale, 1986). Type I diabetes is characterized by a combination of genetic susceptibility and immunologic destruction of beta cells, with progressive and eventually complete insulin insufficiency. The presence of circulating autoantibodies against insulin, beta cells and/or glutamic acid decarboxylase usually precedes the development of hyperglycemia or clinical signs.

Type II diabetes mellitus is characterized by insulin resistance and "dysfunctional" beta cells; defects thought to be genetic in origin and which are evident for a decade or longer before hyperglycemia and clinical signs of diabetes develop. Deleterious effects of type II diabetes mellitus can be accentuated by environmental factors such as obesity (Warram et al, 1990; Martin et al, 1992). Type II diabetes mellitus has been referred to as a relative insulin deficiency because the amount of insulin actually secreted by the beta cells may be increased, decreased or normal. The concentration of glucose in serum is thus determined by the relative response of peripheral tissues to the secreted insulin, which is usually blunted.

People with type I diabetes depend on insulin to control the disease (i.e., insulin-dependent diabetes mellitus [IDDM]),

whereas control of the diabetic state in people with type II diabetes is usually possible through diet, exercise and oral hypoglycemic drugs. Insulin treatment may be necessary in some type II diabetics if insulin resistance and beta-cell dysfunction are severe. As such, people with type II diabetes mellitus can have IDDM or non-insulin-dependent diabetes mellitus (NIDDM).

Classifying diabetic dogs and cats as type I or type II based on criteria established for people is difficult, in part, because: 1) familial history is rarely available for diabetic dogs and cats, 2) the clinical presentation is usually unhelpful in differentiating type I from type II diabetes, 3) insulin secretagogue tests are not routinely performed and their results may be misleading and 4) autoantibody tests for type I diabetes are not readily available (Nelson et al, 1993; Kirk et al, 1993). It is probably more clinically relevant to classify dogs and cats as insulin-dependent and non-insulin dependent based on their need for insulin.

The overwhelming majority of dogs have IDDM at the time diabetes is diagnosed. Cats are more confusing because islet pathology may be mild to severe and progressive or static; reversible suppression of beta-cell function occurs with chronic hyperglycemia (glucose toxicity), and responsiveness of tissues to insulin varies, often in conjunction with the presence or absence of concurrent inflammatory, infectious, neoplastic or hormonal disorders. These variables affect a cat's need for insulin, insulin dosage and ease of diabetic regulation. Furthermore, these variables may change with time. Cats may have IDDM or NIDDM at the time diabetes is diagnosed. Cats with NIDDM may progress to IDDM with time, cats with apparent IDDM may revert to a non-insulin requiring state after initiation of treatment and cats may have IDDM or NIDDM as severity of insulin resistance and impairment of beta-cell function waxes and wanes.

Patient Assessment

History

Dogs and cats with diabetes mellitus are usually examined because of polydipsia, polyphagia, weight loss and diminished activity. Care should be taken to differentiate between polyphagia from underfeeding compared to polyphagia associated with disease (true polyphagia). Less commonly, complaints of blindness (dogs), rear-limb weakness (cats) and lethargy (dogs and cats) may be identified. If diabetic ketoacidosis (DKA) develops, affected animals are often examined for anorexia, vomiting, diarrhea, weakness and a moribund state. DKA may be precipitated by infection, severe stress, hypokalemia, hypomagnesemia, renal failure, drugs that decrease insulin secretion, drugs that cause insulin resistance or inadequate fluid intake (Nichols and Crenshaw, 1995). Concurrent disease such as pancreatitis and bacterial infection is common in dogs and cats developing DKA and often accentuates the clinical signs of DKA, prompting owners to seek veterinary care. A thorough assessment of the patient is critically important for developing an appropriate management protocol for dogs and cats diagnosed with DKA (Feldman and Nelson, 2004, 2004a; Plotnick and Greco, 1995).

Physical Examination

Body condition scores (BCS) for diabetic dogs and cats range from emaciated (BCS 1/5) to obese (BCS 5/5) depending on the severity and duration of disease. Weight loss, which becomes obvious with time, is a hallmark sign of diabetes mellitus. Other physical findings may include lethargy, unkempt coat (cats), hepatomegaly, cataracts (dogs), rear-limb weakness (cats) and dehydration (Plotnick and Greco, 1995; Feldman and Nelson, 2004, 2004a).

Diagnostic Testing

HEMOGRAMS

Results of complete blood counts are usually within normal ranges in uncomplicated cases of diabetes mellitus. An increase in packed cell volume may be present in dogs and cats with DKA due to decreased extracellular water attributable to osmotic diuresis. Occasionally, increased numbers of Heinz bodies may be noticed in cats with diabetes mellitus. Leukocytosis or shifts of white cell morphology to more immature types may indicate an underlying infectious process that confounds the diagnosis of uncomplicated diabetes mellitus.

SERUM BIOCHEMISTRY PROFILES

The most consistent and requisite feature of diabetes melli-

tus is persistent fasting hyperglycemia and glucosuria in the absence of other disease processes. Hyperglycemia, however, may be caused by other disease or physiologic states and drugs (**Table 29-2**). A thorough assessment may help identify the underlying cause of hyperglycemia. Repetitive determination of serum glucose concentrations may be required in cats to differentiate diabetes mellitus from stress hyperglycemia. A diagnosis of DKA is established if ketonuria is present with systemic metabolic acidosis.

Other commonly identified abnormalities include increased serum concentrations of cholesterol and triglycerides. Increased serum concentrations of urea nitrogen and creatinine may be present when dehydration becomes severe enough to impair renal diffusion (prerenal azotemia). Electrolyte and acid-base alterations are more common in animals with DKA and include: 1) hyponatremia, 2) hypokalemia, 3) hypocalcemia, 4) hypomagnesemia, 5) hypophosphatemia and 6) hypochloremia. A shift in acid-base balance towards metabolic acidosis with a compensatory respiratory alkalosis may occur.

Increased activity of alanine aminotransferase in serum may be present in cases in which hepatic lipidosis has resulted in hepatocellular damage. Activity of serum alkaline phosphatase may also be increased. Increased serum alkaline phosphatase activity is primarily associated with hepatomegaly and biliary stasis; however, pancreatic inflammation resulting in extrahepatic biliary obstruction may also be present. Less commonly, serum concentrations of bile acids and total bilirubin may be elevated.

Dogs and cats with diabetes mellitus may present with concurrent exocrine pancreatic insufficiency or pancreatitis (Williams and Minnich, 1990). Increased activity of amylase and lipase in serum may indicate pancreatitis; however, the correlation of these two enzyme activities with pancreatitis is poor, especially in cats. Other disease processes may also result in increased activity of these enzymes in serum.

OTHER BIOCHEMICAL TESTS

Determination of insulin concentration in serum is not routinely performed in suspected cases of diabetes mellitus. A reliable radioimmunoassay must be used when measuring serum insulin, especially in cats. Insulin exhibits variance in the primary amino acid sequence between species; therefore, the test methodology must be validated for each species. Serum insulin concentrations, when they are determined, may be high, normal or low. Concentrations of insulin greater than 15 µU/ml in animals not receiving exogenous insulin indicate the presence of functional beta cells. Conversely, concentrations of insulin less than 10 µU/ml do not preclude the possibility of functional beta cells. Serum pancreatic lipase immunoreactivity (increased activity) and trypsin-like immunoreactivity (decreased activity) can help identify pancreatitis and exocrine pancreatic insufficiency, respectively (Chapters 66 and 67).

Serum thyroid-hormone concentrations are usually normal in diabetic dogs and cats. However, both hypothyroidism and hyperthyroidism may be associated with insulin resistance and can occur in conjunction with diabetes mellitus. As such, evaluation of thyroid function may be useful in patients with diabetes mellitus that are difficult to control with insulin and dietary intervention (**Case 29-2**). Care must be exercised in the interpretation of serum thyroxine (T_4) concentrations in sick dogs and cats because concentrations of T_4 may be falsely low in poorly regulated cases of diabetes mellitus. This alteration is presumed to be attributable to the euthyroid sick syndrome (Feldman and Nelson, 2004c).

URINALYSES

Urine specific gravity is typically greater than 1.025 in diabetic dogs and cats. Urine specific gravity less than 1.015 should increase suspicion for concurrent disorders, such as renal insufficiency or hyperadrenocorticism. Glucosuria is a hallmark finding in untreated diabetic dogs and cats. Lack of glucosuria rules out diabetes mellitus as the cause of polydipsia and polyuria. Other common urinalysis findings include ketonuria, proteinuria and changes consistent with urinary tract infection (i.e., bacteriuria and pyuria). Proteinuria may result from either bacterial infection or glomerulopathy secondary to basement membrane damage from the primary disease process.

Risk Factors

Risk factors for development of diabetes mellitus in dogs and cats include genetics, age, sex, obesity and concurrent problems causing insulin resistance. Although diabetes can occur in dogs and cats of any age, gender and breed, the disease is more common in older dogs and cats with a peak prevalence of seven to nine years of age in dogs and nine to 11 years in cats (Panciera et al, 1990; Goossens et al, 1998). Juvenile-onset diabetes occurs in dogs and cats less than one year of age, but is uncommon. In dogs, females are affected about twice as frequently as males, whereas in cats, diabetes occurs predominately in neutered males (Panciera et al, 1990; Goossens et al, 1998). Breeds of dogs at risk for diabetes mellitus include Australian terriers, standard and miniature schnauzers, bichons frisés, spitz, fox terriers, miniature and toy poodles, Samoyeds, Cairn terriers, keeshonds, Maltese, Lhasa apsos and Yorkshire terriers (Guptill, 1999; Hess et al, 2000). There is no apparent breed predisposition in cats; however, Burmese cats may be overrepresented in Australia (Rand et al, 1997).

The presence and severity of insulin resistance is an important variable in the development and successful treatment of diabetes mellitus in dogs and cats. Insulin resistance increases the demand for insulin secretion. A sustained demand for insulin secretion in response to insulin resistance can lead to islet pathology and loss of beta cells. The more severe and chronic the insulin resistance and the more severe the loss of islets, the more likely hyperglycemia will develop. Persistent hyperglycemia can, in turn, suppress function of remaining beta cells, causing hypoinsulinemia, worsening hyperglycemia and further reducing the population of beta cells. Any chronic insulin-resistant disorder can have a deleterious effect on the population and function of beta cells and play a role in the development of NIDDM or IDDM (**Figure 29-1**). Examples include obesity, chronic pancreatitis, acromegaly, hyperadreno-

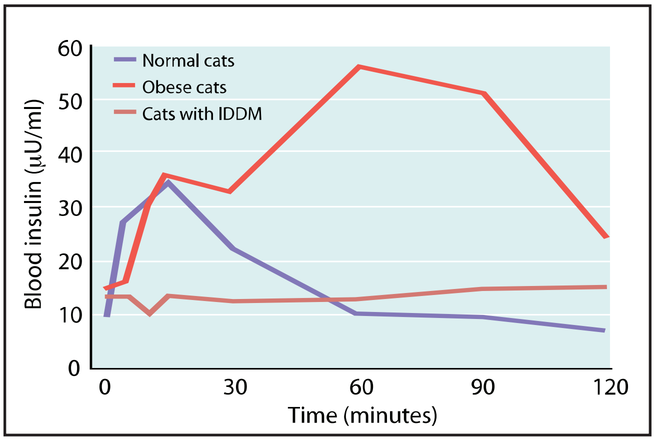

Figure 29-1. Mean blood insulin concentrations following the intravenous injection of 0.5 g glucose/kg body weight in normal cats, extremely obese cats and cats with type I diabetes mellitus. The insulin secretory pattern in obese cats is similar to that of people with NIDDM. (Adapted from Nelson RW. Disorders of the endocrine pancreas. In: Ettinger SJ, ed. Textbook of Veterinary Internal Medicine, 3rd ed. Philadelphia, PA: WB Saunders Co, 1989; 1676.)

corticism and long-term administration of glucocorticoids or progestagens. Obesity-induced carbohydrate intolerance is the classic insulin-resistant disorder affiliated with development of NIDDM in people and increases the risk for diabetes in cats by fourfold (Scarlett, 1997).

Etiopathogenesis

INSULIN PHYSIOLOGY

Insulin is produced in the beta cells of the endocrine pancreas and is released in response to increased concentrations of glucose in plasma. Active insulin is a dipeptide that is linked by disulfide bonds between cysteine amino acid side chains. Insulin is first synthesized as proinsulin in beta cells and is subsequently processed by a cleavage step that produces C-peptide and active insulin (Muench, 1986).

Active insulin released into the bloodstream normally interacts at target tissues via cell surface receptors specific for insulin. Most tissues have insulin receptors but some (e.g., skeletal and cardiac muscle and adipose tissue) depend more on insulin for the acquisition of glucose and amino acids than others, and are classified as insulin-dependent tissues (Harris, 1986; Granner, 1988). For example, brain tissue has insulin receptors, but is quite capable of transporting glucose intracellularly without the help of hormonal stimuli; therefore, it is considered an insulin-independent tissue.

Insulin receptors are membrane glycoproteins composed of two subunits; a larger alpha subunit that extends extracellularly, which is involved in binding the insulin molecule, and a smaller beta subunit that is predominately cytoplasmic, which is responsible for activating the signaling cascade that ultimately leads to increased glucose transport, increased glycogen and lipid synthesis and stimulation of other metabolic pathways (Masharani and Karam, 2001). Because cell membranes are impermeable to glucose, all cells require carrier proteins to transport glucose across the lipid bilayers into the cytosol. At least five glucose transporters have been described, to date, in people, each having a different affinity for glucose. GLUT 1 and GLUT 3 are present in all tissues and mediate basal glucose uptake and neuronal uptake of glucose, respectively. GLUT 2 is the major glucose transporter in beta and hepatic cells. It has a low affinity for glucose, and acts as a transporter during periods of hyperglycemia. GLUT 5 is found on the brush border of human small intestinal cells and is mainly a fructose transporter. GLUT 4 is found intracellularly in insulin-dependent tissues, most notably skeletal muscle and adipose tissue. Activation of the insulin signaling cascade results in movement of GLUT 4 transporters to the cell surface where the transporter facilitates glucose entry into cells (James et al, 1988; Thorens et al, 1990).

DIABETES MELLITUS IN DOGS

The most common clinically recognized form of diabetes mellitus in dogs is IDDM. In our hospital (School of Veterinary Medicine, University of California, Davis), virtually all dogs have IDDM when diabetes mellitus is diagnosed. IDDM is characterized by permanent hypoinsulinemia and an absolute necessity for exogenous insulin to maintain glycemic control. The etiology of IDDM has been poorly characterized in dogs, but is undoubtedly multifactorial and may be similar to human type I diabetes. Genetic predispositions have been suggested by familial associations (Guptill, 1999; Hess et al, 2000). Common histologic abnormalities in dogs include a reduction in the number and size of pancreatic islets, a decrease in the number of beta cells within islets and beta-cell vacuolation and degeneration. In some dogs, an extreme form of the disease may occur, represented by a congenital absolute deficiency of beta cells and pancreatic islet hypoplasia or aplasia. Less severe pancreatic islets and beta-cell changes may predispose adult dogs to diabetes mellitus after exposure to environmental factors, such as insulin-antagonistic diseases and drugs, obesity or pancreatitis. Environmental factors may induce beta-cell degeneration secondary to chronic insulin resistance or may cause release of beta-cell proteins that induce immune-mediated destruction of the islets (Nerup et al, 1994). Studies designed to detect anti-beta-cell autoantibodies in diabetic dogs have been conflicting; they were identified in newly-diagnosed diabetic dogs with IDDM in one study (Hoenig and Dawe, 1992) but not in another (Haines, 1986). Immune-mediated insulitis has also been described in diabetic dogs (Alejandro et al, 1988). Seemingly, autoimmune mechanisms, in conjunction with genetic and environmental factors, may play a role in the initiation and progression of diabetes in dogs.

DIABETES MELLITUS IN CATS

Common histologic abnormalities in cats with diabetes mellitus include islet-specific amyloidosis, beta-cell vacuolation and degeneration and chronic pancreatitis (Goossens et al, 1998). The cause of beta-cell degeneration is unknown. Still, other diabetic cats have reduced numbers of pancreatic islets and/or insulin-containing beta cells based on immunohisto-

chemical evaluation, suggesting additional mechanisms may be involved in the physiopathology of diabetes mellitus in cats. Although lymphocytic infiltration of islets, in conjunction with islet amyloidosis and vacuolation, has been described in two diabetic cats (Nakayama et al, 1990), this histologic finding is very uncommon. Beta-cell and insulin autoantibodies have not been identified in newly diagnosed diabetic cats (Hoenig et al, 2002). The role of genetics remains to be determined.

Non-insulin-dependent type II diabetes may be identified in as many as 50 to 70% of newly-diagnosed diabetic cats. In contrast, clinical recognition of NIDDM is very uncommon in dogs and is usually associated with a concurrent insulin antagonistic disease or drug. Islet amyloidosis is an important factor in the development of non-insulin-dependent type II diabetes in people and presumably cats. Islet-amyloid polypeptide (IAPP), or amylin, is the principal constituent of amyloid in people with NIDDM and in adult cats with diabetes (Johnson et al, 1989). IAPP is stored in beta-cell secretory granules (Westermark et al, 1987, 1987a; Johnson et al, 1988), and is cosecreted with insulin by beta cells (Lutz and Rand, 1996). Stimulants of insulin secretion also stimulate amylin secretion. Increased long-term secretion of insulin and amylin, as occurs with obesity and other insulin resistant states, results in aggregation and deposition of amylin in the islets as amyloid. IAPP-derived amyloid fibrils are cytotoxic and associated with apoptotic cell death of islet cells (Hiddinga and Eberhardt, 1999). If amyloid deposition is progressive, islet cell destruction progresses and eventually leads to diabetes mellitus. The severity of islet amyloidosis determines, in part, whether diabetic cats have IDDM or NIDDM. Total destruction of the islets results in IDDM and the need for insulin treatment for the rest of the cat's life. Partial destruction of the islets may or may not result in clinically-evident diabetes; insulin treatment may or may not be required to control glycemia, and transient diabetes may or may not develop after treatment is initiated. If amyloid deposition progresses, cats will progress from a subclinical diabetic state to NIDDM and ultimately to IDDM. The presence and severity of insulin resistance are important variables that influence the clinical picture in cats. A sustained demand for insulin secretion in response to insulin resistance can lead to worsening islet pathology and further reduce the population of beta cells. Our current understanding of the etiopathogenesis of diabetes in cats suggests that the difference between IDDM and NIDDM is primarily a difference in the severity of beta-cell loss and severity and reversibility of concurrent insulin resistance.

Key Nutritional Factors

Key nutritional factors consist of nutrients of concern and other factors such as food type. This section emphasizes key nutritional factors that vary significantly in commercial foods and markedly affect management of diabetes mellitus (**Table 29-3**). The degree to which any of these factors affects management of diabetes mellitus greatly depends on the efficacy of primary disease control through insulin or other pharmacologic treatment. However, it has been shown that appropriate nutritional support may allow for less medical intervention, and in some cases, precludes the need for medical intervention (Bennett et al, 2006; Farrow et al, 2002; Frank et al, 2001; Nelson et al, 1998, 2000; Rand et al, 2004; Thiess et al, 2004).

WATER

Increased water loss due to osmotic diuresis from glucose, and ketone bodies if DKA is present, must be compensated. Generally, a source of potable water is recommended in amounts sufficient to meet the increased water requirement. This is usually accomplished via free-choice access to water. Dehydrated patients and those with DKA may require parenteral fluid administration. Caution should be observed with type and rate of fluid replacement because of electrolyte perturbations. Rapid replacement of fluid loss with hypotonic solutions may lead to water intoxication and cerebral edema (Schaer, 1975).

DIGESTIBLE CARBOHYDRATE

Concerns have been raised about the composition of carbohydrate in cat foods because cats have a different capacity to metabolize carbohydrates than dogs (Maskell and Graham,

Table 29-4. Effect of feeding insoluble dietary fiber to dogs and cats with diabetes mellitus.*

Twelfth Annual Veterinary Medical Forum, American College of Veterinary Internal Medicine, San Francisco, CA, 1994: 993. Nelson R, Scott-Moncrief C, DeVries S, et al. Dietary insoluble fiber and glycemic control of diabetic cats (abstract). In: Proceedings. Twelfth Annual Veterinary Medical Forum, American College of Veterinary Internal Medicine, San Francisco, CA, 1994: 996.
**By the parameters shown here, dogs and cats eating the higher fiber food had better glycemic control than comparable animals eating the low-fiber food.

1994). The composition and quantity of carbohydrates in foods for management of diabetes mellitus differ between dogs and cats, in part, because dogs are omnivores and tolerate digestible (soluble) complex carbohydrates better than diabetic cats. In general, foods containing 55% or less digestible carbohydrate on a dry matter (DM) basis are acceptable for dogs with diabetes mellitus, especially when the food also contains an increased amount of dietary fiber (Nelson et al, 1991, 1998). In contrast, cats are carnivores and have higher dietary protein requirements than omnivores such as people and dogs. The activity of hepatic enzymes responsible for the phosphorylation of glucose for subsequent storage or oxidation (glucokinase, hexokinase) and the conversion of glucose to glycogen for storage in the liver (glycogen synthetase) are lower in cats, compared with that for carnivores with omnivorous dietary habits (Zoran, 2002). The low activity of these hepatic enzymes suggests that cats primarily use gluconeogenic amino acids and fat rather than starch in their diet for energy, and suggests that diabetic cats may be predisposed to developing higher postprandial blood glucose concentrations following consumption of foods containing a high carbohydrate load and vice versa.

The optimal level of digestible carbohydrates for foods for diabetic cats has not been determined. Currently there are two acceptable approaches: low-carbohydrate/high-protein foods and increased-fiber/high-carbohydrate foods. Limiting carbohydrate intake results in blood glucose being maintained primarily via hepatic gluconeogenesis. The advantage is that glucose resulting from gluconeogenesis is released into the circulation at a slow and steady rate. Wider fluctuations in postprandial blood glucose levels, such as would be expected from feeding higher-carbohydrate foods, are avoided (Kirk, 2006). The end result of feeding increased-fiber/high-carbohydrate foods is similar. Increased dietary fiber also reduces fluctuations in postprandial blood glucose levels (Chandalia et al, 2000; Nelson et al, 2000), even though such foods provide more carbohydrate. Both approaches (low-carbohydrate/high-protein and increased-fiber/high-carbohydrate improve glycemic control in diabetic cats (Mazzaferro et al, 2001; Frank et al, 2001; Bennett et al, 2006; Nelson et al, 2000). In one of the studies comparing the two types of foods, diabetic cats from both groups were able to discontinue insulin and revert to a non-diabetic state; 41% of the cats fed an increased-fiber/high-carbohydrate food vs. 68% of the cats fed a low-carbohydrate/high-protein food (Bennett et al, 2006). Other studies have shown improved glycemic control in both healthy and diabetic cats fed low-carbohydrate/high-protein foods (Massaferro et al, 2003; Frank et al, 2001).

In general, digestible carbohydrates should be less than 20% DM in low-carbohydrate/high-protein foods for diabetic cats, and increased-fiber/high-carbohydrate foods for diabetic cats should contain less than 40% digestible carbohydrates DM (Nelson et al, 2000; Bennett et al, 2006). Digestible carbohydrate content of increased-fiber/high-carbohydrate foods for dogs should probably not exceed 55% DM.

Foods and snacks containing simple sugars rapidly increase blood glucose concentration and should be avoided for diabetic dogs and cats. Fructose should also be avoided in cats. Cats do not appear to metabolize fructose, which leads to fructose intolerance, polyuria and potential renal damage (Kienzle, 1994). Fructose may be found in commercial semi-moist foods, as a humectant in the form of sucrose, or high-fructose corn syrup. The potential effects of fructose in foods for dogs with diabetes mellitus have not been evaluated.

FIBER

As mentioned above, studies in diabetic cats have documented glycemic improvement in response to consumption of foods containing increased amounts of fiber (Nelson et al, 2000; Bennett et al, 2006). Foods containing increased fiber content also benefit glycemic control of diabetes in dogs (**Table 29-4**) (Nelson et al, 1991, 1998). The ability of fiber to form a viscous gel and thus impair convective transfer of glucose and water to the absorptive surface of the intestine appears to be the most important mechanism for slowing intestinal glucose absorption. The more viscous soluble fibers (e.g., gums, pectins) slow glucose diffusion to a greater degree than do the less viscous insoluble fibers (e.g., lignin, cellulose). Studies in diabetic dogs

have documented glycemic improvement in response to the consumption of foods containing increased amounts of soluble and insoluble fiber (Nelson et al, 1991, 1998, 2000a; Graham et al, 1994, 2002).

Although an ideal fiber content has not been established, it is evident that including moderate amounts (approximately 7 to 18% DM) of insoluble or mixed insoluble and soluble dietary fiber in high-carbohydrate foods aids nutritional management of type I and type II diabetes mellitus in dogs and cats. Low-carbohydrate/high-protein foods intended for diabetic cats typically contain lower levels of fiber; between 2 to 7% DM. Whether such levels are important in the efficacy of these type foods for the management of diabetes is unknown. Thus, at this time, dietary fiber is not considered to be a key nutritional factor in low-carbohydrate/high-protein foods for management of diabetes in cats.

Some soluble fibers and mixtures of soluble/insoluble fibers may decrease small intestinal digestion of certain nutrients without affecting total tract digestibility (Muir et al, 1996). Caution should be exercised with use of either fiber type in the management of diabetes mellitus because hyperglycemia inhibits the gastrocolic response, which may predispose to constipation (Sims et al, 1995). In addition, increased fiber levels may trap water in the gastrointestinal tract; therefore, water balance may need to be more closely monitored in patients with poorly controlled diabetes mellitus fed foods with moderate fiber levels.

FAT

Derangements in fat metabolism are common in diabetic dogs and cats and include increased serum concentrations of cholesterol, triglycerides, lipoproteins, chylomicrons and free fatty acids; hepatic lipidosis, atherosclerosis and a predisposition for development of pancreatitis may also occur (DeBowes, 1987; Hess et al, 2003). Feeding high-fat food may also cause insulin resistance and promote hepatic glucose production (Massillon et al, 1997). Feeding a low-carbohydrate, high-protein, high-fat food also increases concentrations of fat metabolites in healthy male cats (Thiess et al, 2004). These findings strongly support feeding foods that are relatively low in fat content, i.e., less than 25% DM. Feeding lower fat foods will help minimize the risk of pancreatitis, control some aspects of hyperlipidemia and reduce overall caloric intake to favor weight loss or maintenance. Foods with a higher fat content may be needed for weight gain in thin or emaciated diabetic dogs and cats.

PROTEIN

Diabetic dogs and cats may have increased loss of amino acids in urine attributable to inappropriate or inadequate hormonal signals and renal glomerulopathy. It is important to provide protein quantity and quality that will meet the requirements of diabetic animals in the face of increased amino aciduria while avoiding excess protein content that may enhance renal damage or contribute to excessive insulin secretion.

As mentioned above, in cats, two basic nutritional approaches are used for diabetes management (and weight loss, see Chapter 27). These include increased-fiber/high-carbohydrate foods and low-carbohydrate/high-protein foods. In one study, obese cats fed isocaloric amounts of a low-carbohydrate/high-protein food vs. obese cats fed a low-protein/high-carbohydrate food, researchers concluded that the low-carbohydrate/high-protein food was beneficial through maintenance of normal insulin sensitivity of fat metabolism, facilitating the loss of body fat during weight loss. Whether or not the beneficial effects were due to high protein, low carbohydrate, or both, was not determined (Hoenig et al, 2006).

Also, as mentioned above, as true carnivores, cats primarily use gluconeogenic amino acids rather than dietary carbohydrates for energy, which suggests that diabetic cats may be predisposed to developing higher postprandial blood glucose concentrations following consumption of high-carbohydrate/lower-protein foods, and vice versa.

The protein content of foods for diabetic patients should be approximately 15 to 35% of the food DM for dogs and 28 to 55% of the food DM for cats.

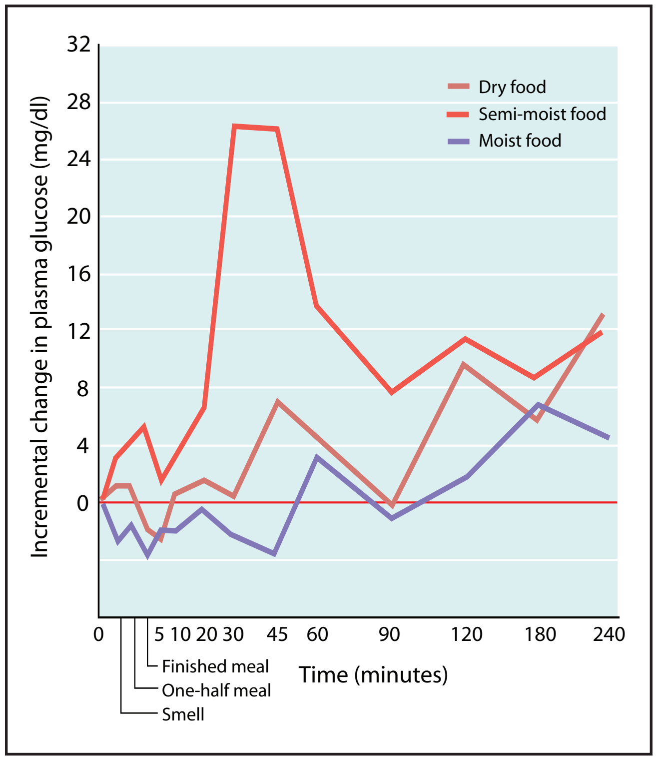

Figure 29-2. Changes in postprandial plasma glucose concentrations in healthy dogs fed commercial dry, semi-moist or moist dog food. Each dog consumed 50 kcal/kg body weight. Results are expressed as means compared with respective time-0 values. Note the profound increase in plasma glucose concentrations that follow consumption of semi-moist foods, which makes them an inappropriate food form for diabetic animals. (Adapted from Holste LC, Nelson RW, Feldman EC, et al. Effect of dry, soft moist, and canned dog foods on postprandial blood glucose and insulin concentrations in healthy dogs. American Journal of Veterinary Research 1989; 50: 987.)

Box 29-1. Trace Minerals and Vitamins in Diabetes Mellitus.

Changes in trace mineral nutrition status associated with diabetes mellitus have been evaluated in multiple species. The role of zinc in diabetes mellitus is controversial; however, it may affect insulin release from the pancreas, glucose tolerance and insulin resistance through changes in insulin binding and activity. Zinc appears to have biphasic activity; low concentrations enhance insulin secretion and activity whereas higher levels reverse this effect. Whole body zinc stores are often low in patients with diabetes mellitus.

Chromium has been proven to be an essential trace element and is thought to have a role in glucose homeostasis. Chromium has no known enzymatic cofactor function, but it may exist as a complex with nicotinic acid and amino acids to form a “glucose tolerance factor” that may aid insulin action. Chromium supplementation may improve glucose tolerance in malnourished subjects and subjects with poor glucose tolerance. Chromium supplements given to diabetic people have mostly proven ineffective in improving glycemic control; however, efficacy may vary on a case-by-case basis and chromium may prove beneficial in some individuals. At present, there is no reliable method to detect marginal chromium deficiency. Cats may display some gastrointestinal side effects when supplemental chromium is administered.

Manganese deficiency has been associated with perturbations in insulin secretion and carbohydrate and lipid metabolism, including impaired glucose usage in laboratory animals; however, its importance in the etiopathogenesis of diabetes is controversial. Repletion of manganese in deficient animals restores normal glucose tolerance and improves insulin secretion. However, treatment of diabetic subjects with manganese supplements had no impact on glycemic control; therefore, it is inferred that manganese deficiency is not a major factor in the pathophysiology of diabetes mellitus.

Iron overload can cause glucose intolerance due to pancreatic damage secondary to hemochromatosis. Overall, iron status does not seem to play a role in diabetes mellitus. Other trace element deficiencies such as vanadium and selenium have been associated with changes in glucose tolerance or insulin-like activity. Vanadium administered to healthy cats caused vomiting and diarrhea but also lowered blood glucose levels in one diabetic cat. Selenium appears to play no role in the development or manifestation of diabetes mellitus.

Substantiation of trace mineral benefits in diabetic dogs and cats has been confounding. Improvement with supplementation appears to occur on a case-by-case basis. In general, until otherwise proven, providing a food with microminerals supplied according to Association of American Feed Control Officials (AAFCO) recommendations for the appropriate lifestage should suffice for most animals with diabetes mellitus.

Diabetes mellitus may increase or decrease vitamin balance (**Table 1**). Conversely, vitamin status may affect the development and manifestations of diabetes mellitus. Much of the investigative work in this area is controversial and needs to be clarified. In general, foods that contain AAFCO recommended levels of vitamins for adult maintenance should meet most of the altered requirements induced by diabetes. In some cases of diabetes mellitus, it may be necessary to supplement the food with exogenous B vitamins.

Diabetic osteopenia is fairly well-documented in people and has a rational paradigm. Diabetes mellitus may lead to hypomagnesemia, which leads to decreased parathyroid hormone secretion and action, which then results in decreased formation of 1,25-dihydroxyvitamin D_3. Insulin deficiency further impairs formation of 1,25-dihydroxyvitamin D_3. The resultant impaired ability to enhance calcium absorption and retention in the face of hypercalciuria leads to calcium depletion.

Vitamin A homeostasis and status may influence development and control of diabetes mellitus. However, studies have yielded conflicting results; therefore, the effect of vitamin A on diabetes mellitus remains clouded. Most commercial pet foods provide abundant vitamin A.

FOOD FORM

Semi-moist foods tend to have a hyperglycemic effect compared to dry foods because they contain increased levels of simple carbohydrates and other ingredients used as humectants (**Figure 29-2**). Semi-moist foods should be avoided in dogs and cats with diabetes mellitus (**Table 29-3**).

Other Nutritional Factors

ELECTROLYTES

The osmotic diuresis induced by glycosuria and ketonuria results in urinary loss of electrolytes such as sodium, potassium, chloride, calcium, phosphorus and magnesium. Total body deficits in electrolytes often exist in poorly-regulated and ketotic diabetic dogs and cats, even when serum concentrations are within the normal range (Feldman and Nelson, 2004b). In addition, treatment of DKA may result in shifts of serum electrolytes between the intracellular and extracellular compartments. Perhaps the most clinically relevant is the shift of potassium, phosphorus and magnesium into intracellular compartments following initiation of insulin treatment for DKA, which

can lead to severe reductions in serum concentrations of these cations. Frequent monitoring of serum electrolytes and adjustments in the electrolyte composition of the intravenous fluids helps prevent life-threatening deficiencies of these electrolytes from developing during treatment of DKA.

Feeding foods containing appropriate amounts of electrolytes is important to achieve and maintain normal homeostasis in diabetic dogs and cats. However, no studies have been performed to establish recommended levels of minerals in foods for animals with diabetes mellitus. Dogs and cats without renal impairment should be fed foods with adequate amounts of phosphorus to avoid and replace whole body phosphorus deficits. However, excess dietary phosphorus should be avoided in animals with renal impairment. Diabetic cats fed foods with low magnesium content should be monitored carefully to avoid magnesium depletion. In general, foods that meet Association of American Feed Control Officials (AAFCO) recommendations for adult maintenance should supply adequate amounts of cations and anions to compensate for the increased losses described above. Most, if not all, commercial veterinary therapeutic foods will provide adequate amounts of these minerals. Diabetes mellitus may also affect micromineral and vitamin status (**Box 29-1**).

OMEGA-3 FATTY ACIDS

Omega-3 (n-3) fatty acids have been used in people with diabetes mellitus to decrease the incidence of atherosclerotic disease (Nettleton, 1995). At present, the recommendation of fish oil (enhanced with omega-3 fatty acids) for management of type I diabetes mellitus is more accepted than for type II diabetes mellitus in people. The dose of fish oil, diet composition and type of diabetes have resulted in confounding results. Administration of supplemental omega-3 fatty acids to diabetic people generally increased high-density lipoprotein concentrations, improved blood viscosity, reduced triglyceride levels and reduced blood pressure. However, reports of reduced glycemic control, increased apolipoprotein B levels and increased low-density lipoprotein levels with concomitant increases in cholesterol concentrations have dampened enthusiasm for the use of omega-3 fatty acids in diabetic people (Nettleton, 1995). Administration of omega-3 fatty acids to diabetic dogs and cats has not been evaluated, but may prove to have benefits similar to those shown in other species

Feeding Plans

Treatment for diabetes mellitus usually involves a combination of commonly available options. Treatment with injectable insulin or oral sulfonylurea agents has been the mainstay of pharmacologic intervention for uncomplicated diabetes mellitus (Feldman and Nelson, 2004, 2004a). Nutritional intervention is the major non-pharmacologic treatment modality for diabetes mellitus and plays an important role in the successful management of diabetic dogs and cats. Adjustments in food and feeding methods (amount fed and timing of feedings) should be considered when insulin therapy is initiated and should be directed at correcting or preventing obesity, maintaining consistency in the timing and caloric content of the meals and furnishing a food that helps minimize postprandial hyperglycemia.

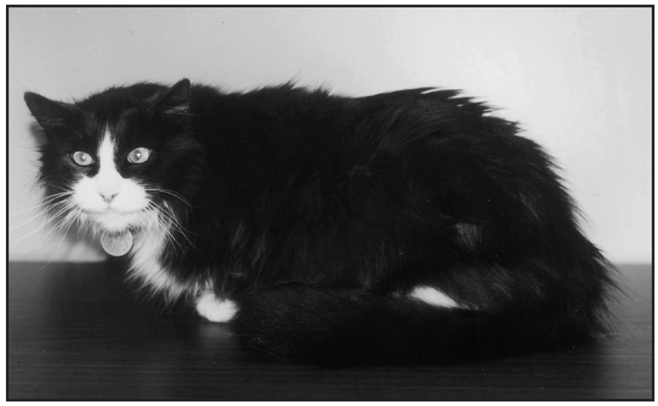

Figure 29-3. This nine-year-old, neutered male domestic longhair cat presented for polydipsia, polyuria, polyphagia and weight loss. The initial diagnoses were diabetes mellitus and concurrent hyperthyroidism. The cat was treated with methimazole for the hyperthyroidism; however, the diabetes mellitus persisted. The diabetes mellitus was controlled with a combination of oral glipizide and a veterinary therapeutic food containing low-fat and moderate fiber levels. Methimazole therapy was continued.

The nutritional plan for cats with non-insulin-dependent type II diabetes is similar to that for type I diabetes mellitus. In many diabetic cats, clinical signs and hyperglycemia resolve with appropriate dietary treatment and proper case management (**Figure 29-3**) (Bennett et al, 2006; Reusch et al, 2006).

Exercise also plays an important role in improving and maintaining control of glycemia by helping promote weight loss, eliminating insulin resistance induced by obesity and promoting glucose usage by muscle (Nishida et al, 2001). The amount and timing of exercise should be consistent from day to day to avoid unpredictable fluctuations in blood glucose that may result in potentially severe hypoglycemia. Finally, changes in diet, body weight and exercise may alter insulin requirements and should be accompanied by concurrent monitoring to assess if glycemic control has been affected. For example, an increase in dietary fiber may decrease blood glucose concentrations and lead to hypoglycemia or the Somogyi response. Similarly, loss of body weight will improve insulin sensitivity and may lead to hypoglycemia unless the insulin treatment regimen is modified.

Assess and Select the Food

Levels of the key nutritional factors should be evaluated in foods currently being fed to diabetic patients. Semi-moist foods should be avoided. Amounts and levels of key nutritional factors should be compared to those established for diabetic dogs and cats (**Table 29-3**). Information from this aspect of assessment is essential for making any changes to foods currently provided. If key nutritional factors in the current food do not match the recommended levels, then changing to a more appropriate food is indicated. **Tables 29-5** through **29-7** list the recommended key nutritional factors for diabetic dogs and cats

and selected commercial veterinary therapeutic foods often fed to patients with either insulin-dependent type I, or non-insulin-dependent type II, diabetes mellitus.

There are two types of foods for diabetic cats: increased-fiber/high-carbohydrate foods and low-carbohydrate/high-protein foods (**Tables 29-6** and **29-7**, respectively). Both have been shown to improve glycemic control in diabetic cats (Mazzaferro et al, 2001; Frank et al, 2001; Bennett et al 2006; Nelson et al, 2000). In one of the studies comparing the two types of foods, diabetic cats from both groups were able to discontinue insulin and revert to a nondiabetic state. Forty-one percent of the cats fed an increased-fiber/high-carbohydrate food and 68% of the cats fed a low-carbohydrate food became nondiabetic (Bennett et al, 2006). On the basis of calculated odds ratios, cats fed a low-carbohydrate food are three times more likely to discontinue insulin therapy and revert to a nondiabetic state (Kirk, 2006). Other studies have shown improved glycemic control in both healthy and diabetic cats fed low-carbohydrate foods (Massaferro et al, 2003; Frank et al, 2001). When choosing a type of food to feed diabetic cats, besides considering the aforementioned study results, the clinician's personal experience with a given approach is also important.

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Assess and Determine the Feeding Method

Determining the amount to feed diabetic dogs and cats requires special consideration. Patients with diabetes mellitus display a classic clinical picture of polyphagia with weight loss. Before making recommendations for daily energy requirement (DER), it is important to emphasize that the clinical response of patients with diabetes mellitus to dietary manipulation depends on the level of control of the primary disease process and the presence or absence of concurrent disease. For example, if weight loss or weight gain is a continuing problem, it may be due to poorly controlled diabetes mellitus or concurrent disease such as thyroid disorders (dogs and cats), lymphoplasmacytic enteritis (cats) or hyperadrenocorticism (dogs), rather than inappropriate calculation of DER. Consistent reevaluation and owner education are important tools in adjusting food dose and managing diabetes mellitus. After a patient's DER is estimated, the amount of food to feed (cups and/or cans) can be determined by dividing the DER by the as fed energy density of the food which can be found in **Tables 29-5** through **29-7**.

The basal metabolic rate may actually be decreased in patients with poorly controlled diabetes mellitus because of the euthyroid sick syndrome. Caution should therefore be taken to

avoid over diagnosis of true hypothyroidism in light of the prevalence of euthyroid sick syndrome. Hyperthyroidism is rare in dogs but may occur in some cats with diabetes mellitus.

The energy intake of diabetic patients must be assessed in relation to body condition. For most patients (BCS 2/5 to 4/5), feeding at the daily energy requirement (DER) for ideal body weight in conjunction with adequate control of diabetes mellitus will achieve desired body weights. It is best to calculate a DER as a multiple of resting energy requirement (RER) based on the standard formulas for normal dogs and cats (Chapter 1). For neutered dogs, a factor of 1.6 x RER, and for intact dogs, a factor of 1.8 x RER are good initial estimates of DER. For inactive/obese-prone dogs (most dogs), a range of 1.2 to 1.4 x RER is suggested. Factors of 1.2 x RER and 1.4 x RER for neutered and intact cats, respectively, are appropriate starting points. For inactive/obese-prone cats (most cats), using 1.0 x RER is appropriate. All patients should be reevaluated regularly with food doses adjusted based on body condition.

Diabetic dogs and cats often present with an obese body condition. For overweight and obese diabetic patients, a conservative weight-loss protocol may need to be instituted after medical problems are stabilized. For controlled weight loss in overweight/obese dogs, a starting point for DER is 1.0 x RER and for overweight/obese cats 0.8 x RER. These calculations assume RER for ideal body weight and are a good initial estimate for calculation of food doses. Frequent monitoring and readjustment should be the norm rather than the exception in weight-loss programs for patients with concurrent disease such as diabetes mellitus. Note that in these patients, improvement in insulin resistance is often accomplished with weight loss. Because many cats with type II diabetes mellitus are obese, caloric restriction may be a requisite part of their dietary management. In cats, care must be taken to avoid rapid weight loss that may predispose to hepatic lipidosis. Loss of 0.5 to 1% of initial body weight per week is considered safe (Chapter 27). Hepatic lipidosis does not seem to be a weight-loss concern for dogs. See **Box 29-2** for a feeding plan for DKA.

Feeding a food with moderate to high levels of fiber may pose problems for weight gain or even maintenance of current weight in diabetic patients that are too lean. These patients may need to be fed a food with less than 10% DM crude fiber and/or with slightly increased fat content to increase food energy density to a level where body weight is increased or maintained. Also, in these cases, feeding an increased quantity of food may prove useful. However, increasing the amount of food may not result in desired effects on body weight and condition if diabetes is poorly controlled.

Regarding when to feed, the feeding schedule should be designed to enhance the actions of insulin, maximize food usage and minimize postprandial hyperglycemia (**Figure 29-4**). The development of postprandial hyperglycemia depends, in part, on the amount of food consumed per meal, the rate at which glu-

cose and other nutrients are absorbed from the intestine and the effectiveness of exogenous insulin during this time. The daily caloric intake should be ingested when insulin is still present in the circulation and is capable of disposing of glucose absorbed from the meal. If meals are consumed while exogenous insulin is still metabolically active, the postprandial increase in blood glucose concentration will be minimal or absent. In contrast, feeding diabetic dogs and cats after insulin action has waned results in increasing blood glucose concentration shortly after consumption of the food. Ideally, several small meals given at regular intervals throughout the day with and following insulin administration result in minimal hyperglycemia (Ihle, 1995; Nelson, 1988). Diabetic dogs and cats that nibble throughout the day should be allowed to continue their pattern of eating (Martin and Rand, 2000). For these dogs and cats, the food should be available at the time of each insulin injection and the dog or cat allowed to choose when and how much to eat. The process is repeated at the time of the next insulin injection. In contrast, diabetic dogs and cats that eat all of the food when offered should be fed a set amount of food (calories) at defined times during the day. Generally, for patients receiving once-a-day insulin, half of the caloric requirement should be fed at the time of exogenous insulin administration and the other half eight to 10 hours later. If insulin is given twice daily, half of the caloric requirement should be fed with each injection. For finicky eaters, food is usually offered before insulin administration to avoid insulin-induced hypoglycemia if the animal does not eat.

Reassessment

Clinical Signs and Physical Examination

The most important initial parameters to assess when evaluating control of glycemia are the owners' subjective opinion of presence and severity of the pet's clinical signs and the overall health of their pet, findings on physical examination and stability of body weight. If the owner is satisfied with the results of treatment, the physical examination is supportive of good glycemic control and the body weight is stable, the diabetic dog or cat is usually adequately controlled. Poor control of glycemia should be suspected and additional diagnostics or a change in therapy considered if: 1) the owner reports persistent clinical signs suggestive of hyper- or hypoglycemia such as polydipsia, polyuria, lethargy, lack of grooming behavior (cats), weakness, ataxia or changes in jumping ability (cats), 2) the physical examination identifies problems consistent with poor control of glycemia such as an unthrifty or thin appearance, poor coat or plantigrade stance caused by peripheral neuropathy in diabetic cats or 3) the dog or cat is losing weight when it should not. Veterinary reassessment should take place every three to four months if the patient is stable and doing well. If the patient is persistently symptomatic, veterinary reassessment should take place every one to two weeks until control of the diabetic state is attained.

Body Weight and Condition

Achievement of weight goals can be measured through assessing body condition and weight. These measurements may also provide insight about the degree of glycemic control and the presence of other disease processes, especially in cases in which adjustments in food dose do not produce expected changes in body condition. Patients should be weighed every two weeks and have body condition assessed at least monthly. The owner should be encouraged to keep a chart of body weights and BCS. It may take several months to achieve weight-loss goals in obese patients. A loss of 10% body weight in already thin animals indicates a need for reassessment of the dietary and pharmacologic regimens.

Food Intake

Food intake, with maintenance of body weight, should decrease in patients with a favorable response to exogenous insulin administration. This response is caused by increased nutrient usage associated with hormonal treatment. If patients are

anorectic or have depressed food intake, the relative palatability of the food may be poor and another food should be tried after ruling out medical causes. It is especially important to monitor food intake in cats because prolonged anorexia is a risk factor for hepatic lipidosis (Barsanti et al, 1977).

Urine Glucose and Ketones

Although most owners can monitor urine for glucose and ketones, urine testing for glucose is a crude indicator of glycemic control status. In the newly-diagnosed or ketotic diabetic dog or cat, a decrease in urinary ketone bodies and glucose signals a favorable response to treatment. Well-controlled diabetic dogs and cats should not have ketone bodies in their urine. Occasional monitoring of urine for glycosuria and ketonuria in the home environment is helpful in those diabetic dogs and cats that have problems with recurring ketosis or hypoglycemia to determine if ketonuria or persistent negative glycosuria is present, respectively. In cats that have reverted to a non-insulin-requiring diabetic state, monitoring helps determine if glycosuria has recurred; in cats treated with oral hypoglycemic drugs, it helps determine if glycosuria has improved or worsened; and in cats with suspected stress-induced hyperglycemia, monitoring helps differentiate transient from persistent hyperglycemia. Owners should not adjust daily insulin dosages based on results of urine glucose testing, except to decrease the insulin dose in dogs or stop insulin treatment in cats with recurring hypoglycemia and persistent negative glycosuria.

Biochemistry Profiles

The biochemistry profile should return to normal with well-controlled diabetes and adequate nutritional intake. The primary exception is hyperglycemia that may or may not be present depending on when the blood sample is obtained in relation to insulin administration. Abnormalities of biochemical constituents in the face of controlled diabetes mellitus should be evaluated as separate disease entities.

Serum Fructosamine

Measurement of glycated proteins (e.g., glycosylated hemoglobin and serum proteins [fructosamine]) is a common method of monitoring glycemic control in diabetic people and animals. Glycosylated hemoglobin is the most common glycated protein measured in diabetic people, but assays are time-consuming, often of questionable accuracy and not routinely evaluated in diabetic dogs and cats. Serum fructosamine is the most common glycated protein measured in diabetic dogs and cats (Reusch et al, 1993; Crenshaw et al, 1996; Elliott et al, 1999). Fructosamines result from an irreversible, nonenzymatic, insulin-independent binding of glucose to serum proteins. Serum fructosamine concentrations are a marker of mean blood glucose concentration during the circulating lifespan of the protein, which varies from one to three weeks, depending on the protein. The extent of glycosylation of serum proteins is directly related to the blood glucose concentration; the higher the average blood glucose concentration during the preceding two to three weeks, the higher the serum fructosamine concentration, and vice versa. Serum fructosamine concentrations increase when glycemic control of diabetic dogs and cats worsens and decrease when glycemic control improves. Serum fructosamine concentration is unaffected by acute increases in blood glucose concentration, as occurs with stress or excitement-induced hyperglycemia, but can be affected by hypoalbuminemia (<2.5 g/dl), hyperlipidemia (triglycerides >150 mg/dl) and hyperthyroidism (Lutz et al, 1995; Crenshaw and Peterson, 1996; Reusch and Haberer, 2001). Interpretation of serum fructosamine in diabetic dogs and cats should consider the fact that hyper-

Box 29-2. Feeding Plan for Diabetic Ketoacidosis.

Intensive care and intravenous fluid administration are not required if the patient is bright, alert and well-hydrated. Administration of short- or intermediate-acting insulin can be initiated in conjunction with feeding recommendations similar to those for type I and type II diabetes mellitus. Some patients with diabetic ketoacidosis may require in-hospital intensive care. Goals are to correct dehydration, electrolyte disorders (hypokalemia, hypophosphatemia, hyponatremia, hypochloremia, hypomagnesemia), ketonuria and acidosis while initiating a feeding plan. Nutritional recommendations are similar to those for type I and type II diabetes mellitus after the patient is stabilized (**Table 29-3**).

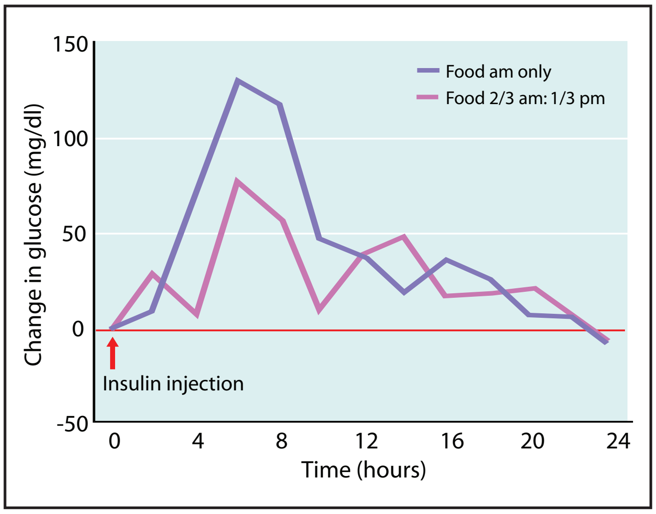

Figure 29-4. Mean change in blood glucose concentrations in eight dogs with insulin-dependent diabetes mellitus (type I) fed 66 kcal/kg body weight of a commercial moist dog food. A fixed amount of NPH insulin was administered to each dog at 8:00 a.m. Food was given either in one meal at 8:00 a.m. or in two meals at 8:00 a.m. (two-thirds of the food) and 6:00 p.m. (one-third of the food). Note the reduction in the mean blood glucose excursion merely by feeding multiple rather than one meal daily. (Adapted from Nelson RW. Disorders of the endocrine pancreas. In: Ettinger SJ, ed. Textbook of Veterinary Internal Medicine, 3rd ed. Philadelphia, PA: WB Saunders Co, 1989; 1694.)

Chapter 30

Cancer

Korinn E. Saker

"Life well spent is long."
Leonardo da Vinci

CLINICAL IMPORTANCE

Cancer is among the most common causes of nonaccidental death of dogs and cats, often ranking first or second (Bonnett et al, 2005; Egenvall et al, 2005; Proschowsky et al, 2003; Moore et al, 2001). One study documented that 23% of 2,000 pets examined at necropsy died of cancer (Bronson, 1982). Additionally, in a more recent study of more than 350,000 insured dogs, cancer was the most common cause of death, accounting for 18% of deaths; cancer occurred more commonly in females than in males for most breeds (Egenvall et al, 2005).

In cats, cancer also commonly threatens life and quality of life. Cats have the largest number of different retroviruses of any companion animal and these are closely linked to feline leukemia virus infection (FeLV). The overall prevalence (number of diagnosed cases/year) of FeLV infection in the United States is between 1 and 3%; however, the prevalence may be as high as 30% in multi-cat households and 11.5% in sick cats (Macy, 1996). In addition, known carcinogens can affect animals as well as people. Recent studies have investigated the link between environmental tobacco smoke and the development of cancers such as lymphoma and squamous cell carcinoma (SCC) in cats, and respiratory tumors in dogs (Snyder et al, 2004; Bertone et al, 2002, 2003; Reif et al, 1998). Additional environmental risk factors for SCC in cats include consumption of canned food and tuna fish, and the use of flea collars. For dogs, the indoor use of kerosene or coal also increased the risk of sinonasal cancer. Furthermore, obesity and insecticide use have been linked to bladder cancer (Bukowksi et al, 1998; Glickman et al, 1989).

Often, cancer results in either rapid weight loss or an inability or unwillingness to eat that is difficult to circumvent. Nutritional options for cats with cancer are less well studied though equally important. Because of their size, cats may necessitate increased frequency of nutritional support. The overall prevalence of cancer in pets appears to be increasing (Macy, 1996) for a variety of reasons, including greater longevity, improved veterinary care and an increased awareness of veterinarians through specialty services and advanced diagnostics.

Cancer incidence continues to increase in the human population as well. Statistics show that approximately 38% of women and 45% of men will develop cancer in their lifetime (Jemal et al, 2007). An estimated 1.3 million people were projected to be newly diagnosed with cancer in 2006, and more than a half million people were projected to die (Jemal et al, 2007). Therefore, it is not unusual to realize that many pet owners have had a personal experience with cancer affecting themselves, family members, friends or acquaintances. Veterinarians and health care teams should approach pets with cancer, and their owners, in a positive, compassionate and knowledgeable manner. Many owners understand or are willing to be educated about the importance of nutrition and how proper feeding can enhance the quality and length of life for

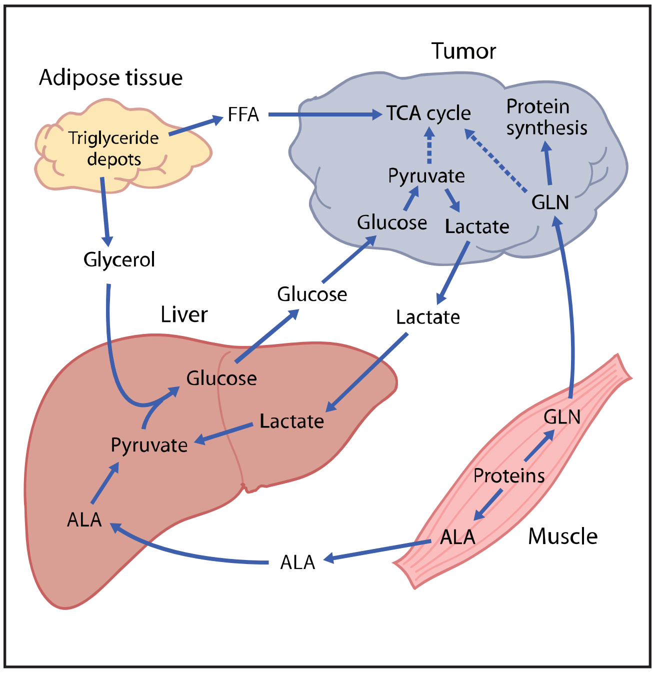

Figure 30-1. Metabolic relationships in cancer lead to increased proteolysis in the host's tissues, especially skeletal muscle. The Cori and glucose-alanine cycles undergo increased activity. High circulating concentrations of alanine (ALA) and glutamine (GLN) result, helping to feed the high glucose demand of the tumor.

pets with cancer.

Nutritional support can reduce or prevent toxicoses associated with cancer therapy and ameliorate the metabolic alterations induced by cancer in dogs and cats. Additionally, there is growing evidence that specific nutrients can be used to treat cancer directly or indirectly. This chapter focuses on the nutritional management of patients with cancer rather than on cancer prevention.

PATIENT ASSESSMENT

History and Physical Examination

The metabolic and clinical alterations in cancer patients have been described in four phases (**Table 30-1**) (Ogilvie and Vail, 1996, 1992, 1990; Ogilvie and Moore, 1995, 1995a; Shein et al, 1976; Theologides, 1979; Buzby and Steinberg, 1981; Landel et al, 1985; Bray and Campfield, 1975; Vail et al, 1990). The first phase is a preclinical "silent" phase in which patients do not exhibit overt clinical signs of disease, but subtle changes in behavior can often be observed. As the underlying malignancy progresses, owners often state that their pet seems to be "slowing down" or aging more rapidly, or is less active and less willing to engage in normal activities. Despite normal clinical appearances, patients in Phase 1 have quantifiable metabolic changes such as hyperlactatemia, hyperinsulinemia and alterations in blood amino acid profiles (**Figure 30-1**).

The second phase is a clinical phase in which patients begin to exhibit anorexia, lethargy and early evidence of weight loss. These patients are likely to exhibit side effects associated with chemotherapy, radiation therapy, immunotherapy and surgery that may alter nutrient intake and use, and thus the nutrition support plan.

The third phase (cancer cachexia) is characterized by marked debilitation, weakness and biochemical evidence of negative nitrogen balance such as hypoalbuminemia. In this phase, cancer patients begin to lose body protein and fat stores. Chronic vomiting, diarrhea, weakness, lethargy and weight loss are reported by owners of dogs and cats with endstage cancer.

A fourth phase (recovery or remission) occurs in those patients undergoing treatment with apparent elimination of their disease. Metabolic alterations persist in some patients despite elimination or control of the cancer via chemotherapy, radiation or surgery. Here again, the therapy itself may cause changes that affect the feeding plan. Animals may develop food aversions at any time because of treatment-induced alterations in taste and smell.

Clinical staging of cancer is performed by assessing tumor size, depth of tumor invasion, presence of tumor in regional lymph nodes and by identifying tumors in distant sites. This information is used to stage tumors by the TNM system: T (tumor size and/or invasion), N (nodal involvement) and M (distant metastasis). Tumor staging may correlate with clinical behavior in certain types of cancer and, in the future, may help determine whether a tumor will respond to nutritional management. To date, body condition scoring and body weight changes are the most practical tools for monitoring the overall nutritional effects of cancer and cancer treatment in dogs and cats (Chapter 1).

Laboratory and Other Clinical Information

Laboratory evaluation of total lymphocyte count, hematocrit, serum glucose, albumin, urea nitrogen concentrations and thyroid hormone levels can be helpful to further evaluate nutritional status. Toxic changes in neutrophils have been seen in cats with cachexia, and were significantly associated with longer hospitalization and higher treatment cost (Segev et al, 2006). Use of these parameters is somewhat limited because they may have causes unrelated to cancer. Albumin also has a relatively long half-life (eight days in normal dogs; the half-life of albumin in cats is unknown, but suspected to be between 5.7 and 8.2 days) and is slow to respond to changes in nutritional status. Plasma levels of triiodothyronine (T_3), reverse T_3, free thyroxine (T_4) and thyroid stimulating hormone (TSH) were severely altered in malnourished patients undergoing surgery for T_1 to T_4 carcinomas of the head and neck, as compared to well-fed cohorts. This study suggests, as starvation and overfeeding modulate thyroid hormone metabolism, thyroid hormone status can potentially be used to evaluate nutritional status of cancer patients (Siroen et al, 2006).

Body weight becomes an insensitive index in patients with severe intestinal malassimilation including marked hypoalbuminemia and ascites due to changes in total body water rather than lean body mass. Apart from this, body weight is a very sensitive long-term (weeks to months) indicator of decline or

recovery of animals. Dogs and cats in the pre-clinical or "silent" phase may appear clinically normal but may gradually lose weight despite a good appetite.

Plasma amino acid profiles and serum lactate concentrations, parameters associated with tumor cell progression in the canine cancer model, have not been used clinically to assess the nutritional status of veterinary cancer patients. Likewise, biomarkers associated with tumor growth and subsequent nutritional support such as serum creatine kinase (Fascetti et al, 1997); mitogen-activated protein kinase (MAPK) (Saker et al, 2002); serum mineral content including zinc, chromium, iron and total iron-binding capacity (Kazmierski et al, 2001) and the vascular endothelial growth factor (VEGF) system, including VEGF and the VEGF receptors, Flt-1and KDR (Millanta et al, 2006) have yet to be instituted clinically. Acute-phase reactant proteins, although not specific for cancer, can be measured in serum and can predict prognosis and response to therapy. The combination of certain acute-phase proteins can be more powerful than one assay (others include C-reactive protein and alpha-fetoprotein). Alpha 1-acid glycoprotein is an acute-phase protein that is increased in cats with cancer, and has been used to predict loss of remission for dogs (but not cats) with lymphoma (Selting et al, 2000; Correa et al, 2001; Hahn et al, 1999).

In certain tumors, grading the degree of malignancy histologically predicts biologic behavior. Although a direct relationship between tumor grade and nutritional status including cancer cachexia has not been established, it is thought that more aggressive cancers tend to cause more pronounced systemic effects on body condition. Conversely, even a benign tumor can significantly affect the nutritional status of a dog or cat if it interferes with intake or assimilation. Oral tumors such as SSC in cats may inhibit food intake, and intestinal tumors such as lymphomas can cause poor nutrient absorption, decreased appetite and diarrhea. Tumor grade may correlate with survival, metastatic rate, disease-free interval or with frequency or speed of local recurrence. Not only can a prognosis be determined based on tumor grade, but more aggressive nutritional therapies may be applied to higher grade tumors. Clearly, no single "gold standard" test exists for determining a cancer patient's nutritional status.

Risk Factors

Numerous studies have outlined risk factors of certain nutrients and their relationship to development of cancer. For example, decreased fiber and increased fat have been most commonly incriminated as causal factors for the development of a wide variety of malignant conditions of the gastrointestinal (GI) tract, breast and urinary bladder in people.

Existing data are controversial regarding the cause and effect relationship between diet and cancer in pets. One group of investigators conducted a case-controlled study of nutritional factors and canine breast cancer (Sonnenschein et al, 1991). Neither a high-fat diet nor obesity one year before diagnosis increased the risk of breast cancer. However, the risk of breast cancer was significantly reduced among neutered dogs that had been thin at nine to 12 months of age. Among intact dogs, a thin body condition at nine to 12 months of age reduced the risk of breast cancer. Results of this study suggest that nutritional factors resulting in altered body composition early in life may be important in canine breast cancer. A case-control study evaluated the possible relationship between diet and dietary management in 86 healthy control dogs and 102 dogs with mammary gland tumors or mammary gland dysplasia (Perez-Alenza et al, 1998). Body composition, diet and reproductive history were reviewed. Nutritional status was evaluated from serum selenium and retinol values and adipose fatty acid profiles. Obesity at one year of age and an obese body condition score (BCS) one year before diagnosis are significantly related to a higher prevalence of mammary tumors and cell dysplasias in dogs. Additionally, intake of homemade meals vs. commercial foods is significantly related to a higher incidence of tumors and dysplasias; increased intake of red meat (beef, pork) strongly influences disease incidence. Results from this study indicated that obesity at one year of age was independently and significantly associated with risk of developing mammary tumors and dysplasia. A five-year retrospective study evaluated the distribution of BCS values for dogs with and without histologically and behaviorally malignant neoplasms (Weeth et al, 2007). A total of 14,760 dogs (1,777 with cancer; 12,893 controls) met the inclusion criteria. Dogs with cancer were further allocated into the general categories of sarcoma (n = 582), carcinoma (n = 428) or round cell tumor (n = 767) based on histologic classification of tumor cells. Using a 9-point BCS system, 21.6 and 14.8% of dogs were classified as overweight or obese, respectively. Overall, the mean BCS of all dogs with cancer was 5.4 ± 1.2 vs. 5.3 ± 1.2 for noncancer controls. Investigators reported a significantly lower prevalence of overweight and obese dogs with cancer compared to control dogs without cancer. The

Table 30-1. Phases of clinical and metabolic alterations in cancer patients.

Phase	Clinical changes	Metabolic changes
1	Preclinical, silent phase No obvious clinical signs	Hyperlactatemia Hyperinsulinemia Altered blood amino acid profiles
2	Early clinical signs Anorexia Lethargy Mild weight loss More susceptible to side effects from chemotherapy, etc.	Similar metabolic changes
3	Cachexia Anorexia Lethargy More susceptible to side effects from chemotherapy, etc.	Similar changes but more profound
4	Recovery Remission	Metabolic changes may persist Changes secondary to surgery, chemotherapy or radiation therapy

study revealed a lower prevalence of overweight and obese dogs with sarcomas and carcinomas, but no difference in distribution of BCS in dogs with round cell tumors compared to controls.

Overweight or obese body condition in dogs may also influence the risk of bladder cancer. Investigators have evaluated the role of diet in preventing bladder cancer in Scottish terriers, a breed predisposed to the development of transitional cell carcinoma of the urinary bladder. This survey-based study evaluated each dog's diet for one year before diagnosis and compared data to that from non-neoplastic counterparts. Results were adjusted for age, sex and weight. There was a statistically significant decreased risk of developing transitional cell carcinoma in dogs fed green leafy and yellow-orange vegetables and for dogs fed vegetables at least three times per week. Although the risk of transitional cell carcinoma was lower in dogs fed cruciferous vegetables, the finding was insignificant. These results suggest diet may play a role in the prevention or management of bladder cancer (Raghavan et al, 2005).

Currently, there is no common thread or single measurable parameter that defines the population at risk for or experiencing cancer. Risk assessment for cachexia and nutritional support for cancer must be tailored to each patient with consideration for breed, age, tumor type and other factors.

Etiopathogenesis

There are three basic steps that ultimately lead to generation of a cancer cell from a normal cell: 1) initiation, 2) promotion and 3) progression (London and Vail, 1996). Initiating agents induce permanent and irreversible changes in the DNA of affected cells. Promoting agents cause reversible tissue and cellular changes up to development of the first autonomous tumor cell. Promoting action generally occurs over a long latency period and requires nearly continuous exposure to the promoting agent. Progressing agents convert initiated cells, or cells undergoing promotion, into cells that exhibit the malignant phenotype capable of developing into a mature neoplasm.

Multi-step carcinogenesis occurs through five basic pathways; more than one pathway may be involved in the generation of a particular tumor (London and Vail, 1996). The five carcinogenic pathways are: 1) heritable, 2) passive, 3) biologic, 4) chemical and 5) physical.

Although little is known about breed-specific genetic alterations that may predispose domestic pets to develop neoplastic disease, certain breeds of dogs have a higher incidence of cancer than others. Recent studies have examined breed-specific predispositions to certain types and subtypes of cancer, such as lymphoma (Modiano et al, 2005). Breeds commonly overrepresented in tumor-bearing cohorts include boxers, rottweilers, German shepherd dogs, Scottish terriers and golden retrievers. Siamese cats appear to be at more risk than other feline breeds. Perhaps the best characterized genetic mutation suspected to cause a specific cancer is found in German shepherd dogs with renal cystadenocarcinoma and nodular dermatofibrosis. The chromosomal region that overlaps the human Birt-Hogg-Dubé (BHD) locus responsible for a phenotypically similar syndrome in people, showed mutation of exon 7 of the canine BHD gene. Genetic analysis and pedigree evaluation support this mutation as causative for this cancer (Lingaas et al, 2003).

Point mutations, chromosomal translocations and gene amplification occur as spontaneous events in any dividing cell population. These changes accumulate over a lifetime, possibly explaining why many cancers arise in mature or aged individuals.

Carcinogens can be found in many different aspects of the environment. The most common biologic agents capable of inducing cancer are retroviruses, DNA tumor viruses and some parasites. Various chemical compounds, some naturally occurring and some synthetic, are capable of inducing malignant neoplasia. In most cases, chemical carcinogens require repeated administration or exposure to demonstrate an effect. Physical carcinogens include ultraviolet radiation, ionizing radiation and foreign materials (London and Vail, 1996).

Cancer Cachexia

Cancer cachexia is a complex paraneoplastic syndrome that adversely alters the functional status of the patient (**Figure 30-2**). It manifests as weight loss, reduced food intake and systemic inflammation as a consequence of the cancer disease process (Fearon et al, 2006). This syndrome differs from simple starvation in that both protein and fat stores are lost almost simultaneously in cachectic patients. Initially in simple starvation, fat stores are lost preferentially followed later by loss of protein stores. The time frame for onset of noticeable cachexia-induced weight loss in dogs and cats with cancer can vary. One survey-based study examined dogs as they were presented to the oncology service (Michel et al, 2004). Body weight before cancer diagnosis was available for 64 of 100 dogs. Twenty-three percent had lost more than 10% of their body weight before diagnosis. Body condition scoring, however, found only 4% of dogs with cachexia and 15% with clinically evident muscle wasting; 29% were markedly overweight (Michel et al, 2004). Although body condition scoring and changes in weight are good clinical measures of body condition, they do not consider the complexity of factors influencing the cachectic state such as the metabolic alterations that can occur even before any overt clinical signs associated with cancer cachexia are identified (Ogilvie and Vail, 1996, 1992; Ogilvie and Moore, 1995).

Cancer cachexia may be partly due to negative energy balance secondary to decreased energy intake or altered energy expenditure (Lawson et al, 1982; Dempsey et al, 1984). Investigators have found alterations in basal metabolic rate and resting energy requirement (RER) that were associated with altered carbohydrate, protein and lipid metabolism in human patients with cancer cachexia (Lawson et al, 1982; Dempsey et al, 1984). Additionally, resting energy expenditure and caloric requirements are increased in some tumor-bearing people and animals when compared to healthy individuals (Dempsey et al, 1986; Hansell et al, 1986; Fredrix et al, 1991; Zyliez et al, 1990; Delarue et al, 1990).

Several studies have evaluated energy expenditure in dogs with lymphoma and non-hematopoietic malignancies. Dogs with osteosarcoma have been compared to normal beagles to evaluate metabolic alterations using indirect calorimetry (rest-

ing energy expenditure and respiratory quotient), stable isotope tracers (protein synthesis and glucose flux) and dual x-ray absorptiometry scans (body composition). Dogs with osteosarcoma were described as being "weight-stable." These dogs had higher resting energy expenditure before and after surgery, decreased rates of protein synthesis, increased urinary nitrogen loss and increased glucose flux postoperatively (Mazzaferro et al, 2001).

Earlier studies evaluated energy expenditure in dogs with carcinomas and sarcomas (Ogilvie et al, 1997; Walters et al, 1993). These studies found no significant differences in energy expenditure (and presumably caloric requirements) in dogs with a wide range of malignancies compared to healthy, client-owned dogs. This finding suggested that, in general, dogs with cancer and no evidence of weight loss do not have energy requirements higher than those of apparently healthy dogs without cancer. Furthermore, these parameters did not change significantly in dogs with cancer when the tumor was removed surgically (Ogilvie et al, 1996).

Because the thyroid gland and its hormones are intimately involved in the control of energy homeostasis (Premachandra et al, 1981; Sestoft, 1980), investigators have speculated that perturbations in thyroid function or thyroid hormone concentrations play a role in altering energy states in tumor-bearing individuals. In one study, researchers compared thyroid hormone concentrations in dogs with cancer (with and without chronic weight loss) with those in nontumor-bearing dogs (with and without chronic weight loss) (Vail et al, 1994). Diminished serum concentrations of T_4, T_3 and free T_3 occurred in proportion to the degree of weight loss, regardless of tumor-bearing status. Apparently, these reductions in hormone concentrations are related to the abnormal nutritional state or severity of illness rather than to a tumor-related phenomenon. This has been termed "euthyroid sick syndrome." Taken together, these studies illustrate that daily energy requirement (DER) in animals with uncomplicated cancer are similar to those of normal animals, and there is a complexity of metabolic alterations that can occur in cancer patients even in the absence of clinically evident cachexia.

The endstage of cancer cachexia is weight loss that is due not only to primary effects of the tumor, such as compression or infiltration of the alimentary tract, but also to: 1) therapy (e.g., chemotherapy-induced anorexia, nausea or vomiting) or 2) alteration of metabolic pathways composing this paraneoplastic syndrome (**Figure 30-2**) (Ogilvie and Vail, 1996, 1992; Ogilvie and Moore, 1995). Many tumor-bearing animals have altered metabolism, which necessitates special methods for delivering nutrients and specific types of fluid and nutrient support (Ogilvie and Vail, 1996, 1992, 1990; Ogilvie and Moore, 1995, 1995a; Shein et al, 1976; Theologides, 1979; Buzby and Steinberg, 1981; Landel et al, 1985; Bray and Campfield, 1975; Vail et al, 1990, 1990a, 1990b; Ogilvie et al, 1992).

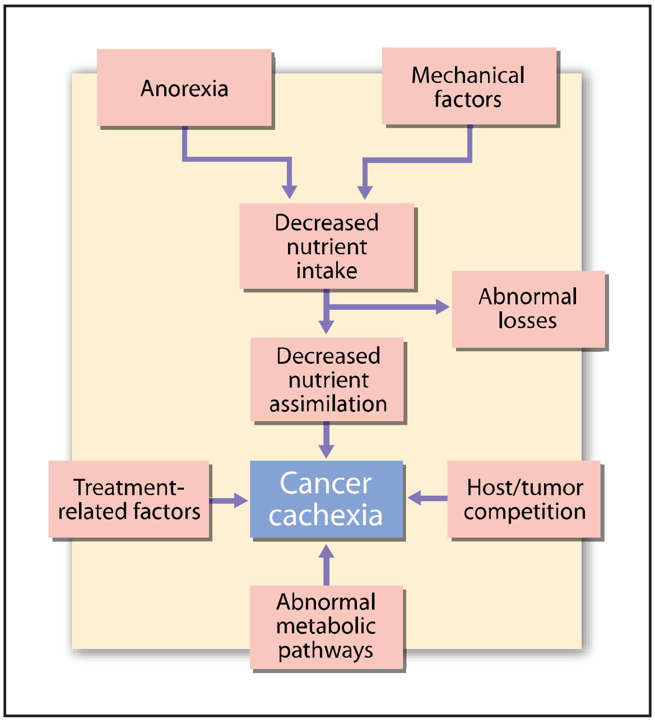

Figure 30-2. Mechanisms of cancer cachexia.

Nutritional Effects from Cancer Treatment

Besides the effects of cancer itself, various modalities used to treat cancer (radiation, chemotherapy and surgery) may adversely affect a patient's nutritional status. The malnutrition that results from treatment assumes even more importance given that many cancer patients are already debilitated from their disease. Anticancer therapy may produce only mild, transient disturbances, such as mucositis, or it may lead to severe, permanent problems, as in small bowel resection or disabilities of mastication and swallowing after head and neck surgery or radiation. Generally, nutritional problems should be anticipated, feeding tubes placed and patients fed earlier to lessen the adverse effects of treatment.

Surgery

Surgery is used in the treatment of cancer in an attempt to remove tumors or alleviate clinical signs (e.g., intestinal or urinary tract obstruction). Nutritional problems that may develop depend on the surgical location and type of procedure performed (**Table 30-2**). Preliminary studies in dogs suggest that metabolic alterations associated with cancer persist even after tumors are removed surgically (Ogilvie et al, 1997). In general, feeding tubes (esophagostomy, gastrostomy, jejunostomy) should be placed at the time of surgery to avoid additional anesthesia and to allow early feeding.

Radical head or neck surgery may lead to significant malnutrition by altering a patient's ability to eat. Although some of these changes are temporary, many patients have permanent difficulty with chewing and/or swallowing with subsequent risk of aspiration. Proactive placement of gastrostomy tubes (Chapter 25) during head and neck surgery will facilitate enteral feeding during the immediate postoperative period. These tubes may be used for long-term enteral feeding of some cancer patients (Chapter 25). In one retrospective study of cats

Table 30-2. Effects of surgery that may have nutritional implications for cancer patients.

Cancer sites	Surgical procedures	Possible nutritional problems
Head, neck, tongue	Mandibulectomy Maxillectomy Glossectomy	Difficulty prehending, chewing and swallowing food
Esophagus	Esophagectomy, with or without reconstruction	Dysphagia Regurgitation
Stomach	Gastrectomy, partial or complete	Altered gastric emptying Diarrhea
Small intestine	Resection	Malabsorption Diarrhea Intestinal obstruction
Large intestine	Colectomy, partial or complete	Fluid and electrolyte imbalances
Pancreas, liver	Pancreatectomy Cholecystectomy Cholecystoduodenostomy	Diabetes mellitus Maldigestion

Vomiting

undergoing mandibulectomy for oral neoplasia, nearly half had an enteral feeding tube placed at the time of surgery, and tubes were used for a median of 74 days postoperatively. Tube placement was deemed an appropriate aspect of management for oral neoplasia as 72% of the cats experienced dysphagia postoperatively, and 12% never regained the ability to eat. Additionally, 83% of owners were satisfied with the outcome of treatment (Northrup et al, 2006).

The nutritional sequelae of gastric and intestinal resection are directly related to the site and extent of resection and to the individual functions of the various segments. The ability of various segments of the small intestine to increase absorptive capabilities over a period of several months prevents major clinical problems after small bowel resection unless the resection is massive. With massive resection, malabsorption (short bowel syndrome) becomes the primary nutritional problem (Chapter 59). In people, colon surgery is usually well tolerated. The large water and electrolyte losses in the early postoperative period decrease rapidly after surgery. Feeding frequency and nutrient composition of the diet should be closely managed to optimize nutritional support for patients with surgical treatment of GI cancers.

Chemotherapy

Chemotherapeutic agents may contribute to malnutrition through a variety of direct and indirect mechanisms (**Table 30-3**). These problems should be anticipated and feeding tubes placed before therapy because early feeding lessens the adverse effects of therapy. Chemotherapeutic agents affect normal and malignant cells but have the greatest effect on rapidly proliferating cells such as epithelial cells of the GI tract. The degree to which GI function is affected depends on the chemotherapeutic agent, drug dosage, duration of treatment, rate of metabolism and the individual animal's susceptibility.

Small bowel villous damage is a major side effect of some chemotherapeutic agents and may be greatly intensified when radiation therapy is given concurrently. The rapid renewal rate of the alimentary tract epithelium usually means that clinical problems from drug-induced mucositis are short-lived.

Nausea and vomiting commonly accompany the administration of many anticancer drugs. Alterations in smell and taste are reported to occur in people and may occur in animals. Side effects experienced during chemotherapy make it difficult for some patients to consume adequate amounts of food.

Corticosteroids such as prednisone are used in chemotherapeutic protocols for some cancers, most notably lymphoma. High doses or prolonged therapy with corticosteroids causes profound polydipsia and polyuria and increased loss of water-soluble vitamins.

It is important to consider the effects of nutritional manipulation and supplemental therapies on the pharmacokinetics and pharmacodynamics of standard cytotoxic chemotherapy. Clients often regard supplements as harmless and may not report their use to the treating clinician in both human and veterinary medicine. However, growing evidence suggests that certain supplements may have toxicity of their own, and may interact with other drugs, including chemotherapeutic agents. Herbal supplements may affect metabolizing enzymes, interfering with pharmacokinetics of some drugs. Antioxidants may squelch free radicals responsible for the anticancer effect.

Because omega-3 (n-3) fatty acids have been associated with improved survival and decreased side effects in dogs with lymphoma, and have many possible anticancer properties, the effect of these fatty acids on the handling of doxorubicin was recently examined. Dogs with lymphoma were enrolled prospectively and randomized to receive a food either high or low in omega-3 fatty acids. There was no significant difference between food groups in this study (Selting et al, 2006).

Fatty acids, vitamins and herbal remedies are readily available over the counter and it is important to understand the possible effects of these and other supplements, such as singular amino acids, antioxidants and flavonoids on cancer therapy.

Radiation

Veterinary patients receiving radiation therapy may have complications that affect food intake. The complications of radiation vary according to the region of the body radiated, dose, fractionation and associated antitumor therapy such as surgery or chemotherapy. Complications may develop acutely during radiation or become chronic and progress even after radiation therapy has been completed (**Table 30-4**).

Radiation to the head and neck affects the oral mucosa and salivary secretions. Saliva production decreases in conjunction with an increase in saliva viscosity, when the salivary glands are in the field of radiation. In addition to causing mouth dryness (xerostomia) and impairing swallowing, the decrease in salivation alters the oral bacterial flora, which in turn may promote dental disease and stomatitis. In people, the thick, scant secretions may also create a feeling of nausea (Ross, 1990).

The mucosa of the mouth and oropharynx is sensitive to radiation, which can produce a sore mouth or throat, painful ulcerations, bleeding or even chronic radiation ulcers. Radionecrosis of oral tissue may result from the combination of trauma and infection superimposed on highly radiated tissues. Radiation damage alters or suppresses taste and smell sensations and affects sensitivity to food texture and temperature. In people, taste returns gradually within two to four months after radiation therapy is completed, but may take up to one year (Sandow et al, 2006). Alterations in smell and taste undoubtedly occur in animals but have not been well documented. These changes create a potentially serious situation because patients are often already anorectic and undernourished.

Radiation to the thoracic area induces esophagitis and dysphagia. These lesions and signs usually disappear after cessation of therapy. Tumor necrosis, however, may produce delayed complications such as ulceration, fistula formation and obstruction from fibrosis and stricture.

Abdominal or pelvic radiation may alter intestinal function. Patients receiving upper abdominal radiation may experience nausea and vomiting whereas those receiving radiation to the lower abdomen often experience diarrhea due to intestinal mucosal damage, loss of villi and accompanying malabsorption. Acute radiation enteritis usually disappears after therapy is discontinued. However, late effects of abdominal radiation may occur months to years after completion of radiation therapy and are manifested as intestinal obstruction, fistula formation and chronic enteritis (Kokal, 1985).

Radiation therapy in animals is usually performed on five successive days per week with patients restrained by general anesthesia, which presents an opportunity to place a feeding tube (Chapter 25). This treatment schedule requires careful planning of the feeding method to ensure that patients consume their required amount of food each day.

Unless nutritional intervention is provided, many patients lose weight during radiation therapy. Assisted feeding is indicated if food intake is inadequate (Chapters 25 and 26).

Key Nutritional Factors

Alterations in carbohydrate, lipid and protein metabolism precede obvious clinical disease and cachexia in cancer patients. These metabolic alterations may persist in patients with clinical remission or apparent recovery from their cancer. Key nutritional factors in cancer patients include digestible (soluble) carbohydrate, fat, fatty acids and protein, including a few specific amino acids, notably arginine. Several other amino acids have been identified as potentially imparting benefits to cancer patients; however, evidence-based studies in companion animals are not yet available. The key nutritional factors for the dietary management of cancer and their recommended amounts are discussed below and listed in **Table 30-5**. Additional nutrients and nutritional factors that have been identified in human cancer nutrition research include polyphenols, flavonoids and specific vitamin and mineral antioxidants. Veterinary patient data are not currently available to recommend specific dietary levels of these other nutrients, but research is ongoing to clarify their benefit or potential harm in the dietary management of veterinary cancer patients.

Table 30-4. Effects of radiation therapy that may have nutritional implications for cancer patients.

Treatment areas	Acute effects	Chronic effects
Head and neck	Mucositis of mouth, tongue, esophagus	Dry mouth Dental disease Alterations in smell Alterations in taste
Thorax	Esophagitis	Esophageal fistula Esophageal stricture
Abdomen	Nausea, vomiting Enteritis, diarrhea Malabsorption	Intestinal obstruction Fistula formation Chronic enteritis

Table 30-5. Key nutritional factors for foods for canine and feline cancer patients.

Factors	Dietary recommendations
Digestible carbohydrate (NFE)*	Avoid excess digestible carbohydrate NFE = ≤25% DM or <20% of the food's ME
Fat	Provide a large proportion of energy from fat Fat = 25 to 40% of DM or 50 to 65% of the food's ME
Omega-3 fatty acids	Provide foods with increased levels of omega-3 fatty acids (>5% DM)
Omega-6: omega-3 fatty acid ratio	Provide foods with an omega-6:omega-3 ratio as close to 1:1 as possible
Protein	Avoid protein deficiency Provide protein in excess of adult requirements Dogs: protein = 30 to 45% of DM or 25 to 40% of the food's ME Cats: protein = 40 to 50% of DM or 35 to 45% of the food's ME (Taurine is always a necessary inclusion in feline diets)
Arginine	Provide foods with arginine DM levels >2%

*Key: NFE = nitrogen-free extract, DM = dry matter, ME = metabolizable energy.

Digestible Carbohydrate

The complex role of carbohydrates in mammalian tumor cell metabolism was identified more than 50 years ago by biochemist Otto Warburg (Ristow, 2006). Warburg noted that tumor cells have high rates of anaerobic glycolysis and impaired respiration. Others have since confirmed these metabolic alterations and numerous mechanisms have been proposed to explain oxidative metabolism in cancer cell growth. Recent studies indicate that neoplastic cells require not only ATP derived from glycolysis, but also biosynthetic precursors from

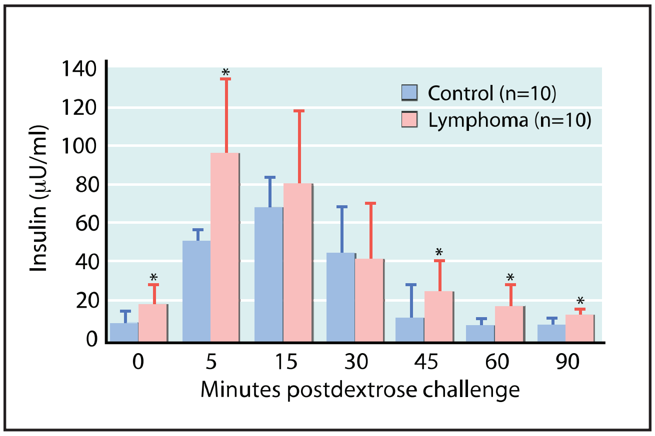

Figure 30-3. Serum insulin concentrations from dogs with and without lymphoma before and after intravenous administration of 500 mg glucose/kg body weight. Asterisks indicate values from dogs with lymphoma that differ significantly (p <0.001) from control dog values obtained at the same time. (Adapted from Vail DM, Ogilvie GK, Wheeler SL, et al. Alterations in carbohydrate metabolism in canine lymphoma. Journal of Veterinary Internal Medicine 1990; 4: 307.)

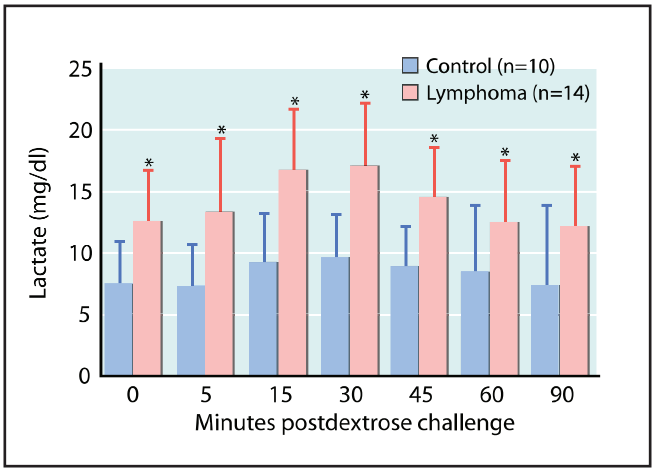

Figure 30-4. Serum lactate concentrations from dogs with and without lymphoma before and after intravenous administration of 500 mg glucose/kg body weight. Asterisks indicate values from dogs with lymphoma that differ significantly (p <0.001) from control dog values taken at the same time. (Adapted from Vail DM, Ogilvie GK, Wheeler SL, et al. Alterations in carbohydrate metabolism in canine lymphoma. Journal of Veterinary Internal Medicine 1990; 4: 307.)

glycolytic intermediates in order to proliferate and invade (Chesney, 2006). One such intermediate, fructose-2,6-biphosphate, controls the overall rate of glycolysis in tumor cells. A second intermediate, 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase, controls the intracellular concentration of glucose in tumor cells and is constitutively expressed by several leukemias and solid tumor cells (Chesney, 2006). The high glycolytic flux to pyruvate/lactate observed in tumors also alters intracellular pH, causing apoptosis in normal surrounding cells. Increased glucose transport (Birnbaum et al, 1987) and overexpression of oncogenes associated with glucose transport (Flier et al, 1987) have also been associated with tumors cells. Increased glycolysis in tumors may also be a consequence of hexokinase redistribution in subcellular and mitochondrial compartments, or the altered ability of mitochondria to metabolize substrates other than carbohydrates or their derivatives for energy (Ristow, 2006). Numerous mechanisms have been proposed and studied to clarify the altered mitochondrial metabolism in tumor cells.

Regardless of the exact mechanism(s) involved, increasing the rate of glycolysis in tumor cells promotes tumor cell growth in several species including dogs (Ogilvie and Vail, 1992; Heber et al, 1986), forming lactate as an end product. The host must then expend energy to convert lactate to glucose via the Cori cycle, resulting in a net energy gain by the tumor and a net energy loss by the host (Vail et al, 1990b; Heber et al, 1986; Bozzetti et al, 1980; Dempsey and Mullen, 1985). Abnormalities in dogs have been documented in peripheral glucose disposal, hepatic gluconeogenesis, insulin effects and whole body glucose oxidation and turnover (Vail et al, 1990a, 1990b; Ogilvie et al, 1992).

Following a 90-minute intravenous glucose tolerance test, serum lactate and insulin concentrations were significantly higher in dogs with lymphoma when compared with control values (**Figures 30-3** and **30-4**) (Vail et al, 1990). The noted hyperlactatemia and hyperinsulinemia did not improve when these dogs achieved remission with doxorubicin chemotherapy (Ogilvie et al, 1992). Additionally, a subset of dogs with non-hematopoietic malignancies (e.g., osteosarcoma, mammary adenocarcinoma and pulmonary bronchogenic adenocarcinoma) demonstrated hyperlactatemia and hyperinsulinemia, which did not improve when their tumors were completely excised (Ogilvie et al, 1997). The same metabolic alterations are suspected to occur in cats, but there are no published reports to date to verify this assumption.

The clinical significance of altered mitochondrial respiration and increased glycolysis resulting in altered carbohydrate metabolism is highlighted by hyperlactatemia and its sequelae. Foods high in carbohydrate also appear to increase the total amount of lactate produced when fed to dogs with lymphoma. Mean blood glucose, lactate and insulin concentrations obtained during food tolerance testing were often higher in dogs fed a high-carbohydrate, low-fat food (9% dry matter [DM] fat, 58% DM carbohydrate) compared to those fed a low-carbohydrate, high-fat food (37% DM fat, 14% DM carbohydrate) (Ogilvie et al, 1992). However, although there was a positive initial response to chemotherapy, there was no difference in the duration of remission between the two groups.

Blood lactate concentrations in dogs with lymphoma were significantly elevated compared to values in controls before, during and after lactated Ringer's solution was infused (4.125 ml/kg body weight/hr) (**Figure 30-5**). This lactated Ringer's-induced increase in lactate concentration may create an additional metabolic burden, requiring the host to convert lactate back to glucose, further exacerbating energy demands. This finding may be even more important for septic, critically ill cancer patients that require more intensive fluid therapy. It is also

important to consider that glucose-containing fluids delivered to septic, critically ill patients can exacerbate the septic state.

Because alterations in insulin and glucose metabolism occur in cancer patients, concerns about dietary carbohydrate (glucose) are further warranted from the perspective of oxidative metabolism of tumor cell growth and metabolic mechanisms of stress hyperglycemia (Mechanick, 2006). In acute and chronic cancer patients, as with all critically ill patients, the stress response leads to a plurality of organ-system derangements including glucose allostasis, immune-neuroendocrine axis activation and insulin receptor signal transduction (Mechanick and Brett, 2005). The concurrent inflammation, tissue catabolism and hyperglycemia should be evaluated when designing a feeding protocol. Manipulating the dietary fat, protein (amino acids) and digestible carbohydrate concentrations can potentially minimize physiologic sequelae resulting from the stress response and slow tumor progression. Digestible carbohydrates may be poorly used because of peripheral insulin resistance. Feeding high levels of digestible carbohydrate may lead to hyperglycemia, glucosuria, hyperosmolarity, hepatic dysfunction, respiratory insufficiency and hyperlactatemia. More specifically, until further information is known about the effects of hyperlactatemia on critically ill animals with cancer, glucose- and lactate-containing fluids should generally be avoided. Carbohydrate levels in foods for canine cancer patients should contain no more than 25% DM digestible carbohydrate.

The specific role of dietary carbohydrates has not been reported in feline cancer patients. Although carbohydrate metabolism in healthy cats differs from that of healthy dogs, it is suspected that tumors in cats use carbohydrates as an energy source. Redistribution of hexokinase and its influence on the rate of glycolysis in tumor cells may be of particular interest for managing the nutritional aspect of feline cancer patients. Based on guidelines discussed below for dietary fat of 25 to 40% DM and protein of 40 to 50% DM, the caloric contribution from digestible carbohydrate is limited to 25% DM or less.

Fat and Fatty Acids

In contrast to the ready use of carbohydrates and proteins by tumor cells, some tumor cells have difficulty using lipids as a fuel source. Theoretically, this preferential use of digestible carbohydrates and proteins leaves lipids available as an energy source for the host (Shein et al, 1986). This finding led to the hypothesis that foods relatively high in fat may benefit patients with cancer compared to foods relatively high in carbohydrates. Recent studies have identified alterations of lipid metabolism in canine cancer patients; this knowledge is paramount for developing feeding protocols. An overview of the current literature may help determine if the focus should be on total amount of fat, specific sources of fat or both for cancer patients.

Highly malignant tumors, in rodent models and in vitro cell cultures, can exhibit up to an 85% decrease in the rate of fatty acid usage. This decrease is linked to decreased activity of the key activating enzyme of β-oxidation, acyl thiokinase (Ristow, 2006). Conversely, well-differentiated tumors can retain the ability to metabolize fatty acids, especially under hypoxic conditions (Ristow, 2006; Swinnen et al, 2006; Menendez and Lupu, 2006). Although tumor type may influence fat usage, a high proportion of weight loss in cachectic cancer patients is attributed to loss of body fat. Not surprisingly, people and animals with cancer have marked abnormalities in lipid metabolism (Chlebowski and Heber, 1986; Dewys, 1982; McAndrew, 1986; Ogilvie et al, 1994; Shein et al, 1986; Tisdale et al, 1987; Daly et al, 1991).

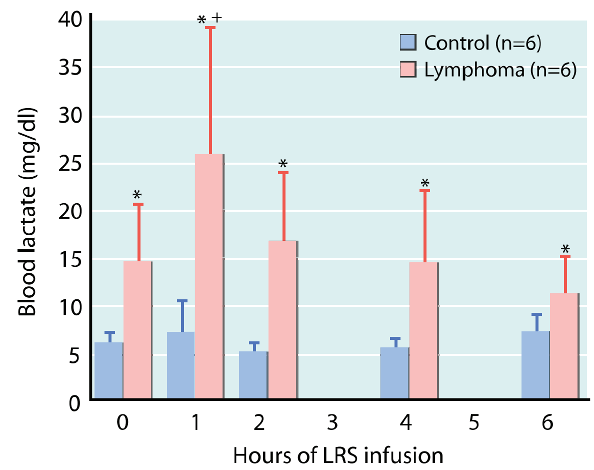

Figure 30-5. Blood lactate concentrations from dogs with and without lymphoma before and during intravenous infusion of lactated Ringer's solution (LRS). Asterisks indicate values from dogs with lymphoma that differ significantly ($p < 0.05$) from control dog values obtained at the same time. Plus signs indicate values that differ significantly ($p < 0.05$) from pre-infusion baseline values within the same test group. (Adapted from Vail DM, Ogilvie GK, Fettman MJ, et al. Exacerbation of hyperlactatemia by infusion of lactated Ringer's solution in dogs with lymphoma. Journal of Veterinary Internal Medicine 1990; 4: 228-232.)

The decreased lipogenesis and increased lipolysis observed in people and rodents with cancer cachexia alter the lipid profile dramatically. Changes include increased blood concentrations of free fatty acids, very low-density lipoproteins (VLDL), triglycerides (TG), plasma lipoproteins and hormone-dependent lipoprotein lipase activity and decreased concentrations of endothelial-derived lipoprotein lipase (McAndrew, 1986). Lipid profiles have been evaluated in dogs with lymphoma to determine if alterations similar to those reported in other species are present (Ogilvie et al, 1994). In contrast to healthy controls, dogs with lymphoma had significantly altered concentrations of cholesterol-associated VLDL, TG, VLDL-TG, low-density lipoprotein (LDL-TG) and high-density lipoprotein (HDL-TG). In dogs with lymphoma, HDL-TG and VLDL-TG concentrations were significantly increased above pretreatment values after remission was lost. Additionally, dogs developed overt signs of cancer cachexia. These abnormalities did not normalize when clinical remission was obtained. The clinical significance of the previously mentioned lipid parameters in dogs with lymphoma is unknown.

Epidemiologic studies and meta-analyses examining the

effects of dietary fat and cancer in people have produced conflicting results. Despite this lack of consensus regarding human data, murine and experimental studies have shown suppression of tumor growth by specific fatty acids, particularly in breast, colon and prostate cancers. Omega-3 fatty acids (eicosapentaenoic acid [EPA], docosahexaenoic acid [DHA]) generally have an inhibitory effect on tumor growth, whereas omega-6 (n-6) fatty acids (linoleic acid, γ-linolenic acid) enhance metastases. In vivo studies have shown that EPA has selective tumoricidal action without harming normal cells (Lowell et al, 1990; Ramesh et al, 1992; Dippenaar and Booyenes, 1982; Begin et al, 1986, 1985; Plumb et al, 1993; Mengeaud et al, 1992; Pascale et al, 1993; Jenski et al, 1993; Roush et al, 1991; Holian and Nelson, 1992).

Similar findings have been reported to occur in canine patients with lymphoma and non-hematopoietic malignancies (Ogilvie et al, 2000). Dogs receiving chemotherapy for lymphoma and fed a food supplemented with arginine and omega-3 fatty acids had elevated plasma arginine, EPA and DHA levels. Plasma levels of arginine and omega-3 fatty acids were positively correlated with survival time. Similarly, in dogs undergoing radiation therapy for nasal carcinomas, plasma levels of arginine, EPA and DHA were positively correlated with quality of life and negatively correlated with inflammatory mediators and mucositis in irradiated areas (Anderson et al, 1997).

Focus on nutritional support of feline cancer patients involves fatty acid influence on the mechanisms of tumor cell signaling. Human estrogen receptor insensitive breast tumor cells have nearly identical histology to feline malignant mammary tumor cells (Perez-Alenza et al, 2004). This provides a two-way model for mammary tumor research. Estrogen receptor insensitive breast tumor cell lines maintained in omega-3 enriched media exhibited significantly reduced activation of MAPK pathway intermediates (Ras, Raf, MEK and MAPK), increased apoptosis, decreased cell proliferation and decreased cyclooxygenase-2 (COX-2) pathway inflammatory eicosanoid expression compared to cells in omega-6 enriched media (Phipps et al, 2004; Saker et al, 2002, 2002a, 2004). Feline feeding studies associated with MAPK expression and dietary fatty acids are equally as compelling.

Healthy adult cats fed diets providing varying omega-6:omega-3 fatty acid ratios (5:1 to 0.4:1) exhibited a ratio dependent decrease in MAPK activation. In addition, omega-6 concentrations decreased and omega-3 concentrations increased in mammary adipose tissue and leukocytes (Saker et al, 2002). Furthermore, a threefold decrease in MAPK activity was detected along with stasis of tumor cell growth as measured by ultrasound and caliper readings in cats with either pancreatic masses or inflammatory mammary carcinomas when the fatty acid content of their food was changed from enriched omega-6 (16:1) to enriched omega-3 (<1:1). MAPK activity increased by 3.5-fold when the original food enriched with omega-6 fatty acids (16:1) was reintroduced. Taken together, these data support the value of enhanced omega-3 fatty acid diets as antitumorigenic and antiinflammatory (**Box 30-1**).

Fish oil may also affect colon cancer development, depending on dietary fiber source. The effect of either omega-3 or omega-6 fatty acids in combination with different fiber types in a rat model of carcinogen-induced colon cancer was reported. Dietary fish oil in combination with pectin was more protective against colon cancer than omega-3 fatty acids with cellulose or omega-6 fatty acids with any fiber type (Chang et al, 1998). The mechanism of enhanced protection appeared to be due to increased colonocyte apoptosis through simultaneously increased reactive oxygen species production and decreased antioxidant enzyme activity (Sanders et al, 2004).

Other potential benefits of omega-3 fatty acids focus on their reported anticachectic effect and association with decreased blood lactate levels. EPA decreases protein degradation without altering protein synthesis; the net effect is anticachectic (Beck et al, 1991; Jho et al, 2002). **Box 30-1** explores suggested mechanism(s) by which fatty acids influence tumor growth and cachexia.

Foods with high omega-3 fatty acid concentrations ameliorate endotoxin-induced lactic acidosis in guinea pigs (Pomposelli et al, 1989). This finding may be of clinical importance because hyperlactatemia occurs commonly in dogs with lymphoma.

Although studies have identified some of the mechanisms involved in lipid use by cancer patients, much more research is needed to match dietary fat levels and omega-6:omega-3 fatty acid ratios to specific tumor types and cancer stages in cats and dogs. Currently, recommendations for canine and feline cancer patients continue to be focused on foods with increased fat calories (25 to 40% DM fat); increased levels of dietary omega-3 fatty acids (>5.0% DM) and an omega-6:omega-3 fatty acid ratio approximating 1:1.

Protein and Arginine

Altered nitrogen balance is observed in human cancer patients, which appears to be a consequence of decreased body muscle mass and skeletal protein synthesis. Increased skeletal protein breakdown, liver protein synthesis and whole body protein synthesis apparently promote tumor growth because tumors often use amino acids for energy (Heber et al, 1986; Bozetti et al, 1980; Dempsey and Mullen, 1985; Chory and Mullen, 1986; Langstein and Norton, 1991; Kurzer and Meguid, 1986; Teyek et al, 1986; Oram-Smith and Stein, 1977). Tumor use of amino acids for energy becomes clinically significant when protein degradation exceeds protein intake. This imbalance can alter immune response, GI function and surgical wound healing (Langstein and Norton, 1991; Kurzer and Meguid, 1986).

In one study, cancer-bearing dogs had significantly lower plasma concentrations of threonine, glutamine, glycine, valine, cystine and arginine and significantly higher concentrations of isoleucine and phenylalanine than did normal control dogs (Ogilvie and Vail, 1990). The results were the same for different types of tumors, and observed alterations in plasma amino acid profiles did not normalize after tumors were surgically removed. This finding suggests that cancer induces

Box 30-1. Omega-3 Fatty Acids, Tumor Growth, Cachexia and Inflammation.

Polyunsaturated omega-6 (n-6) and omega-3 (n-3) fatty acids alter protein-lipid interactions and lipid-based signal transduction pathways in cells. The simultaneous generation of inositol phosphates and diacylglycerol, yielding the secondary release of intracellular calcium and activation of protein-kinase C (PKC) depend on phospholipase C, a lipid-comprised phosphatidylinositol. In addition, the specific lipid composition of the diacylglycerol (i.e., omega-6 vs. omega-3) results in a differing affect on the mitogen activated protein kinase (MAPK) signal transduction pathway. MAPK, one of several cell signal transduction pathways, is paramount in regulating tumor (mammary, uterine, prostate, lung) cell proliferation. Numerous human and murine studies have reported the value of omega-3 fatty acids (eicosapentaenoic acid [EPA], docosahexaenoic acid [DHA]) in inhibiting tumor growth and metastasis through alterations in expression of the pro-angiogenic vascular endothelial growth factor (VEGF) and down-regulation of the proinflammatory regulator cyclooxygenase 2 (COX-2). COX-2 enzyme activity promotes proinflammatory eicosanoid production, which stimulates VEGF and vascularization of tumor tissue. Fatty acids attenuate transcriptional activity of COX-2 and VEGF through anti-MAPK and -AP-1 mechanisms in breast cancer cell lines.

The anticachectic effect of EPA has been reported to influence cytokine release from tumor cells. Administration of omega-3 fatty acids reduced secretion of tumor necrosis factor-alpha (TNF-α), interleukin-1β (IL-1β), interleukin-1α (IL-1α) and interleukin-2. This may be especially important because IL-1 and TNF are important mediators of cachexia and may act as tumor growth factors.

The onset and perpetuation of the anorectic state in cancer and critically ill patients can be influenced through omega-3 fatty acid supplementation. Studies have demonstrated that omega-3 fatty acids modulate changes in the concentrations and actions of several orexigenic and anorexigenic neuropeptides in the brain. These peptides include neuropeptide Y, α-melanocyte stimulating hormone, serotonin and dopamine. In patients with acute or chronic inflammatory conditions, as is thought to occur in many cancer patients, omega-3 fatty acid supplementation suppresses proinflammatory cytokine production and improves food intake by normalizing hypothalamic orexigenic peptides and neurotransmitters.

The Bibliography for **Box 30-1** can be found at www.markmorris.org.

long-lasting changes in protein metabolism.

The anorexia-cachexia syndrome prevalent in cancer patients is associated with profound metabolic perturbations including increased muscle proteolysis. Thus, decreased lean body mass and increased protein requirements in cancer patients are driven by amino acid redistribution for: 1) synthesis of hepatic acute-phase-reactant proteins, 2) support of the cellular immune response, 3) provision of gluconeogenic substrates and 4) direct oxidation for fuel.

To date, there appears to be less of a focus on protein metabolism in cancer patients compared to the focus on fat metabolism. Despite the unique protein requirements of cats, protein use studies in companion animals have been limited to canine cancer patients. Current recommendations for dietary protein are based on a limited number of companion animal cancer studies, well-founded knowledge of protein metabolism in critically ill patients and extrapolation from non-veterinary species.

Dietary protein levels in foods for cancer patients should exceed levels normally used for maintenance of adult animals, assuming renal and liver function is adequate to tolerate enhanced protein. If signs of intolerance are observed, titrate down to tolerable protein levels. Currently, recommended protein levels in foods for dogs with cancer are 30 to 45% DM. Based on dietary protein requirements for critically ill cats, suggested protein levels in foods for cats with cancer are 40 to 50% DM.

Arginine is an essential amino acid for cats and is considered to be a conditionally essential amino acid for dogs. Arginine is synthesized endogenously in the kidney from gut-derived citrulline and is converted by the enzyme arginase into ornithine and urea. Arginine has potent secretagogue effects on several endocrine and neuroendocrine glands. Intravenous administration of arginine induces secretion of growth hormone, prolactin, insulin, glucagon, insulin-like growth factor-1, pancreatic polypeptide, somatostatin and catecholamines (Barbul, 1986). Arginine, given in large doses, exerts numerous beneficial effects on the immune system, particularly on thymus-dependent and T-cell-dependent immune reactions. The exact mechanism whereby arginine stimulates T-cell function is unknown. In addition to its positive effects on immune function, arginine may also influence tumor growth, metastatic rate and survival time in patients with cancer.

Adding arginine to parenteral solutions decreases tumor growth and metastatic rate in rodent cancer models (Tachibana et al, 1985). Increased dietary arginine, in conjunction with increased dietary omega-3 fatty acid intake, influenced clinical signs, quality of life and survival time in dogs with lymphoma (Ogilvie et al, 2000) and enhanced quality of life for dogs undergoing radiation therapy for nasal carcinomas (Anderson et al, 1997). The minimum effective level of dietary arginine for cancer patients is unknown; however, based on work in other species, it is thought appropriate to provide more than 2% DM arginine in foods for dogs with cancer. There are no reports demonstrating efficacy of additional arginine in feline cancer patients. The minimum recommended allowance for queens in late gestation and peak lactation is 1.5% (DM) (NRC, 2006). Therefore, this same recommendation (>2%, DM) is probably minimally satisfactory for dietary arginine in feline cancer patients.

Other Nutritional Factors

Several amino acids, vitamins, minerals and novel foods and ingredients have received considerable attention in cancer prevention and therapy (**Boxes 30-2** through **30-5**).

Box 30-2. Amino Acids and Cancer.

GLUTAMINE

Glutamine may have specific therapeutic value. Glutamine is an essential precursor for nucleotide biosynthesis and is an important oxidative fuel for enterocytes. Supplementation of enteral preparations with glutamine has benefited several animal models of intestinal injury by improving intestinal morphometry, reducing bacterial translocation, enhancing local immunity and improving survival. Glutamine has only recently been recognized as a conditionally essential amino acid in certain pathophysiologic states including stress. Glutamine is added to most human enteral formulas, and has been evaluated in parenteral formulations for its potential to protect intestinal integrity in critically ill, anorectic patients. The parenteral studies have most consistently delivered a 2% solution of L-glutamine.

One study using a feline model of methotrexate-induced intestinal injury failed to demonstrate a beneficial role for glutamine supplementation to an amino acid-based purified food. A recent review indicated glutamine and glutamate metabolism appears to be intact in tumor mitochondria, suggesting that the mitochondrial activity of tumor cells can be restored by using supplemental glutamine as a fuel source. Contrary to these findings, dietary glutamine was reported to suppress mammary carcinogenesis in a 7,12-dimethylbenz[a]anthracene (DMBA)-induced breast cancer animal model. Glutamine supplemented at 1 g/kg/day to tumor-induced rats for 11 weeks significantly decreased tumor glutathione (GSH) levels, altered tumor GSH/GSSG status and enhanced tumor apoptotic activity by Bax, caspase-3 and Bcl-2. Additional studies are needed to determine the potential mechanism(s) by which glutamine alters tumor cell growth, and if commercially available foods supplemented with glutamine improve intestinal integrity during cancer treatments.

BRANCHED-CHAIN AMINO ACIDS

Branched-chain amino acids (BCAA), notably leucine, isoleucine and valine, are neutral amino acids with clinically relevant metabolic effects. Their potential role as anti-anorexia and anticachectic agents has been reported. Numerous human clinical trials indicate anorexia is associated with deranged brain tryptophan/serotonin metabolism. Tryptophan crosses the blood-brain barrier via a specific transport mechanism shared with other neutral amino acids. Therefore, supplementation with competing neutral amino acids (BCAA) reduces tryptophan entry into the brain, thereby inhibiting hypothalamic serotonin synthesis and release with subsequent amelioration of anorexia. Supplemental oral BCAA given to cancer patients at a dose of 14.4 g/day for seven days significantly improved energy intake by Day 3.

The anticachectic value of BCAA, particularly leucine, was evaluated in experimental studies and human clinical trials. Tumor-bearing rats fed a leucine-enriched diet had a 1.4-fold higher rate of protein synthesis and decreased expression of the ubiquitin-proteosome system and chymotrypsin-like activity. Bed-rested, catabolic patients receiving 18 g BCAA/day for a month exhibited improved lean leg mass, strength and protein synthetic rate. The long-term benefit of BCAA administration was evaluated in patients with hepatocellular carcinoma. Those who received 11 g BCAA supplementation/day for one year had lower morbidity, higher serum albumin concentrations and a better quality of life compared to values in control group patients. These findings indicate BCAAs appear to have specific anticachectic effects.

BCAA appear to influence cell growth in canine tumor cell lines. Canine osteosarcoma, bronchoalveolar carcinoma and Madine-Darby kidney cells were cultured under the influence of 0 to 100 mM concentrations of leucine, isoleucine or valine to evaluate the anti-proliferative effects of these BCAAs. Study results were tumor-type dependent; leucine appeared to have the most significant effect in diminishing neoplastic cell growth at supraphysiologic concentrations. Additional studies are needed to establish relevancy in the management of veterinary cancer patients. Available human trial data suggest supplementation with 10 to 15 g/day of BCAA as leucine, isoleucine and valine may provide anti-anorexic and anticachectic benefits.

METHIONINE AND ASPARAGINE

Certain tumor cell lines require methionine for growth. Replacing methionine with its precursor, homocysteine locks these tumor cells into late S and G2 phases of the cell cycle. Because certain cancer chemotherapeutic agents are cell-cycle specific, the percentage of tumor cells sensitive to chemotherapy increases, improving the therapeutic index. Asparagine is essential for tumor cell growth in lymphoma. Treatment of dogs and cats with L-asparaginase has induced complete remissions in up to 80% of dogs and cats with lymphoma.

TYROSINE AND PHENYLALANINE

Tyrosine and phenylalanine restriction has been reported to suppress melanoma cell growth in tissue cultures and in rodent tumor models. Administration of tyrosine and phenylalanine increased the survival of melanoma tumor-bearing mice and increased the effectiveness of levodopa against melanoma.

GLYCINE

Some amino acids may decrease the toxicity associated with chemotherapy. For example, glycine reduces cisplatin-induced nephrotoxicity.

The Bibliography for **Box 30-2** can be found at www.markmorris.org.

FEEDING PLAN

Although cancer and traditional cancer treatments in dogs and cats result in a spectrum of metabolic/nutritional derangements, a number of these derangements are common to most types of cancer and provide the basis for development of a general feeding plan.

The previous sections discussed the clinical fundamentals of cancer from clinical importance to patient assessment and determination of key nutritional factors. This section describes how to feed patients with cancer. It continues the iterative process by developing these feeding plan topics: 1) assess and select the food, 2) assess and determine the feeding method and

Box 30-3. Vitamins and Cancer.

Retinoids, β-carotene, vitamin C and vitamin E all appear to influence the growth and metastasis of cancer cells by a variety of mechanisms. Some of these mechanisms include selected receptor-mediated anti-proliferative activities. These vitamins have been reported to bind their cytosolic receptors followed by translocation of the bound complex to the nucleus where the receptors mediate gene regulation. Other effects result from antioxidant, hormone-like and immunomodulator capabilities.

RETINOIDS

"Retinoids" refer to the entire group of naturally occurring and synthetic vitamin A derivatives, including retinol, retinal and retinoic acid. Retinoids appear to have the potential for regulating cancer cells either alone or in combination with other agents. Specific studies in human and veterinary medicine suggest that retinoids alone or with other agents can be effective for the treatment of certain types of malignancies. The synthetic retinoids, isotretinoin and etretinate, have been used successfully in some dogs with intracutaneous cornifying epitheliomas, other benign skin tumors, cutaneous lymphoma, solar-induced squamous cell carcinoma and associated preneoplastic lesions. The retinoids promote cellular differentiation and may enhance the susceptibility of neoplastic cells to chemotherapy and radiation therapy.

VITAMIN C

Vitamin C (ascorbic acid) has been reported to inhibit nitrosation reactions and prevent chemical induction of cancers of the esophagus and stomach. Processed foods high in nitrates and nitrites, such as bacon and sausage, are often supplemented with vitamin C to reduce the carcinogenic capability of the resultant nitrosamines.

Ascorbic acid may be one therapeutic alternative for overcoming drug resistance in some cancer cells. Studies suggest that an ascorbic acid-sensitive mechanism may be involved in drug resistance to vincristine in certain cancer cell lines. Despite the extensive amount of vitamin C research, few direct data exist proving its efficacy in dogs and cats.

VITAMIN E

Vitamin E (α-tocopherol) can also inhibit nitrosation reactions. Vitamin E also has a broad capacity to inhibit mammary tumor and colon carcinogenesis in rodents. Research indicates that vitamin E influences a variety of cell functions including free-radical scavenging, which can prevent oxidative damage that leads to cell death.

In addition to its anticancer properties, vitamin E may potentially convey therapeutic efficacy against certain malignancies. Vitamin E has been reported to have anti-proliferative activity, which involves the binding of the vitamin to salicylic receptors, followed by translocation to the nucleus where DNA binds on the domains of receptors that mediate gene regulatory events. Recent evidence suggests that the two prominent vitamin E isoforms, vitamin E succinate (VES) and α-tocopherol acetate (α-TEA) have specific anticancer activity. Both isoforms increased apoptosis in human breast cancer cell lines, ovarian and cervical cancer cell lines, mesothelioma cells, lung cancer cells and gastric cells without affecting surrounding normal cells.

Retrovirus-induced tumorigenesis involves transformation of normal cells into tumor cells. Evidence suggests that vitamin E may normalize the immune system by interacting with macrophages and T lymphocytes to inhibit retroviral-induced infections.

The Bibliography for **Box 30-3** can be found at www.markmorris.org.

Box 30-4. Minerals and Cancer.

Minerals that have been suggested as being important in patients with cancer include selenium, iron and zinc. Optimal levels of specific minerals for cancer prevention and treatment have not been established for pet animals.

SELENIUM

Selenium has been one of the most heavily studied minerals associated with the development of cancer. Low serum selenium levels have been observed in human patients with gastrointestinal cancer. In rodents, dietary supplementation with selenium inhibits colon, mammary gland and stomach carcinogenesis.

IRON

Iron transferrin and ferritin have been linked to cancer risk and cancer cell growth. Lung, colon, bladder and esophageal cancer in people have been highly correlated with increased serum iron concentrations and increased transferrin saturation. Because many tumor cells require iron for growth, it has been suggested that the increased use of iron by the tumor depresses serum iron levels in human cancer patients. Mice with low levels of iron have slow tumor growth compared to those with normal iron levels.

ZINC

In people, low levels of zinc in blood and diseased tissue have been observed in esophageal, pancreatic and bronchial cancer. Zinc deficiency appears to enhance carcinogenesis in laboratory animals.

The Bibliography for **Box 30-4** can be found at www.markmorris.org.

3) reassess and modify the feeding plan, as necessary. The key nutritional factors identified in the previous section are used here as benchmarks for comparing selected foods marketed for the dietary management of cancer.

Nutritional support of cancer patients must be individualized. Nutritional therapy should be undertaken with the overall prognosis of the patient clearly in mind so that the aggressiveness of dietary intervention (e.g., supportive, adjunctive, defin-

itive) can be adjusted appropriately. Owners of cancer patients should be educated about the integral role nutrition plays in the total management of their pet's disease, but at the same time should understand the limitations of the dietary management component of the overall treatment plan. The feeding plan depends on the extent of disease, anorexia, nausea, weight loss and consequences of treatment.

Assess and Select the Food

There is only one veterinary therapeutic commercial food[a] that has been specifically developed for canine cancer patients. This food has been shown to improve the longevity and quality of life of selected canine patients with cancer. However, other veterinary therapeutic foods provide certain key nutritional factors at near recommended levels. **Tables 30-6** (dogs) and **30-7** (cats) include the key nutritional factors from **Table 30-5** and compares them to the levels in selected commercial foods. The food selected should most closely fit the recommended levels for patients with cancer.

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods. Evidence Grade 1 (the highest level) exists for at least one food used for canine cancer patients.[a] See Case 2-1.

Some owners feed debilitated or cachectic pets home-cooked foods to enhance palatability and food intake and as a means of bonding with their pet. Interest in homemade diets has peaked in recent years as a feeding alternative for healthy and ill pets. Numerous references are available that contain published recipes or provide computer-based recipes. Homemade diets must be nutritionally balanced. Adequate provision of protein and energy to maintain the cancer patient and consideration of key nutrient concerns should be the focus of home-cooked diet formulations. (See Chapter 10 for basic guidelines for formulating and evaluating homemade diets.) Research efforts to identify optimal foodstuffs and levels of nutrients for veterinary cancer patients are ongoing. As more experimental and clinical trial data become available, diet selection for cancer patients will expand and likely become tumor-type and disease-stage specific. **Tables 30-6** and **30-7** list commercially available diet choices; however, when selecting a diet, the overall goal of supplying daily water, protein and energy requirements to sustain an acceptable quality of life should not be overlooked. Patient assessment and owner constraints may affect diet selection.

Assess and Determine the Feeding Method

The feeding method includes the amount to feed as well as how often and by what route. Careful assessment of the feeding method is important to determine whether the patient is currently receiving its caloric requirement and if it is able to prehend, masticate, swallow and assimilate its food.

How Much to Feed

Calculation of the patient's energy requirement, determination of the energy density of the food, careful measurement of the amount of food eaten by the animal and body condition scoring will help establish whether cancer patients with weight loss are actually receiving sufficient calories and nutrients. Limitations to the accurate calculation of RER or DER in veterinary patients can offer a challenge to maintaining or improving the patient's body weight and condition. Again, routine assessment is paramount to fine-tuning the feeding protocol for each patient. The general "rule of thumb" is to feed ill, hospitalized patients at RER for their current body weight, and increase to DER for a more optimal body weight during "at home" feeding. As feeding for cancer patients is individualized, these guidelines do not hold true for all cases, but rather should be considered as starting points.

Hospitalized patients should eat enough food to at least meet their estimated RER. Calculations for determination of energy requirements can be reviewed in Chapters 1 and 5. Initiate an assisted-feeding protocol for hospitalized patients that fail to consume enough food to meet RER for three or more days. (See How to Feed below.)

Patients managed at home should eat enough food to meet their estimated DER, which takes into account increased activity and a less controlled environment. Determination of DER should start at current body weight using a species-specific factor that accounts for low activity. As the patient tolerates this intake, a gradual increase in daily calories can be attempted with a goal of feeding DER at a more optimal body weight. Based on individual assessment (including activity, attitude, age, prognosis, etc.) the DER factor typically ranges from low activity (1.1 to 1.3 x RER) to adult maintenance (1.4 x RER for cats and 1.6 x RER for dogs). Frequent recording of body weight and condition helps ascertain the appropriateness of the feeding plan.

Some underweight animals with cancer will stabilize at a less than optimal BCS (2/5 rather than 3/5). It may be difficult to achieve weight gain in these patients; therefore, the goal should change to maintaining this leaner body condition (Chapter 25, Accommodation).

How to Feed

Enteral feeding is the preferred route for providing nutritional support because it is less complicated and safer for patients fed at home. Additionally, enteral feeding is more physiologic because it improves intestinal mucosal thickness, stimulates gut trophic hormones and stimulates IgA production. Enhancing food palatability is the simplest means of increasing voluntary intake. A food can sometimes be made more palatable by heating to improve its aroma and mouth feel. Hand feeding critically ill, weak or depressed pets may enhance intake. Human companionship appears to increase the pet's interest in food. It

Box 30-5. Novel Foods, Ingredients and Cancer.

PROTEASE INHIBITORS

Much information suggests that soybean-derived Bowman-Birk inhibitor can inhibit or suppress carcinogenesis in vivo and in vitro. Extracts of the Bowman-Birk inhibitor suppress carcinogenesis in several animal model systems, including colon- and liver-induced carcinogenesis in mice, anthracene-induced cheek pouch carcinogenesis in hamsters, lung tumorigenesis in mice and esophageal carcinogenesis in rats. Bowman-Birk inhibitor concentration inhibits metastases and weight loss associated with radiation-induced thymic lymphoma in mice. Irradiated rodents treated with dietary Bowman-Birk inhibitor have fewer deaths, lower average grade of lymphoma and larger fat stores than controls. Various soy products produce dramatic protection against methotrexate (MTX)-induced enterotoxicity in rodent models.

One study was performed using a feline model of MTX-induced enteritis to determine the impact of purified foods containing intact protein sources (soybean protein or casein) or crystalline amino acids on intestinal structure and function. Cats receiving a commercially available (complex) food served as the control group. MTX administration was associated with severe enterotoxicity manifested by vomiting and diarrhea, especially in cats receiving crystalline amino acid and casein-based purified foods. Cats receiving the casein-based purified food had the largest decrease in total white blood cell (WBC) and platelet counts, the greatest villous atrophy (**Figure 1**) and the highest incidence of positive mesenteric lymph node and hepatic bacterial cultures (50 and 33%, respectively). Cats fed the soybean protein-based purified food had the least villous atrophy (**Figure 2**) and a significantly smaller magnitude of reduction in WBC counts compared with cats receiving the crystalline amino acid (**Figure 3**) and casein-based purified foods. Feeding complex (**Figure 4**) and soybean protein-based foods was also associated with the greatest secretagogue activity on plasma cholecystokinin (CCK) concentrations after ingestion of the respective meals, compared with concentrations in cats receiving the amino acid and casein-based purified foods. This study showed an association between feeding a soybean protein-based purified food and improved intestinal integrity. These findings might be associated with a greater secretogogue effect in stimulating trophic gut hormones such as CCK. In contrast, the casein-based purified food was associated with increased morbidity, villous atrophy, increased bacterial translocation and decreased secretogogue activity on CCK. Additional studies may determine the underlying mechanism of protection and the exact compound(s) responsible for soybean protein's protective effects.

POLYPHENOLIC COMPOUNDS AND FLAVONOIDS

Numerous health benefits result from consumption of diets rich in phytochemicals such as polyphenolic compounds. Polyphenolic compounds are potent dietary antioxidants and it is thought that

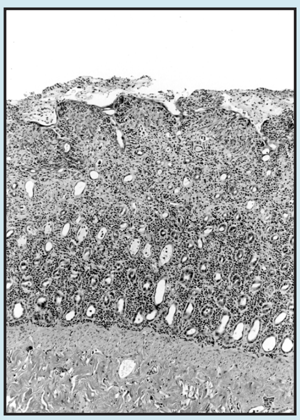

Figure 1.

Box 30-5 continued

the antioxidant properties of these compounds confer protection against certain chronic diseases such as cancer. Antioxidants may act directly by limiting oxidative stress and indirectly through preserving protective enzymatic pathways and modulation of signaling pathways. Flavonoids added to neoplastic cell lines have shown promising results. An interesting example is the phytochemical activity of pomegranate fruit. Pomegranate polyphenolic extracts inhibit growth in human leukemia cells, prostate cancer cell lines and suppress formation of chemically induced skin tumors and colon carcinogenesis in rodent models.

Supplementation of estrogen receptor sensitive and insensitive cells with a 1 or 5% commercial juice extract or fresh fruit extract inhibited in vitro cell proliferation by up to 90%. Although investigations to identify the mechanism(s) of action are ongoing, the potential for using natural food products to manage cancer patients is encouraging.

GARLIC

Epidemiologic studies have suggested a correlation between high garlic consumption and reduced risk of cancer. Garlic, garlic extracts and several thioalkyl compounds inhibit the activation of carcinogens and carcinogen-induced aberrations in the cell nucleus. Garlic extracts have an anti-promotion effect in animals exposed to carcinogens. Furthermore, garlic exerts direct cytolytic effects against cultured human breast cancer and melanoma cells. The concentrations of garlic used in these studies to arrest cancer cell growth had no effect on normal cells.

Pretreatment with garlic protects rodents against subsequent induction of tumors by a variety of carcinogens. There are no studies demonstrating the safety and efficacy of garlic for the prevention or treatment of cancer in people, dogs and cats.

The Bibliography for **Box 30-5** can be found at www.markmorris.org

has been suggested that critically ill patients often have a diminished will to live; their bodily energy and normal GI function including motility, digestion and absorption are likewise diminished. Building a patient's Zheng Qi, or bodily energy, has been addressed using herbs and herbal formulas. This approach to managing critically ill patients by enhancing use of enteral nutrition requires a substantial knowledge of herbs and drug interactions. References and individuals experienced in the area of veterinary botanical medicine are available for consultation by interested pet guardians. Acupuncture appears to have a cumulative "feel good" affect on pets following chemotherapy (Wurth, 2003). The better patients feel, the more likely they are to have interest in eating.

If necessary, drug therapy can be attempted before offering food. Administration of a benzodiazepine derivative (diazepam or oxazepam) or cyproheptadine increases appetite transiently; however, these drugs are unreliable for ensuring adequate caloric intake. Benzodiazepine derivatives are contraindicated in patients with severely reduced hepatic function, especially when signs of hepatic encephalopathy are present. In addition, the appetite-stimulating properties of these agents appear to wane with time when used in sick animals. Megestrol acetate causes weight gain and increases appetite in people with cancer. The clinical benefit of this drug in veterinary patients remains to be determined. Controlled studies with human cancer patients have revealed that cyproheptadine, corticosteroids and nandrolone decanoate have little to no impact on improving food intake, body weight and clinical outcome (Kardinal et al, 1990; Chlebowski et al, 1986; Willcox et al, 1984). A deficiency of B vitamins is associated with anorexia and may occur in some cancer patients fed unbalanced homemade foods or patients that have decreased food intake.

Assisted-feeding techniques should be considered if these appetite-stimulating efforts fail and/or the patient has not voluntarily eaten for three or more days. Enteral and/or parenteral techniques can be used for nutritional support while patients are hospitalized (Chapters 25 and 26). As noted in previous sections, before starting a treatment regimen (i.e., chemotherapy, radiation, surgery), an assisted-feeding device can be proactively placed to ensure adequate nutrition regardless of treatment side effects. Examples include placing a gastrostomy tube in patients with oral tumor resections or before radiation treatment to the nose, oral cavity or neck.

If feeding assistance is required at home, syringe or tube feeding (i.e., nasoesophageal, esophagostomy, gastrostomy tube) protocols can be established to allow the owner to successfully deliver nutritional support to the pet.

Parenteral nutrition (PN) is a more complex system in terms of formulation and delivery of the admixture, as well as patient monitoring (Chapter 26). PN is less physiologic with respect to gut health; however, evaluation of admixture supplementation with specific nutrients to promote gut integrity is ongoing (Burke et al, 1989; Sheng-Long et al, 1992), which may help promote the efficacy of PN for critically ill patients. Nevertheless, PN is generally reserved for patients that are unable to assimilate nutrients or those with intractable vomiting. An example is a patient with GI lymphoma that is stabilized with PN until remission is obtained with chemotherapy. Optimally, the next step would entail DER being met with a combination of PN and enteral nutrition. Eventually, as appetite and tolerance improve, the enteral route can be used exclusively. PN in human cancer patients is still controversial; some clinical trials have failed to demonstrate benefit, whereas others demonstrate a positive effect with respect to nutritional parameters, survival or tumor response (McGeer et al, 1990; Chlebowski, 1991). Large clinical trials have not been performed with veterinary cancer patients; however, one author (KES) has reported PN to be beneficial for managing individual canine and feline cancer patients. Benefits have been assessed by weight maintenance, enhanced immunocompetence and wound healing, improved attitude, maintenance of normoglycemia and hydration status and successful transition from the ICU to at home feeding.

REASSESSMENT

Reassessment of cancer patients should include monitoring the effects of: 1) cancer on the animal, 2) treatment and nutrition-

al management on the tumor and 3) treatment and nutritional support on the patient. The frequency of reassessment depends on each patient's treatment protocol, response to treatment, the complexity of the feeding plan and prognosis. Initially, reassessment may be required daily or multiple times per day. After the patient is discharged and managed at home, reassessment may be conducted weekly, monthly or quarterly until the patient's condition stabilizes.

Comparing the current body weight and BCS with previous assessments best assesses the overall effects of cancer, cancer treatment and nutritional management on the animal. The patient's appetite should be assessed and the daily caloric intake monitored closely. These parameters are most accurately assessed by frequent (daily) record keeping by the pet owner. The veterinarian can review these records and correlate them with recheck physical examination and diagnostic findings to ascertain the adequacy of the overall treatment and feeding plan. Additionally, nutrient status influences stabilization of organ function, protein status, leukocyte number, hydration, blood glucose and electrolyte status; these parameters are easily monitored through routine blood work and urinalysis. Additional markers of tumor growth and disease staging, which are currently more amendable to monitoring in a research setting, have been reviewed in previous sections. Appropriate modifications to the feeding plan should be made as the patient's status changes.

Food and feeding method changes may be part of the management plan. An important goal of assisted feeding is to transition the patient to voluntary intake. This can be facilitated by: 1) decreasing the amount of food administered and/or the feeding frequency and 2) offering an appropriate palatable form of food for voluntary consumption before, or in place of, the scheduled tube feeding. As the patient increases voluntary caloric intake, calories delivered via the assisted route should be decreased proportionately. After the patient is consuming 75% of DER calories voluntarily, assisted-feeding devices can be removed.

Patient management may require diet alternatives due to physiologic changes that result in food aversion or inability of the patient to consume a certain form of diet. In the case of suspected food aversion, first choose an alternate diet with novel protein sources. A second attempt might include increasing the fat and/or sodium content. If aversions persist with commercial diet options, consider a home-cooked diet.

Assess the patient's ability to adequately prehend and swallow the form of diet offered. Moist diets may be easier to consume in adequate amounts compared to dry kibble. Moistening dry food with warm water or a flavored broth may enhance intake.

CASE 30-1

Diarrhea and Weight Loss in a Gordon Setter

Stanley L. Marks, BVSc, PhD, Dipl. ACVIM (Internal Medicine, Oncology) and ACVN
School of Veterinary Medicine
University of California, Davis
Davis, California, USA

Patient Assessment

A seven-year-old, 23-kg, intact male Gordon setter was examined for anorexia, lethargy, diarrhea and weight loss of six weeks' duration. Physical examination revealed a depressed, cachectic dog (body condition score 1/5). The remainder of the physical examination was unremarkable except for mild dehydration (5%). Abnormal results of a complete blood count, serum biochemistry profile and urinalysis included hypoalbuminemia (2.1 g/dl, normal 2.8 to 3.5) and hypoglobulinemia (2.3 g/dl, normal 3.0 to 3.5). Thoracic and abdominal radiographs were normal. Intestinal lymphoma was confirmed based on histopathologic evaluation of biopsy specimens taken from the small intestine during flexible endoscopy of the upper gastrointestinal (GI) tract.

The cachexia was likely due to a combination of diminished caloric intake, malassimilation and altered metabolism secondary to malignancy (**Table 1**). The anorexia was probably associated with the intestinal lymphoma, secondary abdominal pain and hyperlactatemia. The dehydration and lethargy were probably secondary to the underlying problems causing cachexia.

Chapter 31

Adverse Reactions to Food

Philip Roudebush

W. Grant Guilford

Hilary A. Jackson

"For this changed concept of reactivity, I propose the term allergy. 'Allos' implies deviation from the original state, from the behavior of the normal individual..."
Von Pirquet, 1906

CLINICAL IMPORTANCE

An adverse reaction to food is an abnormal response to an ingested food or food additive. Adverse reactions to food are composed of a variety of subclassifications based on pathomechanisms (**Figure 31-1**) (Anderson, 1986; Strombeck and Guilford, 1991). The terms food allergy and food hypersensitivity should be reserved for those adverse reactions to food that have an immunologic basis. Food intolerance refers to a large category of adverse food reactions due to nonimmunologic mechanisms. Traditionally, the terms food hypersensitivity and food allergy have been used to describe all adverse reactions to food in dogs and cats, including reactions that were truly food intolerances.

In view of the number of diverse foods that are routinely ingested by dogs and cats, it is not surprising that adverse reactions develop. That food-related reactions appear relatively infrequently is testimony to the effectiveness of the gastrointestinal (GI) mucosal barrier and oral tolerance. Adverse reactions to food were reported in dogs and cats as early as 1920 and have been blamed for a variety of clinical syndromes usually involving the skin and GI tract.

Carefully controlled prevalence studies of adverse food reactions in dogs and cats have not been performed. The major problem with establishing prevalence is that adverse food reactions mimic other diseases, especially other pruritic dermatoses, and they often coexist with other allergic conditions. Veterinary dermatologists suggest that adverse food reactions account for 1 to 6% of all dermatoses in general practice and that food allergy constitutes 10 to 49% of allergic responses in dogs and cats (MacDonald, 1993; Scott et al, 2001; Chesney, 2002; Loeffler et al, 2004; Jackson et al, 2005). Several investigators have suggested that adverse food reactions are relatively more common in cats than in dogs (MacDonald, 1993; Scott et al, 2001). Food allergy is one of the most common causes of hypersensitive skin disease in dogs and cats along with arthropod (flea) hypersensitivity and atopic dermatitis triggered by environmental allergens (MacDonald, 1993; Scott et al, 2001; Jackson et al, 2005). Adverse food reactions can cause a wide variety of cutaneous lesions and should be considered as a cause of any pruritic disease in dogs or cats. Most of the reported adverse food reactions causing dermatoses have been termed food allergy or food hypersensitivity, although no specific tests were performed to confirm an immunologic basis for the clinical signs.

Adverse reactions to foods also appear to be an important cause of GI signs in cats and dogs. In one study of chronic idiopathic GI problems in cats, 16 of 55 cats (29%) were diagnosed as food sensitive by elimination-challenge tests (Guilford et al, 2001). Furthermore, the clinical signs of 11 cats (20%) in this

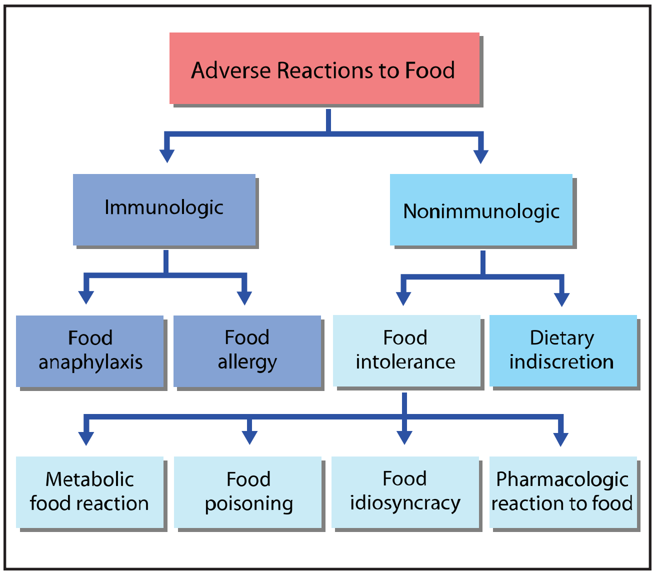

Figure 31-1. Classification of adverse reactions to food.

study resolved when they were fed the elimination food but signs did not recrudesce when the previous food was fed. Food sensitivity may also be involved in some cases of inflammatory bowel disease (IBD) in dogs and cats, particularly lymphocytic-plasmacytic enteritis and eosinophilic gastroenteritis (Elwood et al, 1994; Rutgers et al, 1995; Guilford, 1996). Clinical response to a modification in the feeding plan suggests that hypersensitivity to food antigens plays a role in dogs with chronic idiopathic or lymphocytic-plasmacytic colitis (Simpson et al, 1994; Leib et al, 1989; Nelson et al, 1988). It is unknown if chronic colitis or other forms of inflammatory disease of the small bowel are a direct manifestation of an adverse food reaction or if modifying the feeding plan is merely palliative in some patients.

PATIENT ASSESSMENT

Nutritional History

The authors of two series of dermatologic cases due to adverse food reactions could not relate the onset of clinical signs with recent food changes (Walton, 1967; Baker, 1974). This finding suggests that dogs and cats may develop food allergies after prolonged exposure to one brand, type or form of food. In contrast, adverse reactions due to food intolerance may occur after a single exposure to a food ingredient because immune amplification is unnecessary.

The nutritional history of the patient should be reviewed carefully for ingredients thought to be commonly associated with adverse food reactions. The nutritional history should include a complete list of the foods used in the pet's regular feeding plan or as treats including: 1) specific commercial foods, 2) commercial snacks and treats, 3) supplements, 4) chewable medications, 5) chew toys, 6) human foods and 7) access to other food sources. As an example, a dog might be given a dry commercial food as its main source of nutrition, but may also be given rawhide chews, commercial dog biscuits, flavored monthly oral heartworm prophylactic medication and leftover foods from human meals, and it may have access to commercial food fed to cats in the household. All of these ingested items could be sources of adverse food reactions. It is often helpful to have the pet owner keep a diary for several weeks documenting the types of food and other items the pet ingests daily. Nutritional assessment is described in more detail later in this chapter.

History and Physical Examination

Dermatologic Responses to Adverse Food Reactions in Dogs

Reports of adverse food reactions in dogs with cutaneous disease did not document a gender predisposition and ages ranged from four months to 14 years (MacDonald, 1993; Scott et al, 2001; Walton, 1967; Baker, 1974; August, 1985; White, 1986; Carlotti et al, 1990; Jeffers et al, 1991; Kunkle and Horner, 1992; Rosser, 1993; Harvey, 1993; Paterson, 1995; Roudebush and Schick, 1995). Up to one-third of cases, however, may occur in dogs less than one year of age (Rosser, 1993; Harvey, 1993). Most investigators have not found a breed predilection, although when compared to the local hospital case population, West Highland white terriers were found to be at increased risk (Rosser, 1993; Chesney, 2002; Jackson et al, 2005).

Adverse food reactions in dogs typically occur as nonseasonal pruritic dermatitis, occasionally accompanied by GI signs (MacDonald, 1993; Scott et al, 2001; Walton, 1967; Baker, 1974; August, 1985; White, 1986; Carlotti et al, 1990; Jeffers et al, 1991; Kunkle and Horner, 1992; Rosser, 1993; Harvey, 1993; Paterson, 1995; Roudebush and Schick, 1995). The pruritus varies in severity. Lesion distribution is often indistinguishable from that seen with atopic dermatitis triggered by environmental allergens; feet, face, axillae, perineal region, inguinal region and ears are often affected (MacDonald, 1993; Scott et al, 2001; Walton, 1967; Baker, 1974; August, 1985; White, 1986; Carlotti et al, 1990; Jeffers et al, 1991; Kunkle and Horner, 1992; Rosser, 1993; Harvey, 1993; Jackson, 2005). The similarity of clinical presentation has prompted the International Task Force on Canine Atopic Dermatitis to publish a position statement to the effect that canine atopic dermatitis should be considered a disease condition that can be triggered by environmental and or food allergens and both should be considered in dogs with nonseasonal disease (Olivry et al, 2007).

In one report, one-fourth of dogs with adverse food reactions had lesions only in the region of the ears (Rosser, 1993). This finding suggests that adverse food reactions should always be suspected in dogs with pruritic, unilateral or bilateral otitis externa, if accompanied by secondary bacterial or *Malassezia* infections (MacDonald, 1993; Scott et al, 2001). Unusual or atypical dermatologic responses to adverse food reactions in dogs include: erythema multiforme (Scott and Miller, 1999), claw disease (Mueller et al, 2000) and generalized erythematous wheals (urticarial vasculitis) (Nichols et al, 2000).

Adverse food reactions in dogs produce no set of pathognomonic cutaneous signs. A variety of primary and secondary skin lesions occur and include: 1) papules, 2) erythroderma, 3) excoriations, 4) hyperpigmentation and 5) seborrhea sicca. Adverse food reactions often mimic other common canine skin disorders including pyoderma, pruritic seborrheic dermatoses, folliculitis and ectoparasitism (MacDonald, 1993; Scott et al, 2001). Twenty to 30% or more of dogs with suspected adverse food reactions may have concurrent allergic disease, such as flea-allergic or atopic dermatitis (Baker, 1974; Jeffers et al, 1991; Rosser, 1993; Hillier and Griffin, 2001; Jackson et al, 2005). Some dogs present with only recurrent bacterial pyoderma, with or without pruritus, wherein all clinical signs resolve temporarily with antibiotic therapy (Scott et al, 2001; White, 1986; Harvey, 1993).

Food anaphylaxis is an acute reaction to food or food additives with systemic consequences. The most common clinical manifestation in dogs occurs in localized form referred to as angioedema or facioconjunctival edema (Scott et al, 2001; Thompson, 1995). Angioedema is typically manifested by large edematous swellings of the lips, face, eyelids, ears, conjunctiva and/or tongue, with or without pruritus (Scott et al, 2001; Thompson, 1995). The same types of substances that induce systemic anaphylaxis evoke angioedema (Thompson, 1995). Most veterinary practitioners attribute angioedema solely to insect envenomation (biting or stinging insects) but a number of other common causes include food, drugs, vaccines, infections and blood transfusions (Scott et al, 2001; Thompson, 1995; Nichols et al, 2001). These reactions usually occur within minutes of allergen exposure and generally subside after one to two hours.

One of the authors (PR) has seen angioedema of the tongue, palate and throat repeatedly in the same dogs after ingestion of mushrooms, domestic flowers or other plants. This presentation resembles the oral allergy syndrome in people, which is a form of contact urticaria confined almost exclusively to the oropharynx (Sampson, 1993). Clinical signs in people include rapid onset of pruritus and angioedema of the lips, tongue, palate and throat. Signs usually resolve rapidly. This syndrome is most commonly associated with ingestion of various fresh fruits and vegetables. Affected people are often primarily sensitized to certain airborne pollens (especially birch or ragweed pollen); the immunologic basis for this syndrome is IgE cross reactivity. One report details the clinical and immunologic findings in a dog that developed oral allergy syndrome to tomato after prior sensitization with Japanese cedar (Fujimora et al, 2002).

Dermatologic Responses to Adverse Food Reactions in Cats

The age of cats affected with food sensitivity has ranged from six months to 12 years; a gender predisposition has not been documented (Carlotti et al, 1990; White and Sequoia, 1989; Rosser, 1993a; Guaguere, 1995; Roudebush and McKeever, 1993; Medleau et al, 1986). In one study, almost half the cats developed the disease by two years of age (Rosser, 1993a). Siamese or Siamese cross cats accounted for nearly one-third of cases in two studies, suggesting a potential increased risk (Carlotti et al, 1990; Rosser, 1993a).

Dermatologic signs include several different clinical reaction patterns such as: 1) severe, generalized pruritus without lesions, 2) miliary dermatitis, 3) pruritus with self trauma centered around the head, neck and ears, 4) self-induced alopecia, 5) pyotraumatic dermatitis and/or 6) scaling dermatoses (MacDonald, 1993; Scott et al, 2001; Carlotti et al, 1990; White and Sequoia, 1989; Rosser, 1993a; Guaguere, 1995; Roudebush and McKeever, 1993; Medleau et al, 1986). In one study, angioedema, urticaria or conjunctivitis occurred in one-third of cats with adverse food reactions (Rosser, 1993a). Adverse reactions to food may also be implicated in cats with the so-called eosinophilic skin diseases such as eosinophilic plaques, eosinophilic granulomas and indolent ulcers of the lips (MacDonald, 1993; Scott et al, 2001; Roudebush and McKeever, 1993; Waisglass et al, 2006). Concurrent flea-allergy or atopic dermatitis triggered by environmental allergens may occur in up to 30% of cats with suspected adverse food reactions (Carlotti et al, 1990; Rosser, 1993a).

It has been suggested that moderate to marked peripheral lymphadomegaly is found in up to one-third of cats with dermatologic manifestations of food allergy (Scott et al, 2001). Absolute peripheral eosinophilia occurs in 20 to 50% of feline cases (Scott et al, 2001; White and Sequoia, 1989; Medleau et al, 1986).

GI Responses to Adverse Food Reactions in Dogs and Cats

Gender predilections have not been established for GI disease resulting from adverse reactions to foods (Walton, 1967; Baker, 1974). Similarly, there are no well-documented breed predispositions to GI food allergy, but Chinese Shar-Pei and German shepherd dogs are commonly affected. Furthermore, gluten-sensitive enteropathy has been well documented in Irish setter dogs (Batt et al, 1984). A wide age range of patients can be affected, including dogs and cats as young as weaning age.

Every level of the GI tract can be damaged by food allergies. In dogs, cats and people, clinical signs usually relate to gastric and small bowel dysfunction, but colitis can also occur (Heyman, 1989; Guilford and Badcoe, 1992; Sampson et al, 2001). Vomiting and diarrhea are prominent features. The diarrhea can be profuse and watery, mucoid or hemorrhagic (Guilford and Badcoe, 1992; Baker, 1990). Intermittent abdominal pain, intermittent diarrhea, weight loss, flatulence, irritable demeanor, soft feces and increased frequency of defecation are also seen (Guilford et al, 2001; Loeffler et al, 2004). Concurrent cutaneous signs may be seen. GI disturbances occur in up to half of dogs and cats with cutaneous manifestations of food hypersensitivity (MacDonald, 1993; Scott et al, 2001; Loeffler et al, 2004, 2006). In experimentally induced food hypersensitivity, the most common clinical signs are diarrhea, an increase in the number of bowel movements and occasional vomiting (Roudebush and McKeever, 1993; Frick, 1991). Pruritic dogs with more than three bowel movements per day are more likely to have an adverse reaction to food as part of the reason for

Box 31-1. Gastroscopic Food Sensitivity Testing.

Gastroscopic food sensitivity testing (GFST) is a diagnostic technique in which food extracts (5,000 to 15,000 protein nitrogen units/ml) are dripped onto the gastric mucosa by means of the operating channel of an endoscope. The site is then observed for two to three minutes. Mucosal swelling suggests an immediate sensitivity to the food extract tested. Erythema, blanching, edema and petechiation at the mucosal site also suggest the test subject is hypersensitive to the food, and the food, therefore, should not be used as part of the sensitive patient's diet. Sampling of the mucosal site with subsequent measuring of histamine levels, other mediator levels or mast cell degranulation can be used to determine whether the response was immune mediated. The diagnostic accuracy of GFST isn't known.

The Bibliography for **Box 31-1** can be found at www.markmorris.org.

their dermatoses (Scott et al, 2001; Paterson, 1995; Loeffler et al, 2004, 2006). The increased frequency of defecation will normalize with use of an appropriate elimination food (Loeffler et al, 2004).

There are at least five subacute to chronic GI conditions thought to involve food allergy in people: 1) food protein-induced enterocolitis, 2) food-induced colitis syndrome, 3) food-induced malabsorption syndrome, 4) gluten-sensitive enteropathy and 5) allergic eosinophilic gastroenteritis (Sampson, 1991; Sampson et al, 2001; Motala, 2008). All of these conditions can occur in dogs and cats. The role of food allergy in canine and feline IBD is unknown. Hypersensitivity to food is probably involved in the pathogenesis of this syndrome; at least some affected animals could be more appropriately diagnosed as suffering from food protein-induced enterocolitis. Dogs with GI diseases, including IBD, have more food allergen-specific serum IgG than normal dogs, a finding that may reflect increased antigen exposure due to increased mucosal permeability (Foster, 2003). Currently, 10% of dogs with IBD diagnosed by one of the authors (WGG) have positive gastroscopic food sensitivity tests (GFST) to food antigens (**Box 31-1**). Positive GFST results to foods used in the treatment of the disease are often detected during followup endoscopic studies. This finding strongly implies that food allergy is involved in the perpetuation of IBD but that it may not be the primary cause. That is, inflammation of the mucosa predisposes animals to the development of acquired food allergies. Therefore, a change in food antigens may temporarily reduce the immune-mediated mucosal inflammatory response. The longevity of this amelioration is questionable; however, because most of the so-called "hypoallergenic" foods commonly used in veterinary medicine contain intact proteins that are hypoallergenic primarily by virtue of their novelty to the host's immune system. The duration of protein novelty to the gut-associated lymphoid tissue (GALT) is likely to be very limited if the antigen is fed to a patient with a highly porous mucosal barrier. Irritable bowel syndrome is a disease of dogs characterized by chronic recurrent abdominal pain and large bowel diarrhea (Guilford, 1996a). Feeding changes will often alleviate the signs of irritable bowel disease, implying that food sensitivity plays a role in this syndrome. In the experience of one of the authors (WGG), avoiding gas-producing foods (e.g., homemade vegetable-based foods) or foods with a high fat content is particularly advantageous in the management of dogs with irritable bowel syndrome. In affected dogs, the adverse reactions to these nutrients are most likely due to food intolerance rather than food allergy.

Diagnostic Methods

The diagnosis of an adverse reaction to a food is confirmed by elimination-challenge trials (Jackson, 2009). In food-sensitive patients, resolution of clinical signs occurs after elimination of the responsible food from the diet followed by a return of the signs when the patient is challenged with the original food. Subsequently, feeding the elimination food should again alleviate clinical signs. Correct design of elimination-challenge trials is imperative for reliable diagnosis and is described below in the Feeding Plan section.

Failure to challenge a suspected food-sensitive patient will lead to marked over diagnosis of food sensitivity (Guilford et al, 2001). However, whether to challenge the patient or not is a decision that needs to be made collectively with the owner. Many owners are happy with a presumptive diagnosis of food sensitivity and do not wish to undertake a challenge test. After a diagnosis of food sensitivity is made, further cycles of elimination-challenge trials may then be undertaken in an attempt to identify the responsible food ingredients. It is noteworthy that dietary trials confirm or rule out adverse reactions to food but do not indicate the underlying mechanism (allergy or intolerance).

The place of skin tests, laboratory assays and endoscopic provocation tests remains uncertain in the diagnosis of food sensitivity. None of these are suitable as screening tests for adverse reactions to food because they do not screen for the entire spectrum of adverse reactions to foods (both allergy and intolerance). Some tests (e.g., measurement of food-specific serum IgE) suggest that an adverse reaction to a particular food (identified in an elimination-challenge trial) may be due to a type-1 hypersensitivity response rather than another type of allergic reaction or a food intolerance. However, at the present time, intradermal testing, radioallergosorbent tests (RASTs) and enzyme-linked immunosorbent assays (ELISAs) for food hypersensitivity are considered unreliable in patients with dermatologic (Jeffers et al, 1991; Kunkle and Horner, 1992) and GI disease (Foster, 2003). Although it is sensible to avoid feeding proteins that have caused positive gastroscopic or colonoscopic food sensitivity tests (especially more severe reactions such as edema and petechiation), the diagnostic accuracy of these endoscopic provocation tests requires further evaluation (Guilford et al, 1994; Vaden et al, 2000; Allenspach et al, 2006) as does the diagnostic accuracy of ultrasonography for food sen-

sitivity, which has recently shown some promise (Arslan et al, 2006; Gaschen et al, 2008).

Risk Factors

Risk factors for adverse food reactions in animals are currently unknown but may include: 1) certain foods or food ingredients (see below), 2) poorly digestible proteins, 3) any disease that increases intestinal mucosal permeability (e.g., viral enteritis), 4) selective IgA deficiency, 5) genetic predisposition, 6) age (six months to four years) and 7) concurrent allergic disease.

Etiopathogenesis

Normal Mucosal Barrier and Oral Tolerance

Ingested food represents the greatest foreign antigenic load confronting the immune system. The defense against hypersensitivity to food antigens includes an effective mucosal barrier and oral tolerance generated by the cellular immune system of GALT (Strombeck and Guilford, 1991; Sampson, 1993; Walker, 1987; Murphy and Walker, 1991).

An important adaptation of the GI tract is the development of a mucosal barrier that prevents the overwhelming uptake of food antigens (Sampson, 1993; Walker, 1987; Murphy and Walker, 1991). Efficient functioning of the mucosal barrier excludes the majority of ingested antigens, thus minimizing antigen exposure to GALT. The concept of a mucosal barrier includes effective digestion, the mucous layer, intact and functioning epithelial cells and IgA (**Table 31-1** and **Figure 31-2**).

Complete digestion of food protein results in free amino acids and small peptides that are poor antigens. An incompletely digested food protein has the potential to incite an allergic response because of residual antigenic proteins and large polypeptides. The composition of the mucous coat overlying the intestinal surface contributes to the defense against antigen attachment and penetration. Mucus contains carbohydrate moieties that may act as receptor inhibitors, thereby interfering with attachment of antigens to the intestinal microvillous surface (Sampson, 1993; Walker, 1987; Murphy and Walker, 1991). A direct association between intestinal cell membrane protein/phospholipid ratios and antigen uptake has been demonstrated in some species. Changes in cell membrane composition and function occur early in life, but how these changes affect food antigen uptake is unknown. IgA is the major immunologic component of the mucosal barrier because it is present in high concentrations in intestinal secretions. IgA may complex with food antigens in the intestinal lumen or within the mucous coat, thereby preventing their transport.

Despite these defense mechanisms, the mucosal barrier is not completely impervious to macromolecules; food proteins cross the intact intestinal mucosa in small but significant amounts. Antigens that enter and pass through the lamina propria are removed by the mononuclear-macrophage (reticuloendothelial) system of the liver and mesenteric lymph nodes.

The intestine, traditionally viewed as an organ of digestion and absorption of nutrients, maintains an indispensable immunologic function (Walker, 1987; Murphy and Walker, 1991). The gut is probably one of the largest immune organs in the body. GALT is composed of four distinct lymphoid compartments: 1) aggregates of lymphoid follicles throughout the intestinal mucosa, 2) lymphocytes and plasma cells scattered throughout the lamina propria, 3) intraepithelial lymphocytes interdigitated between enterocytes and 4) mesenteric lymph nodes (**Figure 31-3**) (Sampson, 1993).

Although GALT must mount a rapid and potent response against potentially harmful foreign substances and pathogenic organisms, it also must remain unresponsive to enormous quantities of food antigens. Absorbed food antigens (Van Wijk and Knippels, 2007) are presented to GALT in such a manner that a potent gut-associated, cell-mediated suppressive response develops (**Figure 31-4**).

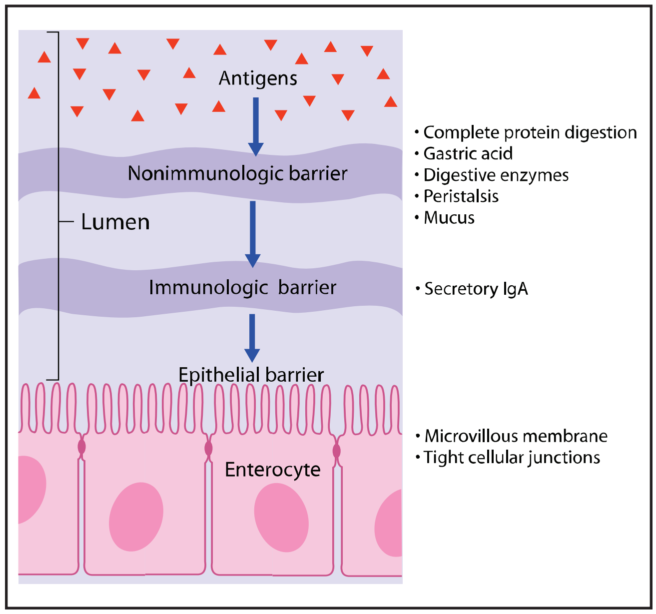

Figure 31-2. Diagrammatic representation of barriers to antigen penetration of the intestinal mucosa. Antigens are prevented from entering the mucosa by nonimmunologic and immunologic mechanisms and the physical structure of the epithelium. (Adapted from lyngkaren N, Abidin Z. Intolerance to food proteins. In: Lifshitz F, ed. Pediatric Nutrition. New York, NY: Dekker, 1981; 453.)

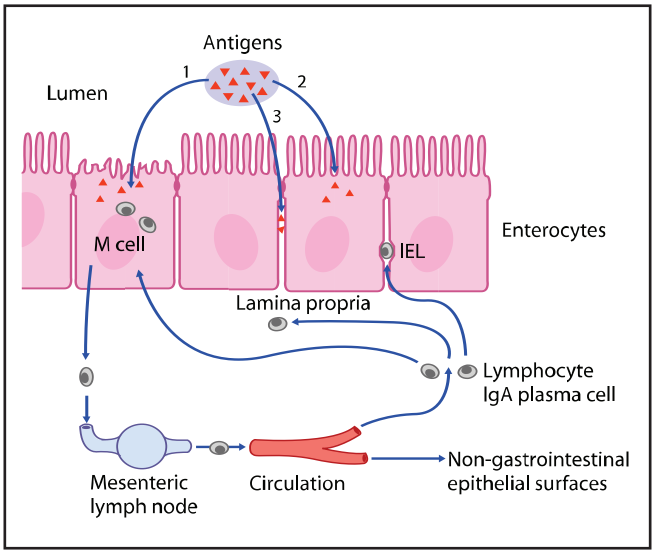

Figure 31-3. Diagrammatic representation of the gut-associated lymphoid tissue (GALT) and the mucosal immune cycle. GALT is composed of Peyer's patches, lamina propria lymphocytes and plasma cells, intraepithelial lymphocytes (IEL) and mesenteric lymph nodes. Food antigens are absorbed via specialized M cells (1) or enterocytes (2,3). These antigens stimulate lymphocytes, which migrate by way of the intestinal lymphatics to mesenteric lymph nodes, ultimately reaching the systemic circulation via the thoracic duct. Specific immune-primed lymphocytes cycle back to GALT or are deposited at other mucosal surfaces. (Adapted from Patrick MK, Gall DG. Protein intolerance and immunocyte and enterocyte interaction. Pediatric Clinics of North America 1988; 35: 17-34.)

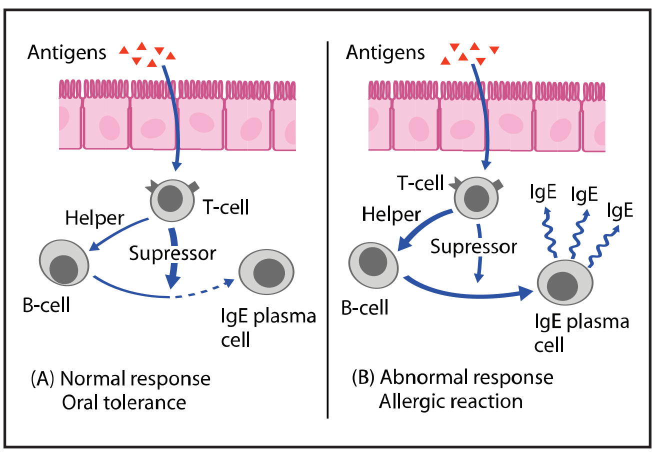

Figure 31-4. Diagrammatic representation of food antigen absorption under different conditions. With a normal response (A), T-cell suppressor activity occurs and contributes to oral tolerance. In (B), an abnormal immune response contributes to production of excess IgE and may result in allergic disease. (Adapted from Walker WA. Pathophysiology of intestinal uptake and absorption of antigens in food allergy. Annals of Allergy 1987; 59: 7-16.)

This immune suppressor response, along with anergy and cell deletion is the basis of oral tolerance. Conversely, an allergic response may result if the antigen encounters a defective suppressor arm of GALT or escapes into the systemic circulation. The concept of "immune exclusion" of food antigens is important because systemic lymphoid tissue responds by active immunoreactivity, which could lead to allergic clinical signs rather than immune suppression (tolerance).

Immunologic Reactions to Food

FOOD ALLERGENS

The specific food allergens or ingredients that cause problems in animals have been poorly documented (**Table 31-2**). In general, the major food allergens that have been identified in people are water-soluble glycoproteins that have molecular weights ranging from 10,000 to 70,000 daltons and are stable to treatment with heat, acid and proteases (Sampson, 1993). Other physiochemical properties that account for their unique allergenicity are poorly understood (Aalberse, 2000; Breiteneder and Ebner, 2000).

The most common food allergens in children are found in chicken egg, peanut, cow's milk, fish, soy and wheat (Sampson, 1993, 1991a, 1988; Yunginger, 1991). In human adults, various fruits, tree nuts, peanut, fish, seafood (mollusks, crustaceans) and cow's milk are confirmed most often as causing food allergy (Sampson, 1993, 1991a, 1988; Yunginger, 1991). Discussion of the specific protein fractions and allergens in these foods that are thought to cause problems are reviewed elsewhere (Sampson, 1993; Yunginger, 1991; Breiteneder and Ebner, 2000; Sicherer, 2001; www.allergen.org).

Fifteen different studies, representing 278 dogs, described primarily cutaneous lesions associated with adverse reactions to specific foods or ingredients (Elwood et al, 1994; Walton, 1967; Carlotti et al, 1990; Jeffers et al, 1991, 1996; Kunkle and Horner, 1992; Harvey, 1993; Paterson, 1995; Mueller and Tsohalis, 1998; Mueller et al, 2000; Chesney, 2002; Tapp et al, 2002; Ishida et al, 2003, 2004) (**Table 31-2**). Beef, dairy products and wheat are most commonly reported as ingredients causing adverse food reactions in dogs. After analysis, specific food allergens identified in dogs include chicken serum albumin, bovine IgG (cow's milk, beef), ovine IgG (lamb), muscle phosphoglucomutase (beef, lamb) and Gly proteins 50 and 75 kD (soy) (Cave et al, 2000; Cave, 2001; Cave and Guilford, 2004; Martin et al, 2004; Serra et al, 2006).

Ten different studies or case reports, representing 56 cats, described cutaneous lesions and/or GI disorders associated with adverse reactions to specific foods or ingredients (Walton, 1967; Carlotti et al, 1990; White and Sequoia, 1989; Guaguere, 1995; Walton et al, 1968; Stogdale et al, 1982; Reedy, 1994; Guilford et al, 1996b, 2001)[a] (**Table 31-2**). Beef, dairy products and fish are most commonly reported as ingredients causing adverse food reactions in cats. Specific food allergens have not been identified in cats.

Human allergy reference books often contain phylogenetic tables of animal and vegetable foods, so food-allergic persons can avoid other closely related foods. In clinical practice, human patients often report cross reactivity among various fish and crustaceans, but less cross reactivity within vegetable food groups (Sicherer, 2001). Results of oral food challenges in children demonstrate that clinically important cross reactivity to

legumes (peanuts, soybeans, green beans, lima beans, peas, lentils) is very rare (Bernhisel-Broadbent and Sampson, 1989). Wheat, rye and barley cross react in allergic people, but oat allergens appear to cross react only weakly (Varjonen et al, 1994). Cross reactivity between milk proteins from cows, goats and sheep is common. In children, chicken egg cross reacts with egg proteins of other birds (Sampson, 1993). Cross reactivity among food allergens has only been investigated to a minor degree in pet animals (Jeffers et al, 1996; Martin et al, 2004).

PATHOPHYSIOLOGIC MECHANISMS

Abnormalities in GI defense mechanisms may predispose patients to food allergies (Strombeck and Guilford, 1991). Predisposing factors for food allergy include: 1) mucosal barrier failure (poorly digestible proteins, incomplete protein digestion, increased intestinal mucosal permeability, age-related changes in microvillous cell membrane composition, inflammatory-induced changes in mucus composition) and 2) defective immunoregulation (decreased IgA secretion, deranged cell-mediated responses of GALT, monocyte-macrophage system dysfunction) (**Figure 31-4**). Which of these pathomechanisms are important predisposing factors in dogs and cats awaits further investigation. The most extensively studied and best-defined food allergic reactions in people and laboratory animals involve IgE-mediated responses that result in clinical signs of immediate hypersensitivity (within minutes to hours) (Sampson, 1993). IgE-activated mast cells also may release a variety of cytokines that mediate a late-phase response (within several hours to days). With repeated ingestion of a food allergen, mononuclear cells are stimulated to secrete histamine-releasing factors that interact with IgE bound to the surface of basophils and mast cells and increase their releasability (Sampson et al, 1989). This in vitro phenomenon has been associated with increased cutaneous reactivity in children with atopic dermatitis (Sampson et al, 1989).

Unlike food allergy in people, the pathogenesis of adverse food reactions in dogs and cats has not been fully elucidated. Canine models of IgE-mediated food hypersensitivity have been developed by repeated exposure to food allergens and adjuvant (Guilford and Badcoe, 1992; Schiessl et al, 2003; Buchanan and Frick, 2002; Kennis, 2001; Cave and Guilford, 2004). More recent reports describe spontaneous food allergy in dogs in which food-allergen specific IgE responses can be demonstrated in association with clinical disease (Ishida, 2003; Jackson and Hammerberg, 2002; Jackson et al, 2003). However, other studies have been unable to detect clinically relevant food antigen-specific IgE in client-owned dogs with known adverse food reactions (Mueller and Tsohalis, 1998; Hillier and Kunkle, 1994). Although IgE may be involved in the pathogenesis of food allergy in some dogs, it is unlikely to be the sole immunologic mechanism of disease, particularly in chronic situations (Foster et al, 2003).

Type II (cytotoxic), Type III (immune complex) and Type IV (cell-mediated) hypersensitivity reactions have been implicated less commonly in food-allergic disorders in people (Sampson, 2004).

Table 31-2. Ingredients commonly associated with adverse food reactions.*

Dogs	
Ingredients	***% of reported cases***
Beef, dairy products, wheat	69
Lamb, chicken egg, chicken, soy	25
Cats	
Ingredients	***% of reported cases***
Beef, dairy products, fish	80

*Data from cases reported in North America, Europe, Australia, Japan and New Zealand. Common food allergens may differ in other geographic locations.

GLUTEN (GLIADIN) ENTEROPATHY

Gluten-induced enteropathy (celiac disease) is an important chronic inflammatory disease of the small intestine of people. The prevalence of gluten intolerance in dogs and cats is unknown. Research has conclusively demonstrated that an analogous disorder affects Irish setter dogs (Batt et al, 1984), and clinical experience suggests that other breeds may also be affected.

Flour from cereal grains contains various proteins including: 1) water-soluble albumins, 2) saline-soluble globulins, 3) ethanol-soluble prolamins and 4) acid- or alkali-soluble glutelin (Yunginger, 1991). Prolamins of wheat, rye and barley have marked sequence homology, but not the prolamins of rice and corn, which do not exacerbate the disorder (Kasadra et al, 1976). The prolamin and the glutelin proteins of wheat are gliadin and glutenin. Gliadin is a glutamine- and proline-rich polypeptide with a molecular weight of 15,000 daltons. Gliadin is composed of four major electrophoretic fractions, the most toxic of which in people appears to be α-gliadin (Kasadra et al, 1976). "Gluten" is a crude mixture of gliadin and glutenin. Pancreatic enzymes in the intestinal lumen and intracellular enzymes of the mucosal brush border normally digest these peptides. Completely hydrolyzed gliadin is nontoxic.

The cause of gluten sensitivity is unknown. Studies involving gluten-intolerant Irish setters have demonstrated that increased mucosal permeability predates development of the disease (Hall and Batt, 1990). The pathogenesis of gluten-sensitive enteropathy has been debated for many years, but researchers now think gluten sensitivity in people is probably mediated by the immune system. Knowledge of the complete sequence of immunologic events is incomplete, but it appears IgE mediates acute responses to gluten whereas the delayed hypersensitivity (and mucosal atrophy) is mediated by IgA and IgG (Vojdani et al, 2008). Gliadin-activated macrophages may possibly recruit lamina propria lymphocytes resulting in a delayed hypersensitivity response and various inflammatory changes such as infiltration of inflammatory cells, mast cell degranulation, production of eicosanoids, increased microvascular permeability and complement activation (Marsh, 1992; Loft et al, 1989). The lymphocyte density of the mucosal intraepithelium is increased and serum total IgA levels are elevated in gluten-sensitive dogs (Hall et al, 1992).

In contrast to findings in people, antigliadin antibody (IgG) levels are lower in affected dogs than in age-matched control dogs. In addition, serum immune complex levels are not elevated in dogs whereas they are frequently elevated in people (Hall et al, 1992). These findings do not support a role for a systemic immune response in the pathogenesis of canine gluten-sensitive enteropathy but do not rule out a mucosal delayed hypersensitivity response.

Nonimmunologic Reactions to Food

Nonimmunologic, abnormal reactions to food include food intolerance and dietary indiscretion (**Figure 31-1**). Like the terms food allergy and food hypersensitivity, the term food intolerance has been applied inappropriately to any and all adverse reactions to food. Food intolerance mimics food allergy except that it can occur on the first exposure to a food or food additive, because nonimmunologic mechanisms are involved. The incidence of food intolerance vs. food hypersensitivity or food allergy is unknown.

FOOD POISONING

Food poisoning or food toxicosis is an adverse effect caused by the direct action of a food or food additive on the host. Examples of food poisoning include ingestion of: 1) nutrient excesses (vitamin A or vitamin D toxicosis), 2) food contaminated with microorganisms or their toxic metabolites (scavenging putrefied material, vomitoxin), 3) specific foods (onions, chocolate) or 4) toxic food preservatives (benzoic acid or propylene glycol in cats) (Chapter 11).

Food poisoning is a frequent cause of GI disease in dogs and cats. In addition to ingestion of pathogenic microorganisms or their toxins, food poisoning can result from the ingestion of plant-derived toxins or irritants. For example, high levels of oxalates and anthraquinone glycosides contained in rhubarb, spinach and beets can lead to a corrosive gastroenteritis, and large quantities of spices such as peppers can cause abdominal discomfort in people.

REACTIONS TO FOOD ADDITIVES

Idiosyncratic adverse reactions to food additives often occur in people (Hannuksela and Haahtela, 1987; Simon and Stevenson, 1993; Metcalfe et al, 1991; Fuglsang et al, 1994). Food additives frequently incriminated in human adverse reactions include sulfites, monosodium glutamate, tartrazine and other azo or non-azo dyes, benzoates, parabens and spices (Hannuksela and Haahtela, 1987; Simon and Stevenson, 1993; Metcalfe et al, 1991; Fuglsang et al, 1994). Few of the adverse reactions to food additives appear to involve an immunologic mechanism, although IgE-mediated reactions may occur (Hannuksela and Haahtela, 1987; Simon and Stevenson, 1993; Metcalfe et al, 1991; Fuglsang et al, 1994). Confirmed reactions to food additives are best described as food intolerances or food idiosyncrasies because clinical signs resulting from their ingestion are not thought to be immunologically mediated. Examples are reactions to azo dyes, non-azo dyes and antioxidants that can directly cause histamine release from leukocytes of clinically normal people (Murdoch et al, 1987).

Although food additives are frequently incriminated as causing problems in dogs and cats, few data confirm this perception (Roudebush and Cowell, 1992; Roudebush, 1993). Propylene glycol has been documented to cause hematologic abnormalities in cats and subsequently has been eliminated from cat foods sold in the United States and some other countries (Hickman et al, 1990; Weiss et al, 1990). Disulfides found in onions (onion powder, onion-based broth and baby foods containing onion) promote oxidative damage to hemoglobin in canine and feline red blood cells (Robertson et al, 1998). The result is Heinz body production and red cell destruction.

REACTIONS TO VASOACTIVE AMINES IN FOOD

Another cause of food intolerance is pharmacologic reactions to substances found in food. Vasoactive or biogenic amines such as histamine cause clinical signs in people when present in excessive levels in food (Taylor, 1986; Morrow et al, 1991). Scombroid fish such as tuna, mackerel, skipjack and bonito that spoil before consumption are a frequent cause of histamine toxicosis in people (Taylor, 1986; Morrow et al, 1991). Clinical signs usually include diarrhea, flushing, sweating, nausea, vomiting, urticaria, facial swelling and erythroderma.

The role of histamine and other vasoactive amines in food intolerance in dogs and cats is unknown. Adverse reactions to ingested scombroid fish have been observed in cats and dogs (Guilford et al, 1994a). Surveys to detect histamine in pet foods found the highest levels of histamine in moist fish-based cat foods and those cat foods containing fish solubles (Guilford et al, 1994a; Guraya and Koehler, 1991). Vasoactive amines such as cadaverine may also exacerbate adverse reactions to spoiled fish by inhibiting histamine metabolism (Taylor, 1986; Bjeldanes et al, 1978). Tyramine, spermine, spermidine, phenethylamine, putrescine and cadaverine are other vasoactive amines found in low levels in pet foods (Paulsen, 2000).[b] Vasoactive or biogenic amines may not be present in levels high enough to cause clinical signs, but could lower the threshold levels for allergens in individual dogs and cats. Idiosyncratic intolerances to small quantities of histamine have been reported to occur in people and animals (Guilford et al, 1994a).

CARBOHYDRATE INTOLERANCE

Adult hypolactasia, infantile lactase deficiency, congenital lactose intolerance and congenital glucose-galactose malabsorption are disorders of carbohydrate intolerance in people (Halliwell, 1992). Fewer conditions are associated with recognized carbohydrate intolerance in dogs and cats. However, neonatal death following episodes of diarrhea is common and the same spectrum of metabolic disorders resulting in carbohydrate intolerance in people may occur in dogs and cats (Strombeck and Guilford, 1991; Halliwell, 1992).

The diarrhea, bloating and abdominal discomfort that occur when animals with lactose intolerance ingest milk are relatively common metabolic adverse reactions in dogs and cats (Hill and Kelley, 1974; Mundt and Meyer, 1989). Puppies and kit-

tens normally have adequate levels of intestinal lactase to permit digestion of lactose in the dam's milk. In many subjects, brush border disaccharidase activity decreases after weaning to a fraction of the activity found in young animals. Osmotic diarrhea will often occur when excessive levels of lactose are consumed. Puppies, kittens or adult animals may develop diarrhea when given cow's or goat's milk because these milk sources contain more lactose than either bitch's or queen's milk. One study showed that adult dogs were able to use up to 1 g of lactose/kg body weight/day (Meyer et al, 1984), an amount equivalent to 20 to 22 ml/kg of cow's or goat's milk. Greater amounts increased intestinal lactose and lactic acid concentrations, fecal water content and frequency of defecation.

Intolerance to disaccharides commonly occurs secondary to enteritis or rapid food changes. Loss of intestinal brush border disaccharidase activity contributes to the diarrhea associated with enteritis. Inadequate intestinal disaccharidase activity is also one of the factors responsible for diarrhea following rapid food changes. Several days are required for intestinal disaccharidase activity to adapt to changes in food carbohydrate sources.

DIETARY INDISCRETION

Dietary indiscretions such as gluttony, pica and garbage ingestion usually cause GI signs and can be suspected based on the environmental and nutritional history. The clinical signs may be caused by ingestion of excessive fat, bacterial or fungal toxins, vasoactive amines or indigestible materials such as bone, plastic, wood and aluminum foil. Note that underlying disease such as hyperadrenocorticism can also induce polyphagia and resultant dietary indiscretion.

Key Nutritional Factors

Because most food allergens are thought to be glycoproteins, dietary protein in food is the nutrient of most concern in patients with suspected food allergy. The number of different proteins in the food, protein sources and amount of protein comprise the key nutritional factors for foods for diagnosis and management of adverse food reactions. Whether the patient has been exposed previously to the protein is also important.

Because elimination foods replace regular maintenance foods and are fed long term, several key nutritional factors are included because of their relationship to other common health issues rather than specific benefits for patients suffering from adverse food reactions. **Table 31-3** summarizes the key nutritional factors, which are discussed in more detail below.

Table 31-3. Key nutritional factors for foods for the diagnosis and management of adverse food reactions in dogs and cats.

Factors	Dietary recommendations
Dogs	
Protein	Limit dietary protein to one or two sources Use protein hydrolysate or protein sources to which the dog has not been exposed previously Avoid excess levels of dietary protein (dermatologic cases only): protein should be 16 to 22% DM Use a food that is nutritionally balanced for dogs Avoid foods that contain wheat, barley or rye (dogs with diarrhea)
Vasoactive amines	Avoid foods that contain certain fish ingredients (e.g., tuna, mackerel, skipjack, bonito)
Total omega-3 fatty acids	0.35 to 1.8% DM
Phosphorus*	0.4 to 0.8% DM
Sodium*	0.2 to 0.4% DM
Cats	
Protein	Limit dietary protein to one or two sources Use protein hydrolysate or protein sources to which the cat has not been exposed previously Avoid excess levels of dietary protein (dermatologic cases only): protein should be 30 to 45% DM Use a food that is nutritionally balanced for cats
Vasoactive amines	Avoid foods that contain certain fish ingredients (e.g., tuna, mackerel, skipjack, bonito)
Total omega-3 fatty acids	0.35 to 1.8% DM
Phosphorus*	0.5 to 0.8% DM
Sodium*	0.2 to 0.6% DM
Magnesium*	0.04 to 0.1% DM
Urinary pH*	6.2 to 6.4

Key: DM = dry matter.
*Not related to adverse reactions to food but important when elimination foods are used for long-term feeding: phosphorus and sodium are considered key nutritional factors for apparently healthy adult dogs and cats for purposes of ameliorating or slowing the progression of subclinical kidney disease and/or hypertension; magnesium and urinary pH are important for reducing the risk of feline lower urinary tract disease.

Protein

Commercial veterinary therapeutic foods containing unique or novel protein ingredients have been available for more than 40 years. Novel protein sources are usually defined as animal or vegetable ingredients containing protein that are not commonly used in pet foods and/or are not commonly associated with adverse food reactions. Examples of such protein sources include lamb, venison, rabbit, various fish, rice, potato and green peas. Beef, dairy products and wheat in dogs, and beef, dairy products and fish in cats are the most commonly reported ingredients causing adverse reactions and should be avoided in patients with adverse reactions to foods. A careful dietary history should disclose these protein sources. Several published clinical studies support the use of commercial foods containing novel protein sources in the management of adverse food reactions in cats and dogs (Roudebush et al, 2002).

Using the product label to determine whether a potentially offensive protein source(s) is/are present in a patient's current food can be challenging. A large number of protein ingredients are used to manufacture typical commercial pet foods. Many protein ingredients differ from those commonly used for human consumption and may be unfamiliar to veterinarians, veterinary health care team members and animal owners. For example, chicken for human consumption, chicken used in moist pet foods and poultry by-product meal used in dry pet

foods may each contain unique allergens. Chapter 8 discusses pet food ingredients and reviews several of the more commonly used protein sources. In the U.S., most commercial foods must adhere to the Association of American Feed Control Official (AAFCO) guidelines for label ingredient listings and definitions (AAFCO, 2008). The definitions can help determine what specific protein sources are in a given ingredient. This information might not be obvious from reading a product's label (Chapter 9).

Another approach to providing novel protein ingredients is the use of hydrolyzed protein(s). Protein hydrolysates offer several hypothetical advantages over intact protein sources. Protein hydrolysates of appropriate molecular weight (<10,000 daltons) are less likely to elicit an immune-mediated response. For example, complete digestion of an initially intact food protein results in free amino acids and small peptides that are poor antigens (Yunginger, 1991). In contrast, poorly digested protein has the potential to incite an allergic response because of residual antigenic proteins and large polypeptides.

Several published clinical studies document the efficacy of foods containing protein hydrolysates in veterinary patients. Clinical improvement was seen in 50 to 80% of dogs allergic to the intact protein (Beale et al, 2001; Jackson et al, 2003; Puigdemont et al, 2006; Serra et al, 2006). Additionally, several clinical trials with protein hydrolysate-type foods have been conducted in canine and feline patients seen in private and specialty practices with dermatologic or GI disease. The results of these studies show similar efficacy of hydrolysates as compared with the more traditional novel protein sources (Loeffler et al, 2004, 2006; Ishida et al, 2004; Biourge et al, 2003; Rosser, 2001). Protein hydrolysates have also been used successfully in cats with self-inflicted alopecia (psychogenic alopecia) and chronic GI disorders (Waly et al, 2006; Waisglass et al, 2006).

Foods containing protein hydrolysates may also benefit patients with increased GI permeability, in which enhanced protein absorption contributes to the pathogenesis of the disease. One study showed positive responses in a small number of dogs with IBD (Marks et al, 2002). Protein hydrolysates have been used for many years in human infant formulas and for human patients with various GI diseases. Novel or unique protein sources are less important with protein hydrolysates. Total protein content, average molecular weight of the hydrolyzed protein and digestibility of nutrients vary among these products.

The value of high protein digestibility in foods with intact protein ingredients has been documented for some commercial pet foods marketed as hypoallergenic or elimination foods (Roudebush et al, 1995). As noted above, more complete digestion of an initially intact food protein results in more free amino acids and small peptides that are poor antigens (Yunginger, 1991). Protein digestibility of at least 87% is recommended for such foods. This degree of protein digestibility is typically met by most veterinary therapeutic pet foods.

Elimination foods that use intact novel proteins should contain preferably only one but no more than two protein sources to which the patient has not been previously exposed. This recommendation includes commercial or homemade foods and either animal or vegetable protein sources.

Excess protein levels should be avoided to reduce the amount of potential allergens to which the patient is exposed. Foods for dogs should provide between 16 to 22% dry matter (DM) protein and foods for cats should provide between 30 to 45% DM protein. A higher protein level may be necessary to counteract losses from the GI tract or impaired absorption in patients with hypoproteinemia and weight loss associated with severe GI disease. Certain protein ingredients are more likely sources of excessive levels of vasoactive or biogenic amines such as histamine. The highest levels of histamine occur in moist fish-based cat foods and cat foods containing fish solubles (Guilford et al, 1994a; Guraya and Koehler, 1991). Pet foods containing these fish may be a source of such amines and probably should be avoided. Human foods that may contain excessive levels of vasoactive or biogenic amines include tomato, avocado, cheese, liver, processed meats such as sausage and certain fish. As mentioned above, vasoactive or biogenic amines may not be present in levels high enough to cause clinical signs, but could lower the threshold levels for allergens in individual dogs and cats.

Omega-3 Fatty Acids

Omega-3 (n-3) fatty acids exhibit multiple antiinflammatory and immunomodulating effects. They have the potential to affect allergic and other inflammatory diseases through modulating cytokine production, inhibiting cellular activation and cytokine secretion, altering the composition and, in the case of dermatologic disease, function of the epidermal lipid barrier (Olivry et al, 2001). Their mechanisms of action, therefore, are likely to be explained by a combination of effects. Generally, however, omega-3 fatty acids are thought to produce less inflammatory cytokines (Sigal, 1991; Lands, 1989; Lokesh et al, 1988; Lokesh and Kinsella, 1987; Broughton et al, 1991; Croft et al, 1987).

Based on levels of omega-3 fatty acid supplementation recommended for use in the management of inflammatory skin diseases (Chapter 32), veterinary therapeutic foods for dogs and cats with inflammatory disease related to adverse food reactions should provide 0.35 to 1.8% DM of total omega-3 fatty acids. However, because of their potential benefit in inflammatory diseases, inclusion of omega-3 fatty acids could confuse the diagnostic phase of managing food sensitivity. The ratio of omega-6 to omega-3 fatty acids that should be included in foods for patients with adverse food reactions is currently unknown.

Phosphorus, Sodium, Magnesium and Urinary pH

Elimination foods used to diagnose patients with possible food sensitivity are fed for short time periods. However, if there is a positive diagnosis of food sensitivity, appropriate veterinary therapeutic foods are fed for prolonged periods of time, in the place of regular maintenance foods. Phosphorus and sodium are recommended as key nutritional factors for maintenance foods for apparently healthy adult dogs and cats for purposes of ameliorating, or slowing the progression of possible concurrent

subclinical kidney disease and/or hypertension. Thus, even though phosphorus and sodium are not associated with food sensitivity, they are included as key nutritional factors for overall health. The recommended allowances for phosphorus and sodium in foods for adult dogs are 0.4 to 0.8% DM and 0.2 to 0.4% DM, respectively. For foods for adult cats, the recommended allowances for phosphorus and sodium are 0.5 to 0.8% DM and 0.2 to 0.6% DM, respectively. In addition, for adult cats, magnesium and urinary pH are also key nutritional factors for foods intended for long-term feeding, based on their role in feline lower urinary tract disease. The recommended allowance for magnesium in foods for adult cats is 0.04 to 0.1% DM. Foods for adult cats should produce a urinary pH in the range of 6.2 to 6.4. Chapters 13 and 20 discuss the rationale for including these key nutritional factors for dogs and cats, respectively.

Other Nutritional Factors

Carbohydrate and Fat

Modification of the total dietary fat and carbohydrate content of foods is usually not required in the management of food-sensitive dermatologic patients. However, choosing foods with highly digestible fat and carbohydrate can be important in the management of food-sensitive GI patients because of the enteropathy and malassimilation that may result from allergic inflammation of the GI tract. Furthermore, a reduction in the content of one or both of these macronutrients may be required in patients with nonimmunologic food intolerances to fat and carbohydrate.

Food Additives

Pet food additives such as antimicrobial preservatives, colorants, antioxidant preservatives and emulsifying agents rarely cause food intolerance or allergy. Additives are found least often in moist pet foods and most commonly in semi-moist foods, treats, snacks and dry foods. Many moist commercial pet foods are free of additives. Two of the most frequently incriminated additives in human foods, benzoates and tartrazine, are rarely found in commercial pet foods. However, other additives that have been documented to cause problems in people are found in pet foods (**Table 31-4**). These include azo dyes, non-azo dyes, sodium bisulfite, sodium glutamate, sodium nitrate, butylated hydroxyanisole (BHA), spices, sodium alginate, guar gum and propylene glycol (Fuglsang et al, 1994).

Table 31-4. Food additives that have been reported as occasional causes of food intolerance in people and that are sometimes present in pet foods or treats.*

Antioxidant preservatives
Butylated hydroxyanisole (BHA)
Butylated hydroxytoluene (BHT)
Antimicrobial preservatives
Sodium nitrite
Humectants
Propylene glycol
Coloring agents/preservatives
Azo dyes
Tartrazine (FD&C No. 5)
Sunset yellow (FD&C No. 6)
Allura red (FD&C No. 40)
Non-azo dyes
Brilliant blue (FD&C No. 1)
Indigotin (FD&C No. 2)
Flavors/flavor enhancers
Monosodium glutamate
Spices
Emulsifying agents, stabilizers, thickeners
Seaweed extracts (carrageenan, alginates)
Seed gums (guar gum)

*These additives are frequently incriminated as causing adverse food reactions in dogs and cats, but there are no well-documented case reports to substantiate this perception.

FEEDING PLAN

Unlike most other clinical conditions, the feeding plan for possible food sensitivity patients includes a diagnostic phase. At the present time, intradermal testing, RASTs and ELISAs for food hypersensitivity are considered unreliable for patients with dermatologic disease (Jeffers et al, 1991; Kunkle and Horner, 1992). Dietary elimination trials are the primary diagnostic method used in dogs and cats with suspected adverse food reactions (Jackson, 2009) and are discussed below in the Assess and Determine the Feeding Method section.

Assess and Select the Food

Commercial Elimination Foods

Ingredient statements on commercial pet food labels in the U.S. are sources of information for identifying all the food ingredients that might cause adverse reactions. An individual dog or cat may develop an adverse reaction to virtually any pet food ingredient. However, particular attention should be directed at those ingredients that contain protein. Unfortunately, pet food labeling requirements in other countries are not necessarily as stringent and ingredient statement information is often incomplete (Chapter 9). Contact the manufacturer or distributor for more detailed ingredient information when the ingredient statement is incomplete.

Several companies manufacture a variety of foods with limited and different protein sources (**Tables 31-5** and **31-6**). These commercial veterinary therapeutic products are convenient, contain protein hydrolysates and/or novel protein sources and are nutritionally complete and balanced for either dogs or cats (approved for long-term feeding of healthy adults by a credible regulatory agency such as AAFCO). Unfortunately, few of these commercial foods have been adequately tested in dogs and cats with known adverse food reactions; only a limited number of foods (approximately 15 of more than 50 veterinary therapeutic foods marketed for adverse food reactions) have undergone the scrutiny of clinical trials using patients with dermatologic or GI disease (Rutgers et al, 1995; Simpson et al, 1994; Nelson et al, 1988; Jeffers et al, 1991; Rosser, 1993; Paterson, 1995; Roudebush and Schick, 1995; Guilford et al, 2001; Loeffler et al, 2004, 2006). In published clinical trials,

usually two-thirds to three-fourths of patients with suspected adverse food reactions had significantly improved clinical signs when fed commercial veterinary therapeutic elimination-type foods. **Tables 31-5** and **31-6** compare the recommended key nutritional factors to those in selected commercial veterinary therapeutic foods intended for patients with adverse food reactions.

Novel or unique protein sources are less important when the patient's nitrogen and amino acid requirements are met by protein hydrolysates. Clinical trials with protein hydrolysates show similar efficacy to more traditional novel protein-source foods (Loeffler et al, 2004, 2006; Ishida et al, 2004; Biourge et al, 2003; Rosser, 2001). Protein hydrolysate foods have also been used successfully in cats with self-inflicted alopecia and chronic GI disorders (Waly et al, 2006; Waisglass et al, 2006).

In general, snacks, chews and treats should be avoided.

Key: Omega 3 = total omega-3 fatty acids, P = phosphorus, Na = sodium, na = not available from manufacturer.
*Values are on a dry matter basis unless otherwise stated.
**A higher protein level may be necessary to counteract protein losses from the GI tract or impaired absorption in patients with hypoproteinemia and weight loss associated with severe GI disease.
***Omega-3 fatty acids are important for dermatologic cases.
†Phosphorus and sodium are not important for adverse food reactions but are important for overall health when feeding these foods long-term.
††Fish source ingredients that can be a source of vasoactive amines.
†††For dogs with diarrhea.

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Homemade Elimination Foods

Results of a survey of veterinarians in the American Academy of Veterinary Dermatology (AAVD) showed that homemade foods were often recommended as the initial test

food for dogs and cats with suspected food allergy (Roudebush and Cowell, 1992). Homemade test foods usually include a single protein source or a combination of a single protein source and a single carbohydrate source. Ingredients typically recommended for homemade feline foods include lamb baby food, lamb, rice and rabbit. Lamb, rice, potato, fish, rabbit, venison, various beans and tofu are often recommended for homemade canine foods.

Most of the homemade foods recommended in the AAVD survey for initial management of dogs and cats with suspected food allergy were nutritionally inadequate for growth or adult maintenance (Roudebush and Cowell, 1992). Most homemade foods fail to meet nutritional requirements because they are made from a minimum of ingredients. In general, homemade foods lack a source of calcium, essential fatty acids, certain vitamins and other micronutrients and contain excessive levels of protein, which are contraindicated in food allergy cases.

Feeding nutritionally inadequate homemade foods to dogs less than 12 months of age and cats for more than three weeks may result in clinical problems. Anorexia and poor growth occur in puppies within 10 to 20 days of feeding a thiamin-deficient food (NRC, 2006). Anorexia and emesis occur within one to two weeks after a thiamin-deficient food is fed to cats (NRC, 2006). Many previously recommended homemade elimination foods have a severe inverse calcium-to-phosphorus ratio of 1:10. Skeletal disease in young dogs can occur within four weeks of feeding a food with severe mineral imbalances (Goddard et al, 1970; Morris et al, 1971). Such foods should not be fed for longer than three weeks (Codner and Thatcher, 1990).

This book and other references contain complete and balanced homemade food recipes (Lewis et al, 1987; Remillard and Thatcher, 1989; Meyer, 1990; Roudebush, 1994; Brown et al, 1995; Strombeck, 1999). Non-flavored vitamin and mineral supplements are not perceived as causes of adverse food reactions. Additive-free supplements that do not contain animal or vegetable proteins are unlikely to be sources of ingested allergens. Intolerance to calcium supplements has been reported to occur in atopic children, but is rare (Devlin and David, 1990). Homemade rations should also contain a source of essential fatty acids, such as vegetable oil. Vegetable oils are not a routine source of ingested allergens; studies show that people allergic to

peanuts and soybeans can safely ingest peanut oil or soybean oil (Taylor et al, 1981; Nordlee et al, 1981; Bush et al, 1985; Bock, 1991). Homemade food recipes should provide an optimal amount of protein and foods for cats should be supplemented with taurine.

Assess and Determine the Feeding Method

Feeding method factors to consider include how the food is offered, amount fed, access to other food and who feeds the pet. All of this information should have been gathered when the history of the patient was obtained. If the patient has a normal body condition score (2.5/5 to 3.5/5), the amount of food it was fed previously (energy basis) was probably appropriate. There are two basic phases to the feeding method for patients suspected of having adverse food reactions: the diagnostic phase and the treatment phase.

Diagnostic Phase

PERFORMING AN ELIMINATION TRIAL IN PATIENTS WITH DERMATOLOGIC DISEASE

Before an elimination trial is initiated, the clinician should discuss potential sources of food allergens with the client (**Figure 31-5**). The patient is then fed a controlled elimination food for six to 12 weeks. In addition to the feeding change, no other substances should be ingested including treats, flavored vitamin supplements, chewable medications, fatty acid supplements and chew toys. Flavored chewable medications (e.g., oral heartworm preventive medications) have been proven to cause adverse reactions in dogs and should be changed or discontinued in patients with suspected food allergy or intolerance (Jackson and Hammerberg, 2002a). During the elimination trial, the client should document daily the type and amount of food ingested and the occurrence and character of adverse reactions (**Figure 31-6**). A daily food diary helps document progression of clinical signs during the elimination trial and whether a strict elimination trial was performed in the home environment. The diary will often reveal different findings than those offered to the clinician by the client during the recheck examination.

A tentative diagnosis of an adverse food reaction in dermatologic patients is made if the level of pruritus markedly decreases. This improvement may be gradual and may take four to 12 weeks to become evident. In many cases, concurrent

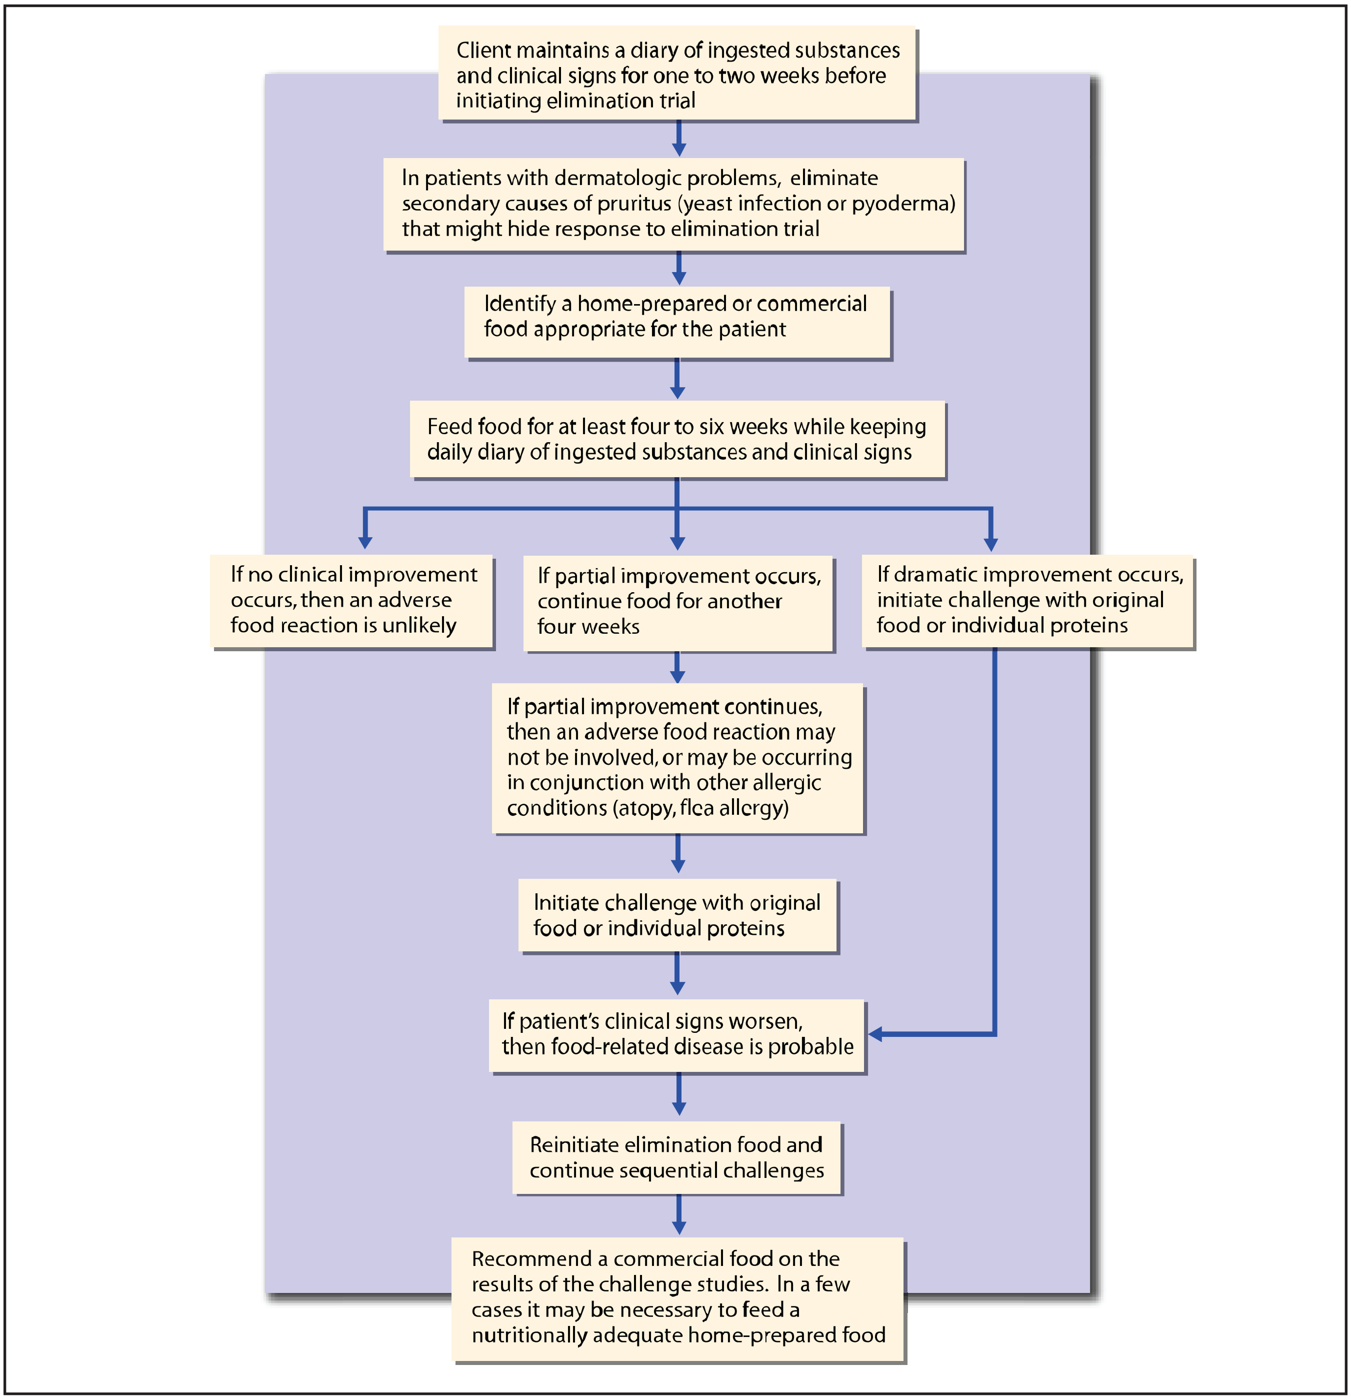

Figure 31-5. Protocol for elimination-challenge trials for the diagnosis of adverse reactions to food.

Malassezia dermatitis, pyoderma and/or otitis externa are present at the time of initial presentation. Treatment for these conditions may be prescribed concurrent with the elimination trial, but after therapy is completed the patient should be fed the elimination food only for two to three weeks before challenge (see below) to ensure that any improvement is maintained. It is also prudent to check that the client is not administering prescribed medications in elicit foods. Patients with chronic otitis externa due to adverse food reactions may require four to six month for obvious improvement to be noted, especially if proliferative lesions are present.

A diagnosis of an adverse food reaction is confirmed if clinical signs reappear after the patient's former food and other ingested substances are offered as a challenge. Clinical signs may be evident within hours of challenge or take up to 14 days. Reinstituting the elimination food should resolve the clinical signs induced by the food challenge. Food challenges can be performed in an "open," "single-blind" or "double-blind" manner. In an open food challenge, both the client and veterinarian are aware that a specific food or previous food is being fed. In a

single-blind food challenge, only the veterinarian is aware of what food is being given. In a double-blind food challenge, neither the client nor veterinarian is aware of whether a specific food is being given. Double-blind, placebo-controlled food challenges are considered to be the "gold standard" for the diagnosis of adverse food reactions in people (Sampson, 1993; Bock, 1991). Only half of human patients thought to be allergic to a food react to the food when challenged in controlled, blinded conditions (Bock, 1991). Unfortunately, all reports and most food challenge recommendations in the veterinary literature have been open challenges. Open challenges will continue as the most practical method of establishing tentative diagnoses of adverse food reaction in dogs and cats, but are subject to false interpretation by clients and veterinarians.

Provocation involves introducing single ingredients until as many positive reactions as possible can be documented. Clients and veterinarians are often reluctant to pursue challenge and provocation after clinical signs have improved or have been eliminated. Provocation may also be difficult to perform in many dogs and cats because commercial pet foods contain large numbers of ingredients and feeding the same ingredients often cannot be duplicated in challenge studies. As an example, use of chicken meat in a provocative food challenge may not duplicate the types or levels of antigens found in poultry by-product meal.

Elimination trials are often difficult to interpret because of concurrent allergic skin disease. In several studies, up to 30% of dogs and cats with adverse food reactions had concurrent hypersensitivities (White, 1986; Carlotti et al, 1990; Rosser, 1993, 1993a; Paterson, 1995; Roudebush and Schick, 1995). These patients may only partially respond to an elimination trial. Flea-allergy and atopic dermatitis triggered by environmental allergens are the most common concurrent diseases and should be eliminated through other diagnostic testing.

PERFORMING AN ELIMINATION TRIAL IN PATIENTS WITH GI DISEASE

Elimination-challenge trial designs for patients with GI disease are similar to those for patients with dermatologic problems. However, shorter elimination periods are usually satisfactory (two to four weeks). One study in cats with GI sensitivity showed that vomiting stopped almost immediately in all affected cats and diarrhea resolved within two or three days (Guilford et al, 2001). In chronic relapsing conditions, the elimination period chosen must be longer than the usual symptom-free period of the patient to allow reliable assessment of how food sensitivity contributes to the patient's signs.

As with skin disease, the degree of clinical improvement during the elimination trial will be 100% only if food sensitivity is the sole cause of the patient's problems. For instance, resolution of allergies acquired as a *result* of GI disease will not eliminate the clinical signs due to the primary GI disease process. A return of GI signs after challenge with the responsible allergen will usually occur within the first three days, but may take as long as seven days, particularly if the responsible allergen was removed from the food for longer than one month (Guilford et al, 2001; Walton, 1967).

Treatment Phase

For most adverse food reactions, avoiding the offending foods or food additives is the most effective treatment. Thus, after a diagnosis of adverse food reaction has been made through the proper use of elimination-challenge trials, the elimination food, if nutritionally complete and balanced, should be fed for maintenance. Ideally, when used for long-term feeding, the food choice should also have appropriate levels of phosphorus and sodium for dogs and cats, and magnesium and the recommended urinary pH range for cats (**Tables 31-5** and **31-6**). An attempt should always be made to find an acceptable commercial food that will increase owner compliance with the feeding change.

REASSESSMENT

How selective or meticulous an avoidance food must be depends on the individual patient's sensitivity. Some dogs and cats may suffer adverse reactions to even trace quantities of an offending food or food additive, whereas others may have a higher tolerance level. Concurrent allergies may influence the threshold level of clinical signs in some patients. Symptomatic therapy for pruritic patients may also include corticosteroids and antihistamines. Corticosteroids along with feeding changes are often used in cats with IBD. One-third of people fed a strict avoidance food for one to two years have tolerated the reintroduction of food allergens (Pastorello et al, 1989). Whether this is the case in dogs and cats is not known.

ACKNOWLEDGMENT

The authors and editors acknowledge the contribution of Dr. Kevin J. Shanley in the previous edition of Small Animal Clinical Nutrition.

Chapter 32

Skin and Hair Disorders

Philip Roudebush
William D. Schoenherr

"Dermatoses affecting various species of animals are more commonly associated with malnutrition than they are with . . . a good state of nutrition."
F. Kral and B.J. Novak, Veterinary Dermatology, 1953

CLINICAL IMPORTANCE

Very little information is available concerning the demographics of canine and feline skin and hair disorders. Surveys and textbooks suggest that skin disorders are the most common reason for patient visits to the veterinarian's office (Scott et al, 2001). Surveys also indicate that 15 to 25% of all small animal practice activity is involved with the diagnosis and treatment of problems with the skin and coat (Scott et al, 1995).

The most commonly diagnosed canine skin disorders are: 1) allergy (flea-bite hypersensitivity, atopic dermatitis), 2) cutaneous neoplasms, 3) bacterial pyoderma, 4) seborrhea, 5) parasitic dermatoses, 6) adverse reactions to food (food hypersensitivity or food intolerance), 7) immune-mediated dermatoses and 8) endocrine dermatoses (Sischo et al, 1989; Scott and Paradis, 1990). The most common feline skin disorders are: 1) abscesses, 2) parasitic dermatoses, 3) allergy (flea-bite hypersensitivity, atopic dermatitis), 4) miliary dermatitis, 5) eosinophilic granuloma complex, 6) fungal infections, 7) adverse reactions to food, 8) psychogenic dermatoses, 9) seborrheic conditions, 10) neoplastic tumors and 11) immune-mediated dermatoses (Scott and Paradis, 1990; Nesbitt, 1982).

Clearly, skin and hair disorders are an important part of small animal practice; bacterial infections, ectoparasitism, allergies, fungal infections and neoplasia are common problems. Aside from adverse reactions to food, nutritional skin diseases in pets fed nutritionally adequate commercial pet food appear to be very uncommon. However, the skin and coat can be affected by many nutritional factors (**Table 32-1**), and many pet owners want to improve the quality and appearance of their pet's coat. The tactile and visual interactions between people and pets are among the greatest pleasures of the companion animal-human bond (Credille et al, 2000). This emphasizes the importance of understanding the nutritional factors that affect normal skin and hair and the nutritional factors that should be investigated in patients with skin disorders. This chapter discusses the nutritional factors that affect skin and hair, except for adverse reactions to food, which are specifically addressed in Chapter 31.

This chapter is divided into two sections: 1) nutrient-deficient dermatoses and 2) fatty acids for inflammatory skin disease. The first section covers dermatoses related to nutrient deficiencies. These deficiencies usually occur when pets in a nutritionally demanding lifestage are fed homemade foods, poor quality commercial foods, commercial foods that contain nutrient excesses or even high quality commercial foods that are inappropriately supplemented. Breed predilection can also be a factor. The second section focuses on the use of antiinflammatory fatty acids in the management of skin diseases that have an inflammatory or pruritic component. These dermatoses are responsive or partially responsive to antiinflammatory intervention. Many commonly diagnosed skin disorders have an inflammatory component.

Table 32-1. Key nutritional factors for foods and supplements for dogs and cats with nutrient-responsive dermatoses.

Factors	Associated conditions	Nutritional recommendations
Protein and fat	Keratinization abnormalities	Avoid protein and energy deficiency
	Loss of normal hair color	Adult maintenance
	Secondary bacterial or yeast infection	Dogs: Protein = 25 to 30% dry matter (DM)
	Impaired wound healing	Fat = 10 to 15% DM
	Decubital ulcers	Cats: Protein = 30 to 45% DM
	Telogen defluxion	Fat = 10 to 15% DM
	Anagen defluxion	Growth/lactation
		Dogs: Protein = 30 to 35% DM
		Fat = 15 to 30% DM
		Cats: Protein = 35 to 50% DM
		Fat = 20 to 35% DM
		Phenylalanine + tyrosine >1.3% DM
		Use a food with DM digestibility >80%
Essential fatty acids (EFA)	Excessive scales (seborrhea sicca)	Avoid fatty acid deficiency
	Alopecia	Dogs: Linoleic acid >1.0% DM
	Dry, dull coat	Cats: Linoleic acid >0.5% DM
	Lack of normal hair growth	Some dogs and cats respond to levels in excess of those listed above
	Erythroderma	Provide adequate levels and availability of zinc, B-complex vitamins and vitamin E to ensure adequate use of EFA
	Interdigital exudation	
Zinc	Alopecia	Avoid zinc deficiency
	Skin ulceration	Dogs: 100 to 200 mg/kg food DM
	Dermatitis	Cats: 50 to 150 mg/kg food DM
	Paronychia	Avoid excess calcium
	Footpad disease	Higher levels of zinc are required in foods with calcium >1.5% DM
	Slow hair growth	Avoid excess copper (copper <200 mg/kg food DM)
	Buccal margin ulceration	Avoid EFA deficiency (see above)
	Hyperkeratotic plaques	Zinc supplementation (Do not give with food)
	Secondary bacterial or yeast infection	Zinc sulfate: 10 mg/kg body weight/day per os
		10 to 15 mg/kg body weight/week IV
		Zinc methionine: 2 mg/kg body weight/day
Copper	Loss of normal color	Avoid copper deficiency
	Dull or rough coat	Dogs: >5 to 10 mg/kg food DM
	Reduced density of hair	Cats: >15 mg/kg food DM
	Alopecia	Avoid excess zinc (zinc <1,000 mg/kg food DM)
		Avoid ingredients that have low copper availability
		Copper oxide
		Liver from simple-stomached mammals
		Avoid excess calcium
		Higher levels of copper are required in foods with calcium >1.5% DM
Vitamin A	Seborrheic skin disease (mainly cocker spaniel breed)	Treatment with retinoids (**Table 32-5**):
		Vitamin A alcohol
	Keratinization disorders	625 to 1,000 U/kg body weight, q24h, per os
	Chin acne	10,000 U q24h, per os (cocker spaniel, miniature schnauzer)
	Nasodigital hyperkeratosis	50,000 U q24h, per os (Labrador retriever)
	Ear margin seborrhea/dermatosis	Tretinoin
	Callus	Apply topically q12 to 24h
	Actinic keratosis	Isotretinoin
	Cutaneous neoplasms	1 to 3 mg/kg body weight, q24h, per os
	Schnauzer comedo syndrome	Acitretin
	Sebaceous adenitis	0.75 to 1.0 mg/kg body weight, q24h, per os
	Lamellar ichthyosis	
Vitamin E	Discoid lupus erythematosus	Treatment with vitamin E:
	Systemic lupus erythematosus	Dogs: 200 to 800 IU twice daily, per os
	Pemphigus erythematosus	
	Sterile panniculitis	
	Acanthosis nigricans	
	Dermatomyositis	
	Ear margin vasculitis	

NUTRIENT-DEFICIENT DERMATOSES

Patient Assessment

History

The signalment (species, breed, age, gender, reproductive status, hair color) is an important part of the historical information that should be obtained for patients with dermatologic problems, especially those with possible nutritional disorders (**Table 32-2**). Both dogs and cats develop nutritionally related skin and hair disorders, although certain conditions such as zinc-responsive dermatoses are best characterized in dogs.

The age of the patient is important; most skin and coat changes due to nutritional deficiencies occur in young growing animals or adult females during gestation and lactation. The requirement for most nutrients is highest during growth and reproduction, which accounts for the increase in nutritionally related skin and hair problems seen during these lifestages. As an example, a biotin-deficient food will cause dermatitis, alopecia, dull fur and achromotrichia when fed to young growing kittens but will not cause similar clinical signs when fed to non-lactating adult cats (Pastoor et al, 1991). Many other examples of nutritional skin diseases exist that occur during periods of increased nutritional demand but do not occur during normal adult lifestages. This age-related phenomenon is complicated by the fact that congenital defects of the integument and certain parasitic, fungal and bacterial infections of the skin are also more common in dogs and cats younger than six months. Gender and reproductive status affect the prevalence of certain skin problems, but they are not usual risk factors in nutritional skin disorders, unless the increased nutritional demands of pregnancy or lactation are present.

The clinician should obtain a complete medical history in all cases. Specific details of the dermatologic history are found elsewhere (Scott et al, 2001). The nutritional history should focus on the adequacy of the specific food for the patient's lifestage, and types and dosages of nutritional supplements. The veterinarian or a veterinary nutritionist should evaluate homemade foods for nutritional adequacy (Chapter 10) because nutrient deficiencies or imbalances are more likely to occur in dogs or cats eating homemade vs. commercial foods. Excessive nutrient levels in food can cause skin disease due to direct toxicosis or interaction/interference with the use of other nutrients in the food.

Table 32-2. Breed predilection for non-neoplastic skin diseases often managed by food changes or supplementation.*

Breed	Disease
Airedale terrier	Atopic dermatitis
Akita	Sebaceous adenitis
Basenji	Atopic dermatitis
Basset hound	Atopic dermatitis
Beagle	Atopic dermatitis
Boston terrier	Atopic dermatitis
Boxer	Adverse reactions to food
	Atopic dermatitis
Bull terrier	Acrodermatitis
	Atopic dermatitis
	Zinc-responsive dermatosis
Chesapeake Bay retriever	Atopic dermatitis
Dalmatian	Atopic dermatitis
English bulldog	Atopic dermatitis
German shepherd dog	Adverse reactions to food
	Atopic dermatitis
	Seborrhea, primary
Golden retriever	Atopic dermatitis
Gordon setter	Atopic dermatitis
Irish setter	Atopic dermatitis
	Seborrhea, primary
Labrador retriever	Adverse reactions to food
	Atopic dermatitis
	Seborrhea, primary
Lhasa apso	Atopic dermatitis
Malamute	Zinc-responsive dermatosis
Old English sheepdog	Atopic dermatitis
Poodle, standard	Sebaceous adenitis
Pug	Atopic dermatitis
Schnauzer, miniature	Atopic dermatitis
Shar Pei	Adverse reactions to food
	Atopic dermatitis
Shih Tzu	Atopic dermatitis
Siberian husky	Zinc-responsive dermatosis
Spaniels	Adverse reactions to food
	Atopic dermatitis (American cocker)
	Seborrhea, primary
Terriers	Atopic dermatitis
Vizsla	Sebaceous adenitis

*Atopic dermatitis is often managed with fatty acid supplementation, sebaceous adenitis and primary seborrhea with retinoid supplementation, zinc-responsive dermatosis with zinc supplementation and adverse reactions to food with dietary changes. Specific nutrient deficiencies are usually not breed-specific.

Physical Examination

A comprehensive physical examination that evaluates all body systems should be performed on patients with skin or hair disease. Internal disease is often manifested as skin and coat disease, and this diagnostic possibility should not be overlooked by concentrating on the integumentary changes alone.

The skin can be affected by many nutritional factors, but usually responds in a limited number of ways. The cutaneous changes associated with nutritional abnormalities are often indistinguishable from those caused by other more common skin diseases. Changes that raise the suspicion for nutritional abnormalities include: 1) a sparse, dry, dull and brittle coat with hairs that epilate easily, 2) slow hair growth or regrowth from areas that have been clipped, 3) abnormal scale accumulation (seborrhea sicca), 4) loss of hair, erythema or crusting in areas of friction or stretch such as the distal extremities, 5) decubital ulcers and poor wound healing and 6) loss of normal hair color. Primary lesions such as papules and pustules rarely occur with nutritional abnormalities, but can occur with bacterial pyoderma secondary to nutritional, allergic or other underlying problems.

Laboratory and Other Clinical Information

Common laboratory evaluations including a complete blood count, serum biochemistry profile, urinalysis and thyroid panel are rarely helpful in evaluating nutritional skin disease. However, these tests can be used to rule out internal or metabolic diseases as causes of cutaneous problems.

Routine laboratory procedures for patients with dermatologic problems include skin scrapings for parasites, hair examination, cytologic examination of tissue or fluids, fungal culture, bacterial culture and biopsy for dermatohistopathologic examination. Of these procedures, hair examination and dermatohistopathology are most helpful for evaluation of potential nutritional problems.

HAIR EXAMINATION

Plucking hairs from the skin and examining them microscopically is termed trichography. This procedure helps diagnose a number of conditions including nutritional diseases. Trichography is performed by grasping a small number of

Box 32-1. The Hair Cycle.

HAIR FOLLICLE STRUCTURE

Most omnivores and herbivores have "simple" hair follicles, which means that each infundibulum contains a single hair shaft. In contrast, dogs, cats and carnivores have "compound" hair follicles, where multiple follicles grow closely together and share a common infundibulum; multiple hairs exit through a common opening. By convention, the largest hairs in a compound follicle are called primary or guard hairs and the smaller hairs that make up the majority of the hair shafts in a compound follicle are called secondary or undercoat hairs. There is a distinct orientation of primary and secondary hairs. Primary hairs are always the most cranial (toward the head) with secondary hairs caudal (toward the rear) of the primary hairs. The secondary hairs that are closest to the primary hairs are the largest and become progressively smaller the more caudally they are positioned. In this way, hair follicles are designed so that hairs will lie down smoothly, with guard hairs on top of the fine undercoat. The ratio of secondary to primary hairs can be greater than 10 to 1.

THE HAIR CYCLE

The growth of hair is cyclical and each cycle consists of an active growth phase (anagen), a transitional involutionary phase between active and no growth (catagen) and a stage of senescence (telogen), during which hair is retained in the follicle. The length of time required to complete the hair cycle varies between different species and is different among dog breeds. In human scalp hair, anagen is the longest phase of the cycle; thus, hair grows almost constantly. In most mammals, the hair cycle is telogen based; hairs grow to a predetermined length and then enter a long period of inactivity during which the telogen hair follicle firmly retains the hair shaft. Most dogs and cats appear to have telogen-dominant hair cycles in which the hair shafts are retained in telogen follicles for long periods of time. How long the follicle remains in telogen appears to be a breed-specific phenomenon. Some breeds of dogs, such as poodles and schnauzers, have anagen-dominant hair cycles with hair that grows almost constantly. Hair follicles have an intrinsic rhythm that can be altered by intrinsic (local growth factors, cytokines) and extrinsic (photoperiod, hormones, nutrition) factors.

One theory for why many canine breeds have such a long telogen phase is conservation of energy and protein required for active hair growth. For example, Nordic breeds appear to have a longer telogen phase than other canine breeds. They need a thick coat to provide insulation during cold weather and conserve the energy and protein needed to grow hair during the winter months when food may be more difficult to obtain. These breeds may benefit from maintaining hair in a state of "suspended animation." Preliminary studies have been conducted on the nutritional effects on canine hair follicles of various breeds. Further studies are needed to document how nutrition might influence hair follicle function, the hair cycle of various breeds and shedding.

The Bibliography for **Box 32-1** can be found at www.markmorris.org.

hairs with the fingertips or hemostats, pulling them out completely, placing them on a microscope slide, adding mineral oil and examining them with the low-power objective of the microscope. One study evaluated the impact of anatomic location on trichogram analysis. Results of this study indicated that the shoulder was the site of choice for plucking hair (Diaz et al, 2004).

The hair bulbs are examined first. Hairs do not grow continuously but rather in cycles. Each cycle consists of a growing period (anagen), during which the follicle is actively growing hair, a transitional period (catagen) and a resting period (telogen), during which the hair is retained in the follicle as a dead or club hair that is subsequently lost (Scott et al, 2001). More details about hair follicles and normal hair-growth cycles can be found in **Box 32-1**. Anagen hair bulbs are rounded, smooth, shiny, glistening, often pigmented and soft, so the root may bend. In some cases, the end of the anagen bulb is tightly attached to the dermal papilla and when plucked the hair appears squared at the tip with a slight flair (i.e., like a "pant's leg"). Telogen bulbs are club- or spear-shaped, rough-surfaced, nonpigmented and generally straight. Normal adult dogs and cats have a mixture of anagen and telogen hairs, the ratio of which varies with the season and other factors. Estimation of the ratio of anagen to telogen hair bulbs can be useful. All the hair of normal patients should not be in telogen; this finding suggests a diagnosis of telogen defluxion or follicular arrest. Inappropriate numbers of telogen hairs (e.g., mostly telogen hairs during the summer when the ratio should be about 50:50) suggest a diagnosis of nutritional, endocrine or metabolic disease (Scott et al, 2001). In people, the ratio of telogen to anagen hair increases with prolonged protein deficiency (Bradfield et al, 1967). Unfortunately, well-established normal trichogram values are not available in veterinary medicine, limiting their usefulness. The use of site, age, breed and climate matched controls, if possible, may increase the usefulness of this diagnostic procedure.

Examination of the hair shaft follows bulbar examination. A normal hair shaft is uniform in diameter and tapers gently to the tip. The hairs may be straight or twisted depending on the coat type of the patient. All hairs should have a clearly discernible cuticle, and a sharply demarcated cortex and medulla. Hair pigmentation depends on coat color and breed. Hairs that are inappropriately curled, misshapen and malformed suggest an underlying nutritional or metabolic disease (Scott et al, 2001). When unusual pigmentation is observed, external sources (salivary staining, chemicals, topical medications), nutritional disorders, color dilution/color mutant disorders and endocrine disorders should be considered (Scott et al, 2001).

Hairs with a normal shaft that are suddenly and cleanly broken indicate external trauma from licking, scratching or groom-

ing. Breakage of hairs with abnormal shafts suggests nutritional disorders, dermatophytosis or congenitohereditary disorders such as color dilution alopecia. Morphologic changes in the hair bulb and hair diameter are sensitive indicators of overall protein status. Hair bulb atrophy, constriction and hair depigmentation may be seen in people after as little as two weeks of protein deprivation (Bradfield et al, 1967). Protein deprivation may not produce changes as rapidly in dog and cat hair because the hair in these species spends more time in telogen and less time in anagen.

BIOPSY AND DERMATOHISTOPATHOLOGY

The following are general guidelines for when a skin biopsy should be performed: 1) all obviously neoplastic or suspected neoplastic lesions, 2) all persistent ulcerations, 3) any case involving a major disease that is most readily diagnosed by biopsy (e.g., immune-mediated skin disease), 4) a dermatosis that is unresponsive to conventional therapy, 5) any unusual or serious dermatosis and 6) vesicular dermatitis. Some nutritional skin diseases, such as zinc-responsive dermatosis, have clearly delineated histopathologic lesions that are easily recognized during microscopic examination of a skin biopsy specimen. In general, the skin should be biopsied within three weeks for any dermatosis that does not respond to appropriate therapy. This includes those dermatoses that do not respond to initial management with a food change or supplementation.

CHEMICAL COMPOSITION OF HAIR

Some investigators and clinicians have advocated the use of chemical analysis of hair as a useful diagnostic technique. Hair is a complex tissue consisting of several morphologic components (epicuticle, exocuticle, endocuticle, medulla); each component has a different chemical composition. Genetic factors, nutrition, environmental effects and cosmetic treatment affect the chemical composition of hair (Robbins, 1988; Stafforst, 1982; Mundt and Stafforst, 1987). These complex factors and the expense of analysis make it unlikely that chemical composition of hair will be routinely useful as a diagnostic technique.

Hair, depending on its moisture content, consists of 65 to 95% protein. The remaining constituents are water, lipids, pigment and trace elements. The amount of moisture in hair plays a critical role in its physical and cosmetic properties. Moisture of hair often depends on relative humidity; as relative humidity increases from 29 to 70%, the approximate moisture content of hair increases from 6 to 14% (Robbins, 1988).

Hair consists of surface (external) lipid and internal lipid. In addition, part of the internal lipid is free lipid and part is structural lipid of the cell membrane complex. Skin surface lipids of cats and dogs contain more sterol esters, free cholesterol esters and diester waxes, but fewer triglycerides, monoglycerides, free fatty acids, monoester waxes and squalene than do skin surface lipids of people (Scott et al, 2001; Dunstan et al, 2000; Watson, 2003). It has been suggested that the skin surface lipids of cats and dogs are mainly of epidermal origin, whereas those of people are mainly of sebaceous gland origin (Scott et al, 2001).

Hair generally has very low mineral content (less than 1%), and it is difficult to determine whether this inorganic matter is derived from extraneous sources or whether it arises during fiber synthesis. Hair length and pigmentation intensity have been reported to affect concentrations of zinc and other trace elements, as well as certain macro elements, in canine hair (Stafforst, 1982; Mundt and Stafforst, 1987). Zinc and copper concentrations in hair from normal cats have also been documented (van den Broek et al, 1992).

SKIN AND HAIR BIOPHYSICAL PARAMETERS

Several studies have evaluated typical skin and hair biophysical parameters in cats and dogs such as skin pH, thickness, hydration, elasticity, transepidermal water loss, coat thickness, hair regrowth and hair length. These parameters are used most often in research studies and are not yet available for routine clinical practice. The skin and hair biophysical parameters measured to date differ widely according to breed, gender, gonadal status and age of the animal, as well as, the season of the year, limiting their routine use (Young et al, 2003; Schroeder et al, 2003; Watson et al, 2001, 2002; Cline et al, 2003; Matousek and Campbell, 2002; Hester et al, 2003; Bourdeau et al, 2004, 2004a; Diaz et al, 2003). Various nutritional studies using these parameters have been published or reported and are described below.

Risk Factors for Nutritionally Related Skin Disease

Genotype, lifestage, food type and food supplementation are risk factors for nutritionally related skin disease. Breed predilection determines the prevalence of some skin disorders. Tables of common skin diseases categorized by breed are readily available (**Table 32-2**). In general, more than 30 canine breeds are at increased risk for skin diseases (Ihrke and Franti, 1985). The nutrient-sensitive skin diseases such as zinc-responsive dermatoses and retinoid-responsive dermatoses often occur in specific breeds. As an example, one form of zinc-responsive dermatosis is frequently seen in arctic-type breeds such as malamutes and Siberian husky dogs.

As mentioned before, nutrient deficiencies that cause skin disease are more likely to occur during growth, gestation, lactation and illness when nutritional requirements are highest.

Some dry, commercial, generic, private label brand and grocery pet foods have lower fat content, lower nutrient digestibility and higher mineral content than other grocery and specialty brands. Low amounts of fat and poor-quality fat are risk factors for essential fatty acid (EFA) deficiency; poor nutrient digestibility contributes to protein-energy malnutrition, especially during growth and lactation; and high levels of minerals such as calcium inhibit the absorption of nutrients such as zinc, which are essential for normal, healthy skin.

A pet that obtains most of its nutrients from homemade foods is at increased risk for several nutritional problems (Chapter 10). In general, homemade foods are more likely to lack adequate calcium, EFA, certain vitamins and other micronutrients (Roudebush and Cowell, 1992). Homemade foods should include: 1) a calcium source such as bone meal,

Box 32-2. Red Coat Syndrome.

The quantity and type of melanin pigments synthesized by follicular melanocytes and deposited in keratinocytes are the prime determinant of mammalian hair color. Hair or fur color is genetically controlled but can be affected by various extrinsic factors, including nutrition. The two melanin pigments, eumelanin and phaeomelanin, are synthesized from a common precursor, dopaquinone, which is a product of tyrosine oxidation.

Reports from breeders and pet owners have identified some cats and dogs that have had their coat change from black to a reddish-brown color or have had hair stripes become less noticeable. Controlled studies in cats and dogs suggest that dietary deficiency of the amino acid tyrosine or its precursor phenylalanine is a significant factor causing black hair to change to a reddish-brown color. When tyrosine is limiting, there is insufficient dopaquinone for full expression of eumelanin formation and the yellow to reddish-brown phaeomelanin is the predominant pigment observed.

Tyrosine has not been regarded as an essential amino acid because phenylalanine is metabolized to tyrosine in all mammals and can supply the total tyrosine needs. Tyrosine contributes to the total aromatic amino acid (phenylalanine plus tyrosine) requirement and can spare about half the phenylalanine requirement. This appears to be a unique situation in which the need for a dispensable amino acid to support maximal melanin synthesis in cats and dogs is much greater than that required for nitrogen balance or maximal growth. Dietary phenylalanine plus tyrosine levels greater than 2% dry matter or addition of L-tyrosine to the food should provide optimal amino acid levels for maximal melanin synthesis in cats and dogs.

The Bibliography for **Box 32-2** can be found at www.markmorris.org.

oyster shell or dicalcium phosphate, 2) a source of EFA such as corn oil, safflower oil or some other vegetable oil and 3) a multivitamin-trace mineral supplement. Also, homemade cat foods should be supplemented with taurine. The final risk factor for nutritionally related skin disease is oversupplementation using naturally occurring foods or commercial supplements. Vitamin A toxicosis is associated with excessive use of liver as a supplement. High levels of minerals such as calcium in commercial supplements can interfere with absorption of essential trace elements such as zinc.

The Skin as a Metabolic Organ

The skin is the largest organ of the body and the anatomic and physiologic barrier between the animal and its environment. The skin protects against water loss and physical, chemical and microbiologic injuries while its sensory components perceive heat, cold, pain, touch, pruritus and pressure (Scott et al, 2001). In addition, the skin is contiguous with several internal organs and may reflect internal pathologic processes. The subcutis, skin and hair of a newborn puppy represent 24% of its body weight, which decreases in some breeds to only 12 to 14% of mature body weight (Miller et al, 1964).

The skin and coat significantly influence nutrient requirements. The ability of an animal's coat to regulate body temperature and energy requirements in cold environments correlates closely with hair length, thickness and density and with the medullation of individual hair fibers. In general, coats composed of long, fine, poorly medullated fibers are the most efficient for thermal insulation at low environmental temperatures and thus help modulate energy requirements. The skin also influences water requirements by minimizing transepidermal moisture loss. Loss of this normal barrier function as a result of fatty acid deficiency can increase a patient's water requirement, which is clinically manifested as polydipsia (Burr and Burr, 1929, 1930; Basnayake and Sinclair, 1956).

The hair cycle, and thus the coat, is influenced by the general state of health, genetics, photoperiod, ambient temperature, hormones, nutrition and poorly understood intrinsic factors (Scott et al, 2001; Scott, 1990). **Box 32-1** provides more details.

Dog breeds can be classified as having high, moderate and low weights of hair. Longhaired breeds with relatively large body surface areas per body weight, such as Pomeranians, have the largest relative amount of hair. Estimates indicate that as much as 30% of protein in food is needed to maintain daily hair growth in small breeds with long coats (Stafforst, 1982; Mundt and Stafforst, 1987). On the other hand, larger dogs with short coats may use less than 10% of food protein to maintain daily hair growth (Stafforst, 1982; Mundt and Stafforst, 1987). Whether dogs of similar body surface areas have different requirements for protein and other nutrients based solely on their type of coat is unknown, but of possible clinical significance. For example, there may be differences in nutrient requirements during peak hair growth for a Pomeranian vs. a Chihuahua or an Old English sheepdog vs. a German shorthaired pointer based on coat type alone.

The epidermis has a renewable cell population. Keratinocytes migrate from the mitotically active pool in the basal layer of the epidermis, through the spinous layer and granular layer, and finally into the superficial stratum corneum, followed by normal exfoliation. The normal canine epidermis has a very slowly renewing cell population. Only 1.5% of epidermal basal cells undergo DNA replication at any point in time (Kwochka and Rademakers, 1989; Kwochka, 1990, 1991). In dogs, it takes approximately 22 days for cells to migrate from the basal layer to, but not through, the stratum corneum.

The upper external root sheath of the hair follicle and sebaceous gland have essentially the same cell kinetic growth characteristics as the surface epidermis (Kwochka and Rademakers, 1989; Kwochka, 1990, 1991). Conversely, the root matrix of anagen hairs is one of the most rapidly renewing cell populations of the body (Kwochka, 1990). In actively growing hair, up to 24% of cells are undergoing DNA replication.

Key Nutritional Factors

The key nutritional factors for foods and nutritional supplements and the recommended amounts and doses for dogs and cats with nutrient deficiency dermatologic problems are sum-

marized in **Table 32-1** and discussed in more detail below.

PROTEIN AND FAT

As mentioned previously, the integument is a metabolically active organ that is affected by the nutritional status of the animal. Protein and energy are required for the development of new hair and skin; fat is the most concentrated source of dietary energy. Developing hair requires sulfur-containing and other amino acids. Therefore, for normal skin and hair, it is important for the pet's food to provide optimal protein quantity, quality (appropriate levels of essential amino acids) and digestibility. Dogs and cats have increased protein and energy requirements during growth, gestation, lactation and some illnesses. Abnormal skin and hair will often be noted if nutritionally inadequate foods are fed during these stages (Ralston Purina Company, 1987; Huber et al, 1991). Key nutritional factor profiles for various lifestages of dogs and cats are listed in Chapters 13 through 24. Optimal levels of protein and fat, and minimum dry matter (DM) digestibility of foods for dogs and cats with skin and hair disorders are listed in **Table 32-1**.

Foods inadequate in protein and energy can cause keratinization abnormalities, depigmentation of hair and changes in epidermal and sebaceous lipids (**Box 32-2**). The skin loses its protective barrier function in patients with protein-energy malnutrition and becomes more susceptible to secondary bacterial or yeast infection. Impaired wound healing and decubital ulcers are also sequelae to protein-energy malnutrition. Protein-deficient dogs and cats have patchy alopecia and coats that are dry, dull and brittle.

Telogen defluxion is usually recognized as hair loss associated with a stressful event (e.g., pregnancy, severe illness, surgery) that causes the abrupt, premature cessation of growth of many anagen hair follicles and the synchronization of these hair follicles in catagen, then in telogen (Scott et al, 2001; Harvey, 1994). Short-term increased requirements of energy, protein and other nutrients during growth, gestation, lactation and illness may cause telogen defluxion if appropriate nutritional changes are not instituted. Bitches and queens in late gestation and lactation, and growing puppies and kittens are at risk unless they are fed nutritionally balanced, highly digestible foods that meet their increased nutritional requirements.

Anagen defluxion is a sudden loss of hair due to an unusual event (e.g., antimitotic drugs, infectious disease, metabolic disease) that interferes with anagen, resulting in abnormalities of hair follicles and shafts. Patients suffering from the stress of illness, injury and surgery often require increased amounts of energy, protein, specific amino acids and other nutrients. Patients with severe illness that do not receive adequate nutritional support are at risk for telogen defluxion, anagen defluxion or other coat abnormalities.

Dogs with severe primary seborrhea may have increased protein and other nutrient requirements. The calculated epidermal cell renewal time is approximately seven to eight days for dogs with primary seborrhea (Kwochka and Rademakers, 1990; Baker and Maibach, 1987). The hyperproliferative nature of the skin of dogs with primary seborrhea, with at least a threefold increase in epidermal cell renewal, may change the nutrient requirements of these dogs. However, no studies to date have evaluated the specific nutrient requirements of dogs with severe primary seborrhea vs. age- and breed-matched controls. Some authors suggest that primary seborrhea worsens greatly in dogs with nutritional inadequacies (Scott et al, 1995). Dogs with severe deep pyoderma secondary to generalized demodicosis or other underlying diseases may have increased nutrient requirements above those found in the normal adult animal.

Metabolic Epidermal Necrosis

Metabolic epidermal necrosis is a rare cutaneous disease that in most cases is a marker for a serious underlying metabolic disorder. In dogs, this syndrome has findings similar to those of necrolytic migratory erythema of people and has also been termed hepatocutaneous syndrome or superficial necrolytic dermatitis. Clinical features include crusting acral dermatopathy with erosions around the mouth, eyes, legs, feet and genitalia (Scott et al, 2001; Angarano, 1993). Hyperkeratosis, ulceration of footpads or both conditions is also prominent. The cutaneous syndrome is typically diagnosed in older dogs and is often associated with hepatic cirrhosis, other hepatopathies, diabetes mellitus, hyperadrenocorticism, and rarely, glucagon-secreting pancreatic tumors. Metabolic changes often include carbohydrate intolerance and marked hypoaminoacidemia (Outerbridge et al, 2002).

Specific treatment is aimed at correcting the underlying metabolic disease. Unfortunately, most cases are associated with irreversible chronic liver disease and hepatic cirrhosis (Chapter 68). Symptomatic treatment includes antimicrobials for secondary infections, insulin therapy as needed for diabetes mellitus, hydrotherapy to help remove crusts and lessen pruritus and glucocorticoids. Treatment of hypoaminoacidemia may reverse the skin lesions. Anecdotal reports suggest that foods for repletion/recovery containing moderate protein levels (Prescription Diet a/d Canine/Feline[a]), zinc, egg yolks or intravenous administration of crystalline amino acid solutions will reverse the skin lesions in some patients.[b,c] A review of 36 canine cases showed that dogs responded better to therapy with intravenous amino acid infusions rather than oral protein hyperalimentation (Outerbridge et al, 2002).

ESSENTIAL FATTY ACIDS

Functions in the Skin

EFA are polyunsaturated fatty acids (PUFA) derived from and including the parent EFA, cis-linoleic acid (LA) and α-linolenic acid (ALA). **Figure 32-1** summarizes the metabolic pathway of EFA. The skin of adult mice, guinea pigs and presumably other animals lacks Δ-6-desaturase and Δ-5-desaturase activity (Chapkin et al, 1987). Thus, the epidermis depends on food to supply EFA or the continuous formation of γ-linolenic acid (GLA), arachidonic acid (AA) and eicosapentaenoic acid (EPA) by the liver, with subsequent transportation to the skin by the blood (Chapkin et al, 1987; Horrobin, 1989; Campbell, 1990).

In the skin, EFA are principally found in phospholipids, and

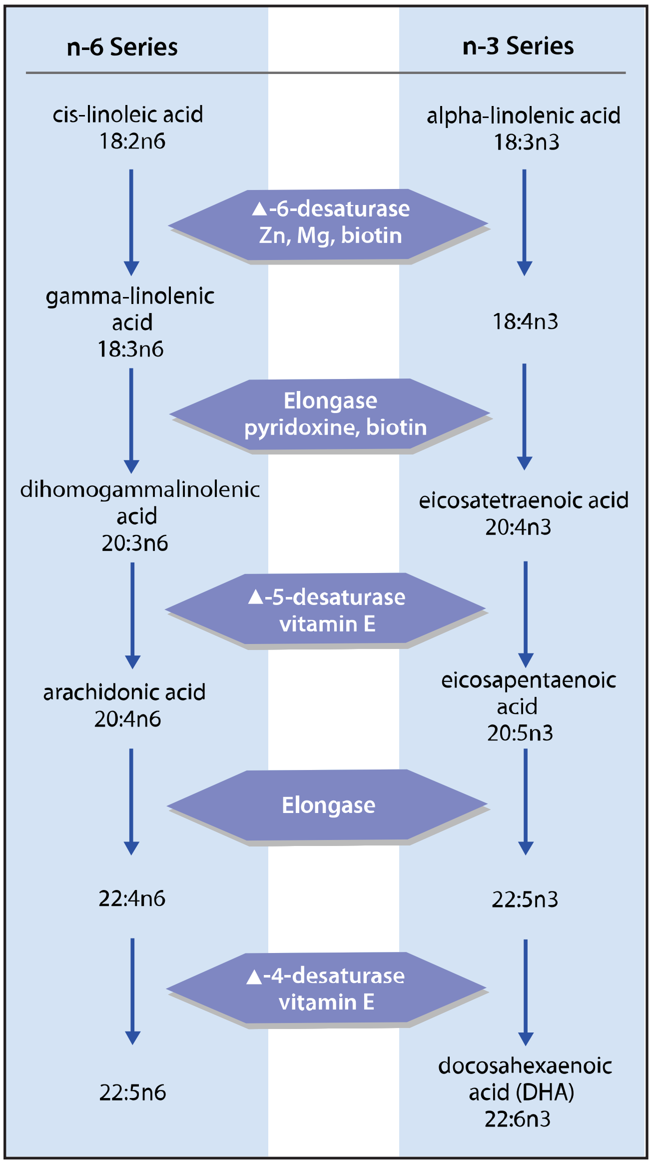

Figure 32-1. Diagram of metabolic pathways for essential fatty acids.

so have an accepted structural function in the lipoproteins of cell membranes. The high degree of unsaturation of EFA bestows fluidity to these structures at physiologic temperatures, allowing conformational changes to occur (Prottey, 1976). One of the most important skin-related functions of EFA is the incorporation of LA into the ceramides of the lipid portion of the epidermal cornified envelope. This envelope serves an essential barrier function to prevent loss of water and other nutrients. EFA are a source of energy for the skin and serve as precursors to a variety of potent, short-lived molecules including prostaglandins (PG), leukotrienes (LT) and their metabolites.

Essential Fatty Acid Deficiency

When mammals are deprived of fats, among other things, they develop characteristic signs of EFA deficiency. The existence of EFA was first recognized when rats deprived of fat had poor weight gain, increased water intake, necrosis of the tail and scaly skin (Burr and Burr, 1929, 1930). The skin scaliness was exacerbated by low ambient humidity or restricted access to water. The increased water intake was later linked to increased transepidermal water loss (Basnayake and Sinclair, 1956). When newly weaned rats were fed foods devoid of EFA, LA and AA levels in the skin rapidly declined (Basnayake and Sinclair, 1956). After five weeks, these acids were virtually absent from the skin, weight loss and increased water intake ensued and scaly skin developed. After 10 weeks, the rate of transepidermal water loss began to increase rapidly to values about 10 times those of normal rats. Growth stunting caused by EFA deficiency is predominantly due to the increase in thermogenesis required to counter heat loss from accelerated transepidermal water evaporation (Phinney et al, 1993).

Cutaneous changes have been described in fatty acid deficiency in dogs (Hansen and Weise, 1951) and cats (Frankel and Rivers, 1978). These cutaneous abnormalities include scaliness (seborrhea sicca), matting of hair, loss of skin elasticity, alopecia, a dry and dull coat, erythroderma, hyperkeratosis, epidermal peeling, interdigital exudation, otitis externa and lack of hair regrowth following plucking. These changes are associated with epidermal and dermal metabolic effects leading to: 1) increased transepidermal water loss, 2) increased epidermal cell turnover, 3) sebaceous gland hypertrophy, 4) increased sebum viscosity, 5) poor wound healing, 6) increased susceptibility to infection and 7) weakening of cutaneous capillaries.

Dogs with cutaneous abnormalities due to low-fat foods have lower levels of fatty acids in serum, skin, liver, kidneys and heart muscle than do animals with healthy skin (Hansen and Weise, 1951). Cats fed an EFA-deficient food developed moderate seborrhea sicca and mild hair loss after six months (MacDonald et al, 1984). Severe seborrhea sicca with large scales developed in EFA-deficient cats when the environmental relative humidity decreased from approximately 75 to 55% (MacDonald et al, 1984). Hair loss is extensive and stroking causes clumps of hair to epilate.

Deficiency of other nutrients, particularly zinc (Ohlen and Scott, 1986), vitamin E (Scott and Sheffy, 1987) and pyridoxine (Cunnane et al, 1984) can cause clinical signs similar to those caused by experimental EFA deficiency. EFA intake influences the requirement of these nutrients. In rodents, clinical signs of zinc deficiency can be largely prevented by EFA supplementation (Cunnane and Horrobin, 1980).

Fatty acid deficiency is rapidly reversible if EFA are introduced orally, parenterally or topically. Various abnormal cutaneous parameters of dogs (Hansen and Weise, 1951) and cats (Frankel and Rivers, 1978; MacDonald et al, 1984) are restored within a few days by LA supplementation.

Supplementation with EFA will increase fatty acid levels in serum of dogs (Campbell et al, 1992; Campbell and Roudebush, 1995) and cats (MacDonald et al, 1984), and in the skin of normal and seborrheic dogs (Campbell et al, 1992; Campbell and Roudebush, 1995; Rees et al, 2001; Marsh et al, 2000). Optimal food levels of EFA for normal dogs and cats

and those with skin and hair disorders are listed in **Table 32-1**.

Use of Fatty Acids for Seborrhea

Fats and fatty acids have been recommended for many years as supplements to improve the sheen and luster of hair. In the past, animal and vegetable sources of fat were recommended to improve coat quality.

Dogs with seborrhea have abnormally low cutaneous levels of LA and increased cutaneous levels of oleic acid (Campbell et al, 1992). These low cutaneous levels are found despite normal food and serum fatty acid concentrations. Following supplementation for 30 days with a vegetable oil high in LA (sunflower oil), the cutaneous fatty acid concentrations return to near normal and clinical signs of seborrhea improve. The clinical signs of seborrhea in dogs may be partly attributable to a localized deficiency of LA, elevated levels of AA in the skin or both (Campbell et al, 1992). However, one study noted no significant differences in the serum and skin fatty acid profiles of normal and a small number of seborrheic dogs (White, 1990).

Seborrhea sicca is also associated with increased transepidermal water loss, which can be reversed with cutaneous administration of vegetable oils rich in LA (Campbell and Kirkwood, 1993). Supplementing food with ALA can also decrease transepidermal water loss (Campbell and Roudebush, 1995). Dietary supplementation with EFA also appears to improve skin and coat condition in normal animals consuming otherwise complete and balanced commercial pet foods (Rees et al, 2001; Marsh et al, 2000).

Antiinflammatory Fatty Acids

See the Fatty Acids for Inflammatory Skin Disease section below.

MINERALS

Minerals in food interact with one another (**Figure 32-2**) and this interaction must be kept in mind when assessing integumentary problems that might be associated with certain homemade foods, commercial foods or nutritional supplements. Skin manifestations of mineral imbalances are seen most commonly with primary (nutritional inadequacy) or secondary (nutrient interaction) deficiencies of copper and zinc.

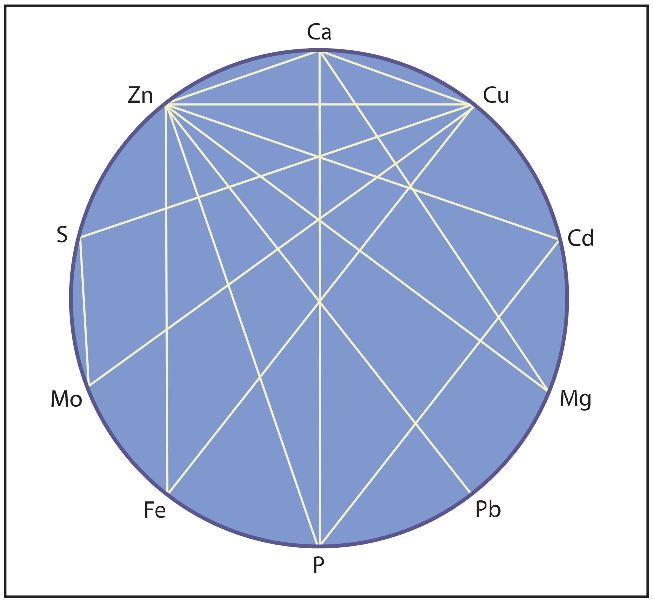

Figure 32-2. Diagram of clinically important mineral interactions in patients with cutaneous disease.

Copper

Copper is an essential trace element of all plant and animal cells (Brewer, 1987). Copper is involved in various biologic functions, primarily as a component of storage and transport proteins and cuproenzymes. One of the enzymes is lysyl oxidase, which is required for maturation of connective tissue and the cross-linking of aldehydes in collagen and elastin (Brewer, 1987). Copper-containing enzymes also catalyze the conversion of carotene to retinal, the formation of keratin from prekeratin and the biosynthesis of melanin from L-tyrosine.

Cutaneous manifestations of copper deficiency include achromotrichia or loss of normal hair coloration, reduced density or lack of hair and a dull or rough coat. Pigmented hair on the head and face loses its normal color, develops a "washed out" appearance and becomes gray (Zentek and Meyer, 1991; Morris and Rogers, 1995; van den Broek and Thoday, 1986). This change may extend over the entire body (Ralston Purina Company, 1987; Morris and Rogers, 1995). In dogs and cats with cutaneous manifestations of copper deficiency, copper concentrations are significantly reduced in plasma, hair, liver, kidney and heart muscle (Zentek and Meyer, 1991; Morris and Rogers, 1995; van den Broek and Thoday, 1986). Copper deficiency is seen most commonly in young puppies and kittens.

Dogs and cats can develop copper deficiency due to: 1) inadequate copper in food, 2) poor availability of copper in food or 3) an excess of competing minerals. Zinc, in particular, can adversely affect copper homeostasis. Zinc is thought to inhibit copper absorption by its action on intestinal metallothioneins, which sequester copper in the intestinal epithelial cells and make copper unavailable for use elsewhere in the body (Fosmire, 1990). The greater the intake of zinc and the lower the intake of copper (absolute or relative), the greater the potential for copper sequestration and ultimately, copper deficiency. Studies involving people and foals have shown increased nutritional copper requirements as the amount of zinc in the food increases (Fosmire, 1990; Bridges and Moffitt, 1990). Optimal levels of copper in foods for dogs and cats with skin and hair disorders are listed in **Table 32-1**.

Copper availability varies widely among feed ingredients (Aoyagi et al, 1993). Copper availability is relatively high in poultry by-product meal, avian liver (chicken and turkey) and ruminant liver (beef and sheep); copper from soybean meal and corn gluten meal is moderately available; copper from monogastric mammalian liver (pork and rat) and copper oxide is poorly available (Morris and Rogers, 1995; Aoyagi et al, 1993; Aoyagi and Baker, 1993; Czarnecki-Mauldin et al, 1993). Risk factors for copper deficiency in dogs and cats include: 1) rapid

Zinc

Zinc Deficiency

Zinc is an important cofactor of numerous metalloenzymes and modulator of many critical biologic functions. Numerous reports have linked zinc deficiency to many dermatoses in dogs and cats.

Zinc deficiency in animals has been well documented through experiments in numerous species including dogs and cats. Investigators reported decreases in plasma zinc concentrations, a dull and rough coat and skin lesions on the abdomen and hind limbs after feeding a calcium-supplemented, zinc-deficient, corn-soy food to dogs (Robertson and Burns, 1963). Another study documented the progressive development of cutaneous lesions when young puppies were fed a corn-soy, zinc-deficient food (Sanecki et al, 1982). Puppies developed alopecia, skin ulceration, dermatitis, parakeratotic hyperkeratosis, follicular hyperkeratosis and generalized acanthosis similar to lesions described in other animals with zinc deficiency (Sanecki et al, 1982). These changes were prominent in areas of contact and trauma (footpads), areas of stretch (skin over joints), areas of friction (axillae, groin), distal extremities and tail, mucocutaneous junctions and ear canals. The feet were severely affected with paronychia and fissured, cracked and focally eroded footpads. The cutaneous lesions were completely reversible within six weeks of adding zinc to the food.

Dogs fed a zinc-deficient food developed skin lesions, which improved dramatically within 72 hours of adding zinc to the food (Banta, 1989). A study in kittens fed a zinc-deficient food described poor coats characterized by hair thinning, slow hair growth, scaliness and buccal margin ulcerations (Kane et al, 1981).

Studies in rodents demonstrated the close linkage of zinc and EFA metabolism (Cunnane and Horrobin, 1980; Cunnane, 1982; Huang et al, 1982). Zinc deficiency accelerates development of clinical signs of EFA deficiency; conversely, supplementing with EFA can largely reverse clinical signs of zinc deficiency. Several of the manifestations of zinc deficiency are mediated by a relative state of EFA deficiency attributed, in part, to reduced Δ-6-desaturase enzyme activity (Cunnane and Horrobin, 1980; Cunnane, 1982; Huang et al, 1982). Zinc deficiency may impair the absorption of EFA and vice versa (Huang et al, 1982). Low zinc intake during pregnancy prevents the normal accumulation of long-chain fatty acids and differentially depletes maternal whole-body stores of LA and ALA (Cunnane et al, 1993). This finding suggests that low zinc intake during pregnancy and lactation may be a risk factor for fatty acid deficiency. It is unknown whether similar interactions of zinc and EFA also occur in dogs and cats.

Zinc-Related Dermatoses

A variety of cutaneous diseases in dogs have been described that are thought to be primary or secondary zinc deficiency, or that respond to zinc supplementation. The classification of these skin diseases is confusing and often overlaps (**Table 32-3**). A crusted dermatosis has been reported to occur in young shorthaired dog breeds termed dry juvenile pyoderma or juvenile hyperkeratosis (Baker, 1974; Anderson, 1977). Many cases were not caused by primary bacterial infection and often resolved spontaneously at sexual maturity. In retrospect, these case reports most likely represent the first clinical descriptions of cutaneous disease caused by zinc deficiency in young dogs. A classification scheme was proposed in 1980 for zinc-responsive dermatoses that included two syndromes (Kunkle, 1980). Syndrome I included Siberian husky and malamute dogs, which usually developed lesions in early adulthood and responded to zinc supplementation. Syndrome II included rapidly growing puppies that developed lesions due to zinc deficiency and responded to food change, zinc supplementation or both. Later, a generic dog food syndrome was described in adult dogs and rapidly growing puppies consuming a poor quality food (Sousa et al, 1988). These animals had lesions consistent with zinc deficiency and responded to a food change. Simultaneously, acrodermatitis was described in bull terriers

and linked to abnormal zinc absorption and metabolism (Jezyk et al, 1986; Mundell, 1988).

In all of these syndromes, the dermatoses were clearly associated with zinc deficiency and possibly a deficiency or abnormal metabolism of other nutrients. A more practical classification scheme for zinc-related cutaneous changes in dogs includes clinical syndromes due to nutritional abnormalities (primary or secondary zinc deficiency) or abnormalities of zinc metabolism (**Table 32-3**).

Zinc-Related Dermatoses Associated with Nutritional Abnormalities. Zinc-responsive cutaneous lesions have been frequently described in rapidly growing puppies and less frequently in adult dogs. Many breeds may be affected, but Great Danes, Doberman pinschers, German shepherd dogs, German shorthaired pointers, beagles, standard poodles, Rhodesian ridgebacks and Labrador retrievers are reportedly affected more often (Scott et al, 1995; Ohlen and Scott, 1986; van den Broek and Thoday, 1986; Kunkle, 1980; Sousa et al, 1988; Fadok, 1982; Wright, 1985; Wolf, 1987; Gross et al, 1992; Degryse et al, 1987). Lesions somewhat resemble those of experimental zinc deficiency in puppies and include erythroderma, alopecia and hyperkeratotic plaques (exudative crusts) on the face, head, distal extremities and mucocutaneous junctions (Scott et al, 1995; Gross et al, 1992). Thickened, fissured footpads are also frequently seen. Severely affected animals have systemic signs of lymphadomegaly, poor growth, fever, depression and anorexia. Microscopic examination of skin biopsy specimens shows hyperplastic superficial perivascular dermatitis with diffuse parakeratotic hyperkeratosis.

Risk factors for development of zinc-responsive cutaneous disease are listed in **Table 32-4**. Foods with high mineral levels (calcium, phosphorus, magnesium), poor digestibility, high levels of phytate and/or low levels of total fat and EFA are significant risk factors, especially when fed to puppies during the rapid growth phase. As shown in **Figure 32-2**, other minerals in the food influence zinc absorption. Foods high in calcium, phosphorus and magnesium adversely affect absorption of zinc. Excessive use of mineral supplements containing calcium in large- and giant-breed puppies is common and can inhibit zinc absorption.

Phytin, phytate and phytic acid are different forms of organic phosphorus, presumably inositol hexaphosphate, found in plant proteins. Foods high in cereal ingredients often have excessive levels of phytate that complex with and prevent normal absorption of zinc. Phytate and calcium also interact to affect zinc absorption (Forbes et al, 1984). The relative effect of phytate on zinc absorption increases with the calcium level in the food. Thus, foods high in phytate and calcium have an even greater negative impact on zinc absorption.

Low-cost commercial generic or private label brand dry pet foods are often low in total fat and EFA because fat is an expensive ingredient. Zinc and EFA metabolism interact and foods with marginal concentrations of zinc and EFA may be more likely to cause clinical disease.

Viral enteritis and prolonged diarrhea adversely affect zinc absorption in swine and similar changes may occur in other animals (Whiteneck et al, 1978).

Zinc Deficiency Associated with Metabolic Abnormalities. Lesions attributed to zinc deficiency develop early in adulthood in Siberian huskies, malamutes and bull terriers and progress at a variable rate (Scott et al, 2001). Skin lesions develop in these breeds despite consumption of well-balanced commercial foods containing adequate levels of zinc. Lesions include erythroderma, alopecia, crusting, scaling and suppuration involving the head, extremities and mucocutaneous junctions. The footpads may become hyperkeratotic. Secondary Malassezia and bacterial infections are common. Some malamute and Siberian husky dogs appear to have a decreased capability for zinc absorption (Brown et al, 1978; Willemse, 1992). Bull terriers that are siblings of those with acrodermatitis may also be affected and probably have abnormal zinc absorption and metabolism (Scott et al, 1995). These patients will probably require zinc supplementation for life to maintain normal tissue zinc concentrations and to avert clinical disease.

Acrodermatitis is an inherited, autosomal recessive metabolic disease reported to occur in bull terriers in the United States, Canada and the United Kingdom (Jezyk et al, 1986; Mundell, 1988; Smits et al, 1991; McEwan, 1993). The syndrome develops shortly after birth and is associated with defects in zinc absorption and metabolism. The condition has been termed lethal acrodermatitis because homozygously affected dogs rarely live beyond 18 months of age.

Cutaneous and systemic clinical signs resemble those of severe zinc deficiency, including growth retardation, gastrointestinal disease, chronic bacterial infections and progressive, erythematous, exfoliative, papular to pustular dermatitis of the distal extremities and skin surrounding the mucocutaneous junctions (Jezyk et al, 1986; Mundell, 1988; Smits et al, 1991; McEwan, 1993). Surface crusts usually contain numerous bacteria and yeast organisms (Smits et al, 1991). Owners complain that their dogs have difficulty eating and are affected by skin disease, poor growth and large, splayed, painful feet (McEwan, 1993). Ulcerated and thick, crusted lesions are prominent on the muzzle and ears. Abnormal keratinization of the footpads, severe nail dystrophy and paronychia are also common. Histopathologic examination of skin reveals massive parakeratotic hyperkeratosis.

A study showed that two affected dogs had significantly lower plasma zinc concentrations, lower zinc and copper concentrations in the kidneys and liver and lower zinc absorption when compared with age-matched control dogs (Mundell, 1988). Serum zinc concentrations may also be normal (Smits et al, 1991; McEwan, 1993). Supplementation with oral or intravenous zinc fails to ameliorate clinical signs. Treatment with systemic antimicrobials, especially for secondary superficial yeast infections, may result in marked improvement, although systemic and cutaneous infections recur. Some apparently normal littermates may develop a zinc-responsive dermatitis (Scott et al, 2001).

Diagnosis and Management of Zinc-Responsive Skin Disease

Diagnosis of zinc-responsive cutaneous disease is based on the history, physical examination and results of skin biopsy evaluation. Hyperplastic superficial perivascular dermatitis with marked diffuse and follicular parakeratotic hyperkeratosis is suggestive of zinc deficiency (Gross et al, 1992a). In general, zinc concentrations in serum, leukocytes and hair are not good indicators of zinc status in dogs (van den Broek and Thoday, 1986; Wolf, 1987; van den Broek et al, 1988; Logas et al, 1993). Age, seasonal variation and many diseases affect serum zinc concentrations (Fisher, 1977; Keene et al, 1981). One study found no significant difference in serum zinc concentrations between normal dogs, dogs that were ill without skin disease, dogs with allergic skin disease and dogs with other dermatoses (Logas et al, 1993).

Treatment generally includes changing to a food that avoids excess minerals and contains adequate amounts of zinc and EFA. Optimal levels of zinc and EFA in foods for dogs and cats with skin and hair disorders are listed in **Table 32-1**. This type of change will usually result in rapid improvement in puppies and some adult dogs. Zinc supplementation will be necessary in those breeds in which decreased ability to absorb zinc is suspected. Oral supplementation with zinc sulfate (10 mg/kg body weight/day) or zinc methionine (2 mg/kg body weight/day) is adequate in most cases. Zinc absorption is maximal if supplements are given between, rather than with, meals. Supplemental zinc from zinc amino acid chelates may be more available to dogs than are inorganic zinc sources (Lowe et al, 1994). Some dogs, especially Siberian huskies, do not respond to oral zinc supplementation. Intravenous injection of sterile zinc sulfate solutions at dosages of 10 to 15 mg/kg body weight has been effective in these dogs (Willemse, 1992). Weekly injections for at least four weeks are necessary to resolve the lesions, and maintenance injections every one to six months may be necessary to prevent relapses.

Existing skin lesions can be improved by hydrating the crusts with wet dressings, applying petrolatum or petrolatum-based topical agents or whole-body warm water soakings. Dogs with evidence of superficial pyoderma or *Malassezia* infections should be treated with appropriate antimicrobials. Some authors also recommend low doses of oral, short-acting glucocorticoids (Kwochka, 1993).

VITAMINS

Vitamin A

Retinol, retinal and retinoic acid are three natural compounds that have vitamin A activity in mammals. Food sources include retinyl esters (vitamin A palmitate) in animal tissues and carotenoids (β-carotene) in vegetables. These sources are assimilated and ultimately stored as retinyl palmitate in the liver. Cats require preformed vitamin A because they lack the ability to effectively convert β-carotene to vitamin A (NRC, 2006).

The general functions of vitamin A include growth promotion, differentiation and maintenance of epithelial tissue and maintenance of normal reproductive and visual functions. Retinoic acid affects differentiation and proliferation of epithelial cells by binding to and activating a specific set of cell nuclear receptors (Wolf, 1990; Blumenberg et al, 1992). In particular, epithelial cells have a specific nuclear receptor for retinoic acid (Blumenberg et al, 1992). The mechanism of action of retinoic acid is similar to that of steroid hormones and thyroxine, and involves activation of specific genes. Retinoic acid and thyroid hormone control overlapping gene networks, regulating growth and differentiation through nuclear receptors that can modify rates of gene transcription.

Retinoic acid influences epidermal differentiation and directly affects keratinization by action of retinoic acid receptors on regulatory sites in keratin genes. Retinoic acid may also influence hair growth through activity at the hair bulb.

Vitamin A deficiency in dogs was among the first of the vitamin deficiencies to be studied experimentally (NRC, 2006). Skin lesions and focal atrophy of the skin have been reported with experimental vitamin A deficiency in dogs and cats, although it is seldom encountered clinically (NRC, 1986, 1985). Some of the earliest work with vitamin A showed that puppies had heavier, more lustrous coats when foods were supplemented with vitamin A (Bradfield and Smith, 1938). It is unlikely that vitamin A deficiency would occur in dogs and cats eating typical commercial pet foods because these foods contain several times the minimum daily requirement of vitamin A (Kallfelz and Dzanis, 1989). The minimum recommended allowance for vitamin A in foods for dogs is 5,050 IU/kg of food (DM) (growth/reproduction and maintenance requirements are the same) and 3,333 and 6,666 IU/kg of food (DM) for growth/maintenance and gestation/lactation for cats, respectively (NRC, 2006).

Retinoid-Responsive Dermatoses

The term "retinoids" refers to the entire group of naturally occurring and synthetic vitamin A derivatives. These therapeutic agents should be reserved for cases in which there are clinical and histopathologic abnormalities most consistent with primary keratinization disorders of the surface and/or follicular epithelium or abnormalities of the sebaceous glands (Power and Ihrke, 1990; Kwochka, 1993a). Other causes of clinical scaling (ectoparasitism, allergies, infections, endocrinopathies) should first be eliminated through other diagnostic testing.

A vitamin A-responsive dermatosis has been described primarily in cocker spaniels but it has also been recognized in a Labrador retriever and a miniature schnauzer (Scott et al, 2001; Kwochka, 1993a). The condition is characterized by adult-onset, medically refractory seborrheic skin disease with marked follicular plugging and hyperkeratotic plaques, primarily on the ventral and lateral thorax and abdomen (Scott et al, 2001; Kwochka, 1993a). A ceruminous otitis externa and unthrifty appearing coat are often present. The clinical lesions are characterized histologically by marked follicular orthokeratotic hyperkeratosis. Improvement is noted within three to four weeks of starting oral vitamin A alcohol (retinol) with complete remission by eight to 10 weeks (Scott et al, 2001; Kwochka,

1993a). It is important to remember that this syndrome represents only a small subset of seborrheic disease in cocker spaniels. However, it is logical to try a four- to eight-week course of vitamin A in dogs with ventral hyperkeratotic plaques that do not respond well to other therapy (Kwochka, 1993a).

Many synthetic retinoids have been developed to offer better therapeutic response and less toxicity than naturally occurring vitamin A compounds. The most commonly used synthetic retinoids include tretinoin, isotretinoin and etretinate.

Tretinoin is effective topically as therapy for localized follicular and epidermal keratinization disorders such as chin acne, nasodigital hyperkeratosis, calluses and ear margin seborrhea/dermatosis (Scott et al, 2001; Power et al, 1990; Kwochka, 1993a). Isotretinoin and etretinate are given orally, in combination with food, and may be useful to manage primary idiopathic seborrhea in cocker spaniels, keratinization disorders in other breeds, schnauzer comedo syndrome, sebaceous adenitis, lamellar ichthyosis, actinic keratosis (solar-induced precancerous lesions) and various cutaneous neoplastic disorders (squamous cell carcinoma, cutaneous T-cell lymphoma, multiple keratocanthomas). Etretinate is no longer available but has been replaced by acitretin, a metabolite of etretinate (Scott et al, 2001).

Retinoid dosages commonly recommended by veterinary dermatologists are outlined in **Table 32-5**. Side effects that occur commonly with retinoids include conjunctivitis, decreased tear production, vomiting, diarrhea, arthralgia/myalgia, moderate to marked elevations in serum triglyceride levels, elevations in liver enzyme activity and teratogenic effects.

Table 32-5. Indications and dosages for retinoids in primary keratinization disorders.

Vitamin A alcohol (retinol)
Subset of seborrheic skin disease, primarily in cocker spaniels
Dosage: 625 to 1,000 IU/kg q24h per os
10,000 IU q24h per os in cocker spaniels and miniature schnauzers
50,000 IU q24h per os in Labrador retrievers
Tretinoin (all-trans retinoic acid)
Chin acne of dogs and cats
Nasodigital hyperkeratosis
Ear margin seborrhea/dermatosis
Dosage: Apply topically q12 to 24h to control; then decrease frequency for maintenance
Isotretinoin (13-cis retinoic acid)
Lamellar ichthyosis
Schnauzer comedo syndrome
Sebaceous adenitis
Dosage: 1 to 3 mg/kg q24h per os with food for control; then try to decrease to alternate-day therapy
Acitretin (analogue of retinoic acid ethyl ester)
Actinic keratosis
Idiopathic seborrhea, especially of cocker spaniels
Lamellar ichthyosis
Sebaceous adenitis
Dosage: 0.75 to 1.0 mg/kg q24h per os for control; then try to decrease to alternate-day therapy

Vitamin E

Eight isomeric forms of tocopherol represent vitamin E activity, with α-tocopherol being most important biologically. Vitamin E quenches free radicals in PUFA of membrane phospholipids. The nutritional requirement of vitamin E is closely related to the dietary intake of PUFA.

Naturally occurring vitamin E deficiency has only been reported to occur in cats. Steatitis occurs when sources of highly unsaturated fatty acids, such as red meat tuna, are fed to cats without adequate vitamin E. Clinical signs and laboratory findings include anorexia, fever, hyperesthesia, hemolytic anemia, leukocytosis and firm subcutaneous nodules. Diagnosis is confirmed by microscopic examination of biopsy specimens from adipose tissue. Typical lesions are firm, yellow to orange-brown fat with lobular panniculitis and ceroid within lipocytes, macrophages and giant cells. Treatment includes a change of food to a complete and balanced ration, supplemental vitamin E (25 to 75 mg/kg body weight/day), corticosteroids and supportive care.

Naturally occurring vitamin E deficiency has not been reported to occur in dogs, but experimentally induced vitamin E deficiency does produce skin lesions (Scott and Sheffy, 1987). Initial lesions consist of a keratinization defect (seborrhea sicca), followed by a greasy and inflammatory stage (erythroderma and seborrhea oleosa) and secondary bacterial pyoderma. The dermatosis rapidly responds to vitamin E supplementation. All lesions respond within eight to 10 weeks. It is unlikely that vitamin E deficiency would occur in dogs and cats that eat typical commercial pet foods because such foods contain three to five times the minimum daily requirement of vitamin E (Kallfelz and Dzanis, 1989).

Because of its role as a barrier, the skin is uniquely challenged by oxidants (i.e., free radicals). The skin is continuously exposed to an oxidative environment, including high oxygen tensions, air pollutants, ultraviolet (UV) radiation, parasites, aerobic microorganisms and oxidants released as a result of normal metabolism. UV radiation causes tissues to produce reactive oxygen species, eicosanoids and cytokines, which can result in acute adverse effects (e.g., sunburn, photosensitivity) as well as long-term sequelae (e.g., actinic keratosis, solar dermatitis, malignant skin tumors) (Scott et al, 2001; Nikula et al, 1992; Kimura and Doi, 1994). Because of the high lipid content of skin, lipophilic antioxidants such as α-tocopherol are expected to play a major role in scavenging reactive oxygen species during oxidative stress (Thiele et al, 2001). Vitamin E protects against UV-induced skin damage through a combination of antioxidant and UV-absorptive properties (Thiele et al, 2001). One study revealed that increasing vitamin E amounts in food significantly increased vitamin E concentrations in serum and skin of cats and dogs (Jewell et al, 2002). Previous studies have shown that increased vitamin E levels decrease serum levels of some biomarkers associated with oxidative stress (Jewell et al, 2000). This suggests that increases in dietary vitamin E concentrations are likely to be beneficial. However, the relationship between increases in serum and skin vitamin E concentrations and the prevention, development and treatment of specific skin diseases remains to be elucidated by intervention studies. The recom-

mendation for vitamin E in foods is at least 400 IU/kg of food (DM) for dogs and at least 500 IU/kg of food (DM) for cats (Chapters 13 and 20). The minimum recommended allowances for foods for adult dogs and cats for maintenance is 30 IU/kg (DM) and 38 IU/kg (DM), respectively (NRC, 2006).

Vitamin E-Responsive Dermatoses

A number of inflammatory dermatoses in animals have been treated with oral vitamin E, including discoid lupus erythematosus, systemic lupus erythematosus, pemphigus erythematosus, sterile panniculitis, acanthosis nigricans, dermatomyositis and ear margin vasculitis. Vitamin E is often used in conjunction with systemic glucocorticoids, topical steroids and other immunosuppressive agents. Large doses of vitamin E may stabilize cell and lysomal membranes against damage induced by free radicals and peroxides, modulate AA and PG metabolism, inhibit proteolytic enzymes, enhance phagocytic activity and enhance humoral and cellular immunity.

Vitamin E appears to have limited value as an antipruritic agent. One uncontrolled study in allergic dogs that received vitamin E failed to document a reduction in pruritus (Miller, 1989). A well-controlled study in adult people with atopic dermatitis also failed to demonstrate improvement with vitamin E or selenium supplementation (Farris et al, 1989).

The oral dosage of vitamin E for inflammatory dermatoses is 200 to 800 IU twice daily (Scott et al, 2001; Rosenkrantz, 1993). This dose is seven to 27 times higher than the lower end of the recommended daily amount (≥400 IU/kg food [DM]) for a 10-kg dog (Chapters 13 and 14). Anecdotal reports suggest that topical vitamin E may help resolve discoid lupus erythematosus lesions (Rosenkrantz, 1993). Vitamin E is one of the least toxic vitamins.

B-Complex Vitamins

Experimental deficiencies of biotin and riboflavin can cause cutaneous lesions in dogs and cats (NRC, 2006). The most common clinical signs include anorexia, weight loss, diarrhea, alopecia and dry, flaky seborrhea. Clinical lesions are more likely to occur in young, growing animals than in adults (Pastoor, et al, 1991).

Several B-complex vitamins act as cofactors in EFA metabolism. LA desaturation and GLA elongation may be impaired in pyridoxine deficiency (Cunnane et al, 1984). EFA may have a sparing effect on the cutaneous lesions caused by B-complex vitamin deficiency and vice versa (Cunnane et al, 1984).

It is unlikely that B-complex vitamin deficiency would occur in dogs and cats that eat commercial pet foods, because most foods contain several times the minimum daily requirement of these vitamins. However, supplementation of complete and balanced pet foods with biotin, pantothenic acid, inositol, choline, other B vitamins, zinc and fatty acids has been shown to alter skin function (reduce transepidermal water loss) and improve coat softness and appearance (Markwell et al, 2004; Watson and Marsh, 2001). Thus, for some patients with skin/coat problems, feeding foods with additional amounts of these nutrients may be beneficial. B-complex deficiency could occur in animals eating homemade foods inadequately supplemented with vitamins.

Feeding Plan

Assess and Select the Food

In general, a patient's food should be changed if one of the following skin or coat conditions develops:

- Loss of normal hair color, especially lightening, graying or reddish-brown discoloration of normally pigmented hair,
- Brittle and easily broken hair,
- Generalized scaling, crusting, alopecia or loss of normal hair sheen for which no underlying skin disorder can be identified through routine diagnostic evaluation,
- Poor wound healing or decubital ulcers,
- Severe, generalized inflammatory skin disease such as deep pyoderma or immune-mediated skin disease,
- Hyperproliferative skin disorder such as primary seborrhea,
- Abnormal hair growth or failure of hair to regrow where clipped or lost.

Table 32-1 summarizes the key nutritional factors for foods for patients with nutrient responsive-dermatoses. A food for patients with skin and hair problems should include the recommended levels of these nutrients, and the nutrients should be available to the patient. Digestibility and assimilation of nutrients are especially important during periods of increased nutrient demand such as growth, gestation and lactation. Use of maintenance-type foods (which are usually lower in protein, fat, minerals, vitamins and digestibility than growth/lactation or foods for repletion/recovery) may be a risk factor for nutritional skin disease during these lifestages. Levels of these nutrients can be found in food tables for normal dogs and cats (Chapters 13 and 20). Otherwise, they can be obtained by contacting the manufacturer or distributor of the food.

A detailed assessment of nutritional supplements is also important. Vitamin supplements are rarely indicated except in those nutrient-sensitive disorders that respond to high levels of vitamins A or E. Excessive use of mineral supplements can interfere with assimilation of zinc and copper. Besides recommended key nutritional factors for foods for patients with nutrient-deficiency dermatologic conditions, **Table 32-1** also provides information about nutritional supplements for patients with skin and hair disorders. When appropriate, nutritional supplements can be used in conjunction with the food change or can be added to the original food. Changing to a food appropriate for the patient's lifestage will usually reverse cutaneous signs associated with a relative nutrient deficiency. Select a food whose nutritional adequacy was determined by animal tests (Chapter 9). This helps ensure that the nutrients in the food are available to the animal. Foods formulated to meet the nutrient profiles set forth by the Association of American Feed Control Officials might be nutritionally adequate but this form of establishing nutritional adequacy cannot ensure nutrient availability. Supplementation alone will not usually improve a poor-quality food. Supplementation with fatty acids, zinc, retinoids and vitamin E usually exceeds levels used to meet nutrient requirements. In these cases, nutrient supplements are being used as therapeutic agents.

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Assess and Determine the Feeding Method

The method of feeding is often not altered in the nutritional management of skin and hair disease. If a new food is fed, the amount to feed can be determined from the product label or other supporting materials. The food dosage may need to be changed if the caloric density of the new food differs from that of the previous food. The food dosage is usually divided into two or more meals per day. The food dosage and feeding method should be altered if the patient's body weight and condition are not optimal.

For clinical nutrition to be effective, there needs to be good compliance. Enabling compliance includes limiting access to other foods and knowing who feeds the animal. If the patient comes from a household with multiple pets, it should be determined whether the pet with skin disease has access to the other pets' food.

Reassessment

Cutaneous disease due to a nutrient deficiency will usually respond rapidly and dramatically to appropriate nutritional change or supplementation. Patients will usually improve within a few days to weeks. Nutrient-sensitive disorders usually respond to supplements more slowly, over several weeks to several months. After a nutritional change or supplementation has been started, the patient should be examined monthly for significant changes in skin lesions and hair quality. Trichograms can be repeated in those patients that have abnormal hair quality or hair growth.

FATTY ACIDS FOR INFLAMMATORY SKIN DISEASE

Clinical Importance

EFA exhibit multiple antiinflammatory and immunomodulating properties. They have the potential to affect allergic and other forms of skin inflammation through modulating cytokine production, inhibiting cellular activation and cytokine secretion and altering the composition and function of the epidermal lipid barrier (Olivry et al, 2001). Their mechanisms of action, therefore, are likely to be explained by a combination of effects.

The most commonly proposed mechanism of action of EFA in the treatment of inflammatory skin diseases is the modulation of cutaneous production of PG and LT (Olivry et al, 2001). AA is the major PUFA in cell membrane phospholipids (Stossel et al, 1974). The normal response of injured tissue is inflammation, a tissue protective mechanism. Under these circumstances, phospholipases are activated and act on phospholipids of cell membranes to release constituent fatty acids. AA, the fatty acid in greatest concentration, is released and converted into eicosanoids, which mediate inflammation.

Eicosanoids are also derived from GLA and EPA. They also include PG, thromboxanes, LT, hydroperoxyeicosatetraenoic acids (HPETE) and hydroxyeicosatetraenoic acids (HETE). Macrophages are the most significant sources of eicosanoids (Lokesh et al, 1988; Meydani et al, 1991; Hwang, 1989; Magrum and Johnston, 1983).

Four AA-derived LT and one PG play a central role in the inflammatory process. LTB_4 stimulates neutrophil and eosinophil chemotaxis and increases vascular permeability. LTC_4, LTD_4 and LTE_4 encourage smooth muscle contraction and increase vascular permeability. PGE_2 inhibits T and B lymphocyte proliferation, reduces cytokine production and limits natural killer cell activity. However, these proinflammatory eicosanoids can result in pathologic conditions when produced in excessive amounts and/or prolonged periods of time (Sigal, 1991; Lands, 1989). Increased production of LT and PGE_2 has been reported in many chronic inflammatory diseases (Goodwin and Ceuppens, 1983).

Modulating the PUFA content of cell membrane phospholipids by dietary means can alter eicosanoid production. Such modulation can affect the intensity and duration of inflammatory and immune responses (Lokesh et al, 1988; Meydani et al, 1991; Hwang, 1989; Magrum and Johnston, 1983). Generally, omega-3 fatty acids are thought to produce less inflammatory cytokines (Sigal, 1991; Lands, 1989; Lokesh et al, 1988; Lokesh and Kinsella, 1987; Broughton et al, 1991; Croft et al, 1987).

Consumption of flax or fish oils with omega-3 PUFA results in replacement of AA in the macrophage membrane with ALA, docosahexaenoic acid (DHA) or EPA. The result is production of fewer AA- (omega-6) derived eicosanoids and more ALA- (omega-3) derived eicosanoids, thereby reducing the inflammatory response (Meydani et al, 1991; Calder et al, 1990; Endres et al, 1989, 1993; Baldie et al, 1993; Lee et al, 1985). Studies using neutrophils from normal dogs have shown that enhanced levels of dietary omega-3 fatty acids inhibit leukotriene generation (Byrne et al, 2000; Vaughn et al, 1994). Studies have also shown alterations in inflammatory response and immune function in normal cats fed foods with enhanced levels of omega-3 fatty acids (Chew et al, 2000). Consequently, changing the type of eicosanoid production and the subsequent alteration in cytokine production can reduce inflammation by eicosanoid-mediated effects (Horrobin and Manku, 1990; Calder et al, 1990; Endres et al, 1989, 1993; Baldie et al, 1993; Lee et al, 1985; Watson et al, 1990). This premise is the basis for using omega-3 fatty acids for treatment of chronic inflammatory conditions.

A similar effect is proposed for the use of GLA, an omega-6 derivative of LA. GLA and DHA reduce histamine release and

alter cell mediator production in canine mast cells (Gueck et al, 2004). If similar changes occur in dermal mast cells from patients with atopic dermatitis, these results suggest that GLA and omega-3 fatty acid supplements or similarly enriched foods might be beneficial. Black currant oil, borage oil and evening primrose oil are sources of GLA (Meydani et al, 1991; Calder et al, 1990; Endres et al, 1989, 1993; Baldie et al, 1993; Lee et al, 1985).

Besides affecting LT and PG production, EFA exhibit numerous additional immunomodulating properties. They have been reported to decrease the synthesis of proinflammatory cytokines, decrease T-cell lymphocyte proliferation and activation, affect expression of cell adhesion molecules, influence signaling within cells of the immune system and regulate cytotoxic activity of phagocytes by modulating the production of reactive oxygen species (Olivry et al, 2001a). Preliminary investigations suggest that dogs with atopic dermatitis also may exhibit abnormal epidermal lipid levels and metabolism (Olivry and Hill, 2001a). EFA have the potential to modulate this abnormal skin lipid barrier function in animals with inflammatory skin disease.

For more information about fatty acid metabolism and fatty acid modulation of the inflammatory response see the Lipids section in Chapter 5.

Patient Assessment

History and Physical Examination

Numerous skin diseases have an inflammatory component. However, dietary fatty acid therapy has been used primarily in patients with allergic skin disease or patients with pruritus or papulocrustous dermatitis for which a specific cause has not been identified.

Pruritus is the most common historical feature of allergic skin disease in dogs and cats. Clinical signs reportedly first occur in most dogs and cats with atopic dermatitis between six months and three years of age (Scott et al, 2001; Griffin et al, 1993; Griffin and DeBoer, 2001). Lesions of canine atopic dermatitis usually involve the muzzle, periocular region, pinnae and external ear canals, paws, axillae, groin and abdomen. Although the face and paws are most commonly involved, many animals will have generalized pruritus by the time they are examined. Chronic licking, rubbing, chewing or scratching can result in alopecia, lichenification, hyperpigmentation, scaling and excoriation. Other common lesions in atopic dogs include papules and erythematous macules, secondary superficial pyoderma, secondary *Malassezia* dermatitis, chronic otitis externa and seborrhea.

Cats with atopic dermatitis most commonly exhibit symmetric alopecia, miliary dermatitis, eosinophilic plaques, indolent ulcer of the lip, pruritus of the head and neck with excoriations or generalized pruritus (Scott et al, 2001; Sousa, 1995). Atopic cats are pruritic, but many are secretive and groom or traumatize themselves without the owner's knowledge.

Cats with miliary dermatitis have numerous small erythematous papules with adherent brownish crusts and various degrees of alopecia and pruritus (Scott et al, 2001; Sousa, 1995). These lesions can usually be palpated over the dorsal lumbar and cervical regions long before they are visualized. Feline miliary dermatitis is most commonly a manifestation of flea allergy, but may occur with other ectoparasite infestations, dermatophytosis, bacterial folliculitis, adverse food reactions, atopic dermatitis, drug eruptions and immune-mediated skin disease.

Canine flea-bite hypersensitivity is characterized by a pruritic, papular dermatitis (Scott et al, 2001). Flea bites induce an initial papule that may then form a crust. Chronic pruritus may lead to alopecia, lichenification, severe crusting and hyperpigmentation. Lesions are typically confined to the dorsal lumbosacral area, caudomedial thighs, ventral abdomen and flanks. Pyotraumatic dermatitis ("hot spots"), secondary bacterial pyoderma and secondary seborrhea are common in chronic cases. The presence of otitis externa, severe pedal pruritus or facial pruritus strongly suggests concurrent atopic dermatitis or adverse food reaction.

Numerous insects besides fleas and arachnids in the normal dog and cat environment can stimulate hypersensitivity reactions. Blackfly, deerfly, horsefly, mosquito, red ant, black ant and tick bites may all contribute to allergic skin disease in dogs and cats (Griffin et al, 1993). The primary clinical sign is pruritus, although an erythematous maculopapular dermatitis may be present (Scott et al, 2001). Nodules and papules induced by mosquito bites are usually found on the bridge of the nose and pinnae of cats. Stable flies occasionally induce a granulomatous reaction, producing nodules or plaques and varying degrees of alopecia on the pinnae. Ticks may induce nodules due to granuloma formation at the site of attachment. Acute-onset nasal dermatitis has also been observed in dogs; pruritic papules and nodules are found on the bridge of the nose.

Adverse reactions to food mimic other allergic diseases. The clinical features and management of adverse food reactions are described in detail in Chapter 31.

Laboratory and Other Clinical Information

Skin biopsy and histopathology can be used to confirm the presence of inflammatory skin disease. Chronic hyperplastic dermatitis is a common histopathologic reaction pattern seen in dogs with chronic allergy (Gross et al, 1992; Olivry and Hill, 2001b). The predominant types of inflammatory cells may suggest the specific allergic disease. However, many chronic dermatoses have similar histopathologic features, making specific diagnosis difficult. The nature of epidermal and dermal inflammatory cell infiltrates in canine atopic dermatitis has recently been characterized using modern immunologic techniques and is described in other sources (Olivry and Hill, 2001b).

Two methods of allergy testing are available to practitioners. Intradermal testing has been performed for many years. More recently, in vitro tests for detection of allergen-specific IgE have become commercially available.

Intradermal testing is widely used by veterinary dermatologists for making a definitive diagnosis of canine atopic disease and for selecting allergens for hyposensitization (Scott et al, 2001; Hillier and DeBoer, 2001). Intradermal allergy tests detect the allergen-specific IgE fixed to the surface of mast cells

in the dermis, and assess the ability of IgE to fix allergen and cause mast cell degranulation and subsequent vasodilatation. In a well-controlled study using allergen mixes, 59% of dogs responded to hyposensitization that was formulated on the basis of intradermal testing results (Willemse et al, 1984).

Intradermal allergy testing has several disadvantages (Hillier and DeBoer, 2001). Negative intradermal results occur in some dogs strongly suspected to have atopic dermatitis. Anti-inflammatory and antihistamine drugs must be withdrawn before testing to prevent false-negative results. The test cannot be performed on dogs with generalized dermatitis. Shaving of the coat and sedation are usually required. Intradermal allergy testing is time-consuming and not cost-effective when performed infrequently. The usefulness of intradermal allergy testing is also limited by lack of standardized allergy extracts and no homogeneous criteria for the interpretation of results. Most intradermal testing is performed at dermatologic referral centers because of these disadvantages. Intradermal testing for food hypersensitivity is unreliable in animals with dermatologic disease (Chapter 31).

In vitro "allergy" tests measure serum concentrations of allergen-specific IgE and avoid many of the disadvantages of intradermal allergy tests (Codner and Griffin, 1996). In vitro tests require only a serum sample; so they are readily available to private practitioners and can be used on patients with generalized dermatitis. Laboratories use several different techniques to detect circulating IgE levels, including a radioallergosorbent test (RAST), enzyme-linked immunosorbent assay (ELISA) or liquid-phase enzyme immunoassay (EIA). Problems with in vitro testing include poor reproducibility and a high false-positive rate (Codner and Lessard, 1993). Results to date suggest that more than 60% of atopic dogs respond to hyposensitization formulated on the basis of in vitro results (Anderson, 1993; Sousa and Norton, 1990). In vitro testing is also available for confirming flea-allergic dermatitis (Cook et al, 1996) but is unreliable for diagnosing food hypersensitivity (Chapter 31).

Controversy continues over whether intradermal or in vitro testing is the better method for confirming a diagnosis of atopic dermatitis and for selecting allergens for hyposensitization (DeBoer and Hillier, 2001). Furthermore, long-term studies are needed to evaluate responses of allergic animals to hyposensitization based on both types of testing.

Risk Factors

Atopy (atopic state) is a genetically-predisposed tendency to develop IgE-mediated allergy to environmental allergens (Olivry et al, 2001c). Atopic disease is any clinical manifestation of atopy including most commonly atopic dermatitis, atopic conjunctivitis and/or atopic rhinitis (Olivry et al, 2001c). Atopic dermatitis is a genetically predisposed inflammatory and pruritic allergic skin disease with characteristic clinical features (Olivry et al, 2001c). It is associated most commonly with IgE antibodies to environmental allergens. Although the exact mode of inheritance is unknown, strong breed predilection and familial involvement in dogs indicate a genetically determined cause. Canine breeds reported to be predisposed to atopy include Cairn terriers, West Highland white terriers, Scottish terriers, wire-haired fox terriers, Boston terriers, Sealyham terriers, Lhasa apsos, Dalmatians, pugs, Irish setters, English setters,

Table 32-6. Key nutritional factors for foods and supplements for dogs and cats with inflammatory dermatoses.

Factors	Nutritional recommendations
Omega-3 fatty acids (ALA, EPA and/or DHA)	Supplements or foods should initially provide 50 to 300 mg total omega-3 fatty acids/kg body weight/day Foods should contain between 0.35 to 1.8% dry matter

Key: ALA = α-linolenic acid, EPA = eicosapentaenoic acid, DHA = docosahexaenoic acid.

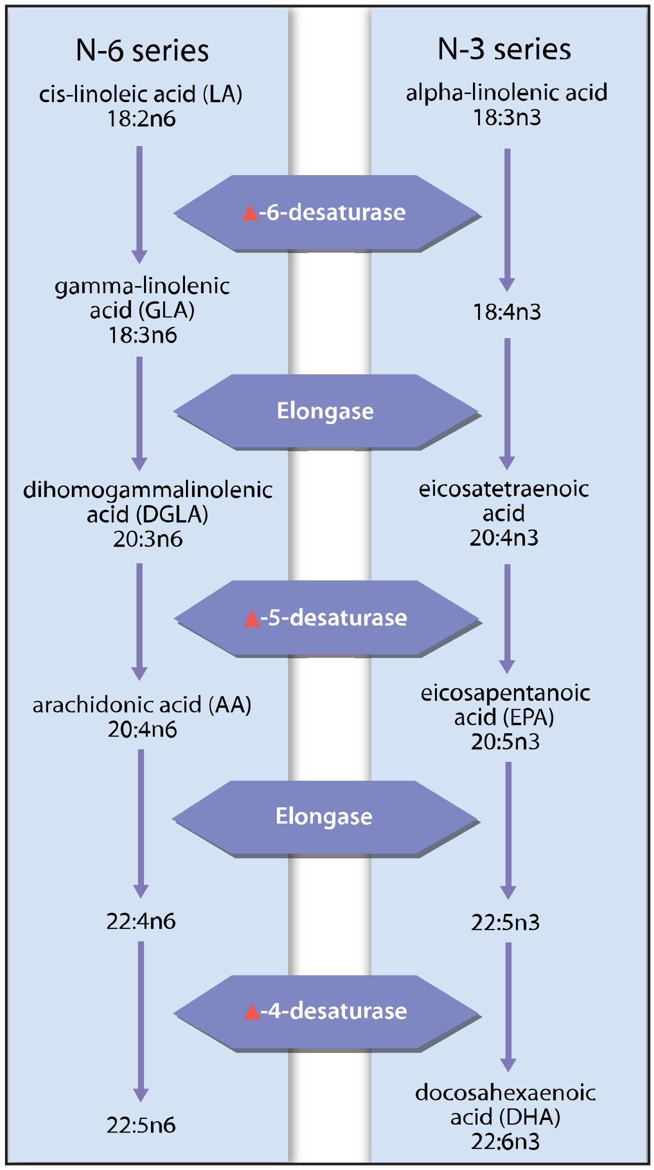

Figure 32-3. Metabolic transformation of two major unsaturated fatty acid families by desaturation and elongation.

Table 32-7. Fatty acids found in pet food ingredients and supplements.

Fatty acids	Ingredients/supplements
Linoleic acid (omega-6)	Vegetable oils (soy oil, corn oil, safflower oil, canola oil, etc.)
	Grains (corn, soybeans)
γ-linolenic acid (GLA, omega-6)	Black currant oil
	Borage oil
	Evening primrose oil
α-linolenic acid (ALA, omega-3)	Flax
	Flax (linseed) oil
Eicosapentaenoic acid (EPA, omega-3)	Fish meal
	Cold water marine oils
Docosahexaenoic acid (DHA, omega-3)	Fish meal
	Cold water marine oils

golden retrievers, Labrador retrievers, boxers, miniature schnauzers, English bulldogs, Bichon Frise, Chinese Shar-Pei, Shih Tzu, German shepherd dogs, Belgian Tervuren, beauceron and cocker spaniels (Scott et al, 2001; Griffin et al, 1993; Anderson, 1993). However, canine atopic dermatitis may be seen in any breed, including mixed breeds. Breed predisposition has not been reported for atopic cats (Scott et al, 2001).

Hypersensitivity requires environmental exposure to flea, other biting insect or arachnid allergens. Depending on the offending allergen, these cases may be seasonal in temperate climates; worse clinical signs occur during warm weather. The onset of clinical signs may be historically correlated with an increase in insect or arachnid numbers in the environment.

Key Nutritional Factors

The key nutritional factors for foods and dietary supplements for omega-3 fatty acid-responsive skin diseases are summarized in **Table 32-6** and are discussed in more detail below.

OMEGA-3 FATTY ACIDS

The use of omega-3 fatty acids as antipruritic agents in dogs and cats has been the subject of numerous studies and considerable debate. The inflammation and dermatitis associated with allergic skin disease may be partially caused by abnormal EFA metabolism and inappropriate eicosanoid synthesis (White, 1993). A unique feature of skin is that it lacks Δ-6- and Δ-5-desaturase enzyme activity, and thus is incapable of making AA from LA or EPA from ALA (**Figure 32-3**) (Campbell, 1990). Skin can elongate GLA to dihomogammalinolenic acid (DGLA) and EPA to DHA. Normal dogs metabolize dietary sources of ALA to EPA and DHA elsewhere in the body. These fatty acids are then incorporated into the skin (Campbell and Roudebush, 1995).

DGLA, EPA and DHA in cutaneous cellular membranes may decrease inflammation through competition with AA for metabolic enzymes or because of the antiinflammatory nature of the eicosanoids produced (White, 1993). The rationale for specifically administering products high in GLA (an omega-6 [n-6] fatty acid) is that GLA can be incorporated into the skin, where it is rapidly elongated to DGLA. Because skin lacks desaturase enzymes, DGLA is not further metabolized to AA. As a result, DGLA competes with AA for metabolic enzymes. Thus there is a decrease in AA-derived eicosanoids and an increase in the antiinflammatory eicosanoids PGE_1 via the cyclooxygenase cascade and 15-HETE via the lipoxygenase pathway. Specific recommendations for food amounts for GLA have not yet been determined. Thus, GLA is not listed as a key nutritional factor at this time. However, evening primrose, borage or black currant oils are used to increase dietary GLA intake.

ALA is an omega-3 (n-3) PUFA that is metabolized to EPA and DHA, and incorporated into the skin of normal dogs (Manku et al, 1982). Findings suggest that atopic dermatitis in human beings is associated with a deficiency of Δ-6-desaturase activity, which prevents the rapid conversion of ALA to EPA and DHA in atopic individuals (Manku et al, 1982, 1984). Comparable studies using atopic dogs and cats have not been published. However, one study suggested that subsets of atopic dogs exist with different fatty acid metabolic capabilities (Scott et al, 1997). Other studies suggest that ALA can modulate inflammatory and immune responses in normal cats (Chew et al, 2000). Flax, flax oil or linseed oil is typically used to provide ALA for supplements or foods.

The use of fatty acids for treating atopic dermatitis and chronic pruritus has been extensively studied in dogs (Scott et al, 1992, 1997; Scott and Buerger, 1988; Miller et al, 1989, 1992; Lloyd and Thomsett, 1989; Lloyd, 1989; Scott and Miller, 1990; Scarff et al, 1990; Paradis et al, 1991; Scarff and Lloyd, 1992; Bond and Lloyd, 1992, 1992a, 1993; White, 1992; Logas and Kunkle, 1994; Schick et al, 1995). Unfortunately, most of these studies have been uncontrolled, masked clinical trials using low doses of fatty acids for short periods. In these studies, 0 to more than 75% of pruritic patients had degrees of clinical improvement. Clinical studies using randomization, placebos and high doses of fatty acids for six weeks or more showed decreased pruritus in 0 to more than 50% of patients (Scarff and Lloyd, 1992; White, 1992; Logas and Kunkle, 1994). Dogs that did not have decreased pruritus still showed improvement in other clinical signs, including less erythroderma and skin edema. The benefit of fatty acid supplementation is maximized in dogs if other contributing diseases such as adverse reactions to food, flea hypersensitivity, bacterial pyoderma and *Malassezia* dermatitis are controlled. Overall, it is probably safe to inform clients that up to 50% of dogs with allergic pruritus will improve with modification in fatty acid intake, if secondary bacterial and yeast infections are controlled. Synergistic effects have been documented between fatty acids and other antipruritic agents such as antihistamines and glucocorticoids (Scott et al, 2001; Scott and Miller, 1990; Paradis et al, 1991). Fatty acid supplementation may also allow lower doses of antihistamines and glucocorticoids to be used to control clinical signs (Sævik et al, 2004; Bond and Lloyd, 1994; Paterson, 1995; Scott et al, 2001).

The use of fatty acids for management of allergic skin disease and papulocrustous (miliary) dermatitis in cats has been reported (Harvey, 1991, 1993, 1993a; Miller et al, 1993). More than

*Laboratory and clinical studies in a number of species have established a daily dosage for total omega-3 fatty acids that seems to be a reasonable starting point in patients with inflammatory disease. An initial dose of 50 to 300 mg of total omega-3 fatty acids/kg body weight/day seems to be effective in a large number of studies.

50% of allergic cats may improve, based on the results of uncontrolled, masked clinical trials published to date. Better clinical studies using randomization, placebos and masked protocols are needed in cats with allergic and other forms of dermatitis.

Laboratory and clinical studies in a number of species have established a daily dosage for total omega-3 fatty acids that seems to be a reasonable starting point in patients with inflammatory disease. An initial dose of 50 to 300 mg of total omega-3 fatty acids (ALA, EPA and/or DHA)/kg body weight/day seemed to be effective in a large number of studies (Endres et al, 1989; Lee et al, 1985; Logas and Kunkle, 1994; Kremer et al, 1987, 1995; Geusens et al, 1994; Hawthorne et al, 1992; Vaughn and Reinhart, 1994; Lorenz et al, 1989; Stenson et al, 1992).[d,e] As a food amount, this dose range translates to approximately 0.35 to 1.8% total omega-3 fatty acids (DM). Also, this total dose can be supplied through a combination of appropriate foods and supplements.

Dietary omega-3 fatty acid supplements are usually derived from cold-water marine fish oils. Food ingredient sources of EPA and DHA are usually fish meal or fish oil. Most commercial pet foods already exceed the omega-6 EFA requirement for LA by using vegetable oil and/or vegetable ingredients in their formulas.

Feeding Plan

Assess and Select the Food and/or Supplement

Patients with dermatitis having an inflammatory component may benefit from changes in dietary fatty acid intake. The most common modification is to increase omega-3 fatty acid intake and/or increase intake of GLA, an omega-6 fatty acid. **Table 32-7** lists typical pet food ingredients and supplements with their associated fatty acids.

Changing the food, adding a supplement or both can modify fatty acid levels in the overall diet. Initially, the EFA levels in the current food should be assessed. Unfortunately, information about fatty acid concentrations in commercial pet foods is sometimes difficult to obtain. This information is not typically found in guaranteed or typical analysis statements on pet food

labels and is often not published by the manufacturer. In those cases, the manufacturer should be contacted directly to obtain information about fatty acid concentrations in specific products. **Tables 32-8** and **32-9** contain information about fatty acid concentrations in selected commercial dog and cat foods, respectively. These tables compare the fatty acid intake of dogs and cats eating specific foods and supplements. If the patient is given a supplement, the fatty acid concentrations in the supplement should also be determined. Most supplements marketed to improve skin and coat list the fatty acid concentrations on the product label or in published technical information. **Tables 32-8** and **32-9** also contain information about fatty acid concentrations in selected commercial fatty acid supplements.

In many cases, fatty acid supplements contain much lower concentrations of fatty acids than concentrations already found in the food being consumed by the patient (**Tables 32-8** and **32-9**). Thus, it may be more appropriate and convenient to change the patient's food to one with higher concentrations of appropriate fatty acids rather than adding a fatty acid supplement to the current food. In some clinical cases, changing the food and simultaneously adding a fatty acid supplement may be appropriate.

The optimal concentrations and ratios of fatty acids have not been established for normal dogs and cats or patients with clinical disease. Trial and error with various food and supplement combinations may be needed in an individual patient to achieve the best clinical response.

The risks and side effects of high levels of dietary fatty acids are few. Soft feces, overt diarrhea, flatulence and oral malodor ("fishy breath") are most commonly noted at levels of fatty acid supplementation used in most patients. These risks and side effects are outweighed by the possibility that fatty acid supplements will allow practitioners to reduce or discontinue corticosteroid therapy for pruritic dogs and cats. Other nutrients such as zinc, magnesium, biotin, pyridoxine, vitamin E and vitamin C are important cofactors in fatty acid metabolic pathways. Most commercial pet foods have adequate levels of these nutrients; routine supplementation would not be expected to improve clinical response. Many fatty acid supplements contain additional amounts of these cofactor nutrients.

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical

nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Assess and Determine the Feeding Method

Other than supplementation, the method of feeding is often not altered in the nutritional management of allergic dermatitis. If a new food and/or a supplement is fed, the amount to feed can be determined from the product label or other supporting materials. The food dosage may need to be changed if the caloric density of the new food differs from that of the previous food. The food dosage is usually divided into two or more meals per day. The food dosage and feeding method should be altered if the animal's body weight and body condition are not optimal.

For clinical nutrition to be effective, there needs to be good client compliance. Enabling compliance includes limiting the patient's access to other foods and knowing who is responsible for feeding the food. If the patient comes from a multiple-pet household, it should be determined whether the pet with dermatitis has access to the other pets' food.

Reassessment

Allergic dermatitis patients receiving appropriate omega-3 fatty acid dietary intervention will usually respond over several weeks to several months (**Tables 32-10** and **32-11**). After a dietary change or supplement has been started, the patient should be examined every four weeks for significant improvement in pruritus or skin erythema. Some patients may not respond for several months or may need concurrent therapy with antihistamines, topical agents (medicated shampoo) or corticosteroids.

CASE 32-1

Seborrheic Dermatitis in a Cocker Spaniel

Dawn E. Logas, DVM, Dipl. ACVD
College of Veterinary Medicine
University of Florida
Gainesville, Florida, USA

Patient Assessment

A four-year-old spayed female cocker spaniel had a two-year history of seborrhea. The dog had previously been treated with antibiotics, steroids and topical antiseborrheic shampoos with minimal improvement. The dog weighed 10 kg and had a body condition score of 3/5.

The only abnormalities noted on physical examination were an odoriferous generalized dermatosis and bilateral otitis externa. The dermatosis was characterized by erythematous and hyperpigmented hyperkeratotic plaques in which the hairs were coated with keratinaceous casts that formed "fronds" (**Figure 1**). Multiple papules and pustules were noted on the ventrum and dorsum. Both ear canals were mildly erythematous and swollen with a thick, yellow waxy discharge.

Skin scrapings for parasites and fungal culture for dermatophytes were negative. Tape preparations of the skin revealed many cocci. Ear cytology revealed numerous yeast organisms. A culture specimen from a pustule grew moderate numbers of *Staphylococcus intermedius* colonies that were sensitive to all antibiotics except penicillin, amoxicillin and tetracycline. Histopathologically, the hyperkeratotic plaques were characterized by marked follicular hyperkeratosis with distended follicular ostia, orthokeratotic hyperkeratosis of the epidermis and irregular epidermal hyperplasia (**Figure 2**).

Assess the Food and Feeding Method
For the three years before presentation, the dog had eaten a commercial specialty brand dry dog food supplemented with table foods.

Therapy Including Feeding Plan
The tentative diagnosis was vitamin A-responsive dermatosis with superficial pyoderma and yeast otitis. Treatment was initiated with 10,000 IU of vitamin A orally along with the dog's original food. The patient was also given an appropriate antibiotic for the pyoderma and a topical antifungal for the yeast otitis.

Questions
1. Why is vitamin A essential for normal epidermal function?
2. Why is this condition referred to as vitamin A-responsive dermatosis?
3. What are possible mechanisms by which vitamin A might correct the keratinization defect of this dermatosis?
4. How long must vitamin A be given to this dog and what potential side effects of vitamin A therapy might be expected?

Figure 1. Hyperpigmented, hyperkeratotic plaques with fronding on the ventrum of a four-year-old cocker spaniel.

Figure 2. Skin biopsy specimen from a seborrheic cocker spaniel. The epidermis is mildly hyperplastic and hyperkeratotic. There is severe follicular hyperkeratosis and dilatation. (Magnification 10X.)

Answers and Discussion
1. Vitamin A appears essential in the control of epidermal differentiation from basal cells to corneocytes. This is best illustrated by comparing the dermatologic signs of vitamin A deficiency with the signs associated with vitamin A excess. Mucous membrane epithelium is normally composed of nonkeratinizing cells. In vitamin A deficiency, nonkeratinizing mucous membrane cells are replaced by keratinizing cells and cells that normally keratinize in the skin become hyperkeratotic. The opposite response occurs when vitamin A is given in excess; mucous or ciliated squamous cells replace cells that normally keratinize.
2. Serum vitamin A levels have been normal in all of the reported cases of vitamin A-responsive dermatosis. This finding suggests that systemic vitamin A deficiency is an unlikely cause of the dermatosis. These cases also fail to show other clinical signs associated with vitamin A deficiency such as retinal degeneration, hind leg weakness and keratinization of mucous membranes. Improvement is noted within three to four weeks of starting oral vitamin A alcohol (retinol) supplementation, with complete remission by eight to 10 weeks. The specific cause of the dermatosis is unknown but may represent a local or functional deficiency of vitamin A.
3. Vitamin A may be able to correct this dermatosis via anti-keratinization effects. Vitamin A normalizes the proliferation of keratinocytes and decreases the epidermal hyperproliferation. Vitamin A also alters the expression of certain structural genes that are important in epidermal differentiation and cornification. Examples include the suppression of transglutaminase, which is important in cell envelope formation, and the alteration of keratins to K19 and K13, which are normally not found in adult skin but are in fetal skin. Finally, vitamin A induces growth factors and the expression of growth factor receptors that also suppress epidermal differentiation.
4. These dogs usually must be given vitamin A for life. Discontinuing vitamin A supplementation usually results in recrudescence of dermatologic signs. Dogs generally tolerate vitamin A therapy quite well with minor side effects. Vitamin A should be used with caution in breeding animals because it may be teratogenic.

Progress Notes
The dog has done very well as long as vitamin A supplementation has been maintained. Cutaneous lesions reappeared when vitamin A supplementation was discontinued.

CASE 32-2

Recurrent Pyoderma in a Chesapeake Bay Retriever
Dawn E. Logas, DVM, Dipl. ACVD
College of Veterinary Medicine
University of Florida
Gainesville, Florida, USA

Patient Assessment
A two-year-old intact male Chesapeake Bay retriever was presented with a 12-month history of recurrent bacterial pyoderma and seborrhea sicca. The dog had previously been treated with two- to three-week courses of various antibiotics at appropriate doses. Response to therapy was partial; papules and pustules would resolve but epidermal flakes and dry brittle hair persisted. All dermatologic signs including papules and pustules would return within weeks after antibiotic therapy was discontinued. Historically, the dog had no other problems.

The dog was slightly underweight (body condition score 2/5), normothermic, alert and well hydrated. Mucous membranes were pink and capillary refill time was 1.5 seconds. Lymph node size, chest auscultation and abdominal palpation were all within normal limits. No abnormalities were noted on ocular or musculoskeletal examination. Both ears had a slight accumulation of yellow waxy exudate but were not inflamed. The coat was thin, dry and lacked sheen. The dermatosis was generalized, sparing only the head and feet. It consisted of large white flakes, papules, pustules, epidermal collarettes and crusts. The dog was only mildly to moderately pruritic; the pruritus historically abated with antibiotic therapy.

Skin scrapings for parasites and fungal culture for dermatophytes were negative. Tape preparation of the skin revealed moderate numbers of cocci bacteria. *Staphylococcus intermedius* was cultured from a pustule. Thyroid profile results were within normal limits.

Assess the Food and Feeding Method
The dog was fed a grocery store brand dry puppy food until 10 months of age at which time the client switched to a generic dry adult dog food. The owner would often purchase whatever generic dog food was on sale.

Therapy Including Feeding Plan
The dog was diagnosed as having a recurrent pyoderma possibly secondary to malnutrition associated with consumption of generic dog food. The pyoderma was treated for six consecutive weeks with an appropriate antibiotic. The food was changed to a grocery brand dry adult dog food supplemented with one tablespoon of corn oil for 12 weeks.

Questions
1. Which major nutrients are essential for normal epidermal function and how might dermatoses due to malnutrition occur in patients eating generic pet foods?
2. How might consumption of generic food have contributed to the dog's recurrent pyoderma?
3. Could nutritional deficiencies account for the dermatologic signs (other than the pyoderma) observed in this dog?

Answers and Discussion

1. Nutrients of special concern for maintaining normal skin and hair include protein, essential fatty acids (EFA), copper, zinc and certain vitamins. A previous report summarized the dermatologic signs that occurred in 13 dogs fed generic pet foods. Generic pet foods are marketed based on low daily cost of feeding. The low cost of the food is usually achieved by using ingredients that often have low total digestibility, low nutrient availability, high mineral content and low quantities of fat and EFA. Foods with high mineral levels (calcium, phosphorus, magnesium), poor digestibility, high levels of phytate and/or low levels of total fat and EFA are a significant risk factor for zinc-responsive cutaneous disease. See the section of this chapter that discusses the dermatologic signs associated with fatty acid and zinc deficiency.
2. Malnutrition resulting from consumption of generic dog food may have contributed to the recurrent pyoderma in this dog. Decreases in zinc and EFA can lead to changes in the microenvironment of the stratum corneum, which allow pathogenic bacteria to colonize the surface of skin. Once colonized, the skin may also be less able to control the infection because decreases in zinc, protein and EFA may diminish normal humoral and cellular immunity. Zinc deficiency impairs macrophage phagocytosis, diminishes chemotaxis and leads to lymphopenia. Decreased levels of EFA, which are normally converted to potent inflammatory mediators called eicosanoids, lead to decreases in chemotaxis, margination and killing ability of leukocytes, particularly neutrophils. Inadequate protein intake, particularly of essential amino acids, can alter the immune response.
3. EFA and zinc deficiency could account for the dry dull coat, fine scale and hyperkeratotic crusts. EFA are necessary for the formation of lamellar granules, which contain much of the epidermal lipids in dogs. These lipids are essential for the formation of the transepidermal water barrier. Without these lipids, the stratum corneum water loss increases and fine scales are formed. EFA are also necessary for the formation of normal sebaceous gland lipids. The sebaceous lipids are important for coating hairs and giving them their sheen.

   Zinc is necessary for normal keratinization. Although the exact mechanisms of zinc's effect on keratinization are unknown, they may be related to the many zinc metalloenzymes, which are found in the epidermis and are essential for epidermal cell differentiation. Therefore, zinc deficiency could lead to the hyperkeratotic crusts noted in this case.

Progress Notes

After six weeks of therapy there was no evidence of bacterial pyoderma or dry flakes. The patient's coat was much softer, shinier and fuller. Eight months after discontinuing antibiotic therapy, the dog's coat and skin remained normal with no recurrence of the pyoderma.

CASE 32-3

Crusting Dermatitis in a Bull Terrier

Candace A. Sousa, DVM, Dipl. ABVP and ACVD
Pfizer Animal Health
Sacramento, California, USA

Patient Assessment

A four-year-old spayed female bull terrier was examined for severe skin crusting. The crusting had been present since the dog was five months old and had progressively worsened. Previous diagnostic tests included multiple skin scrapings for parasites (negative), a fungal culture (negative) and failure of a clinical response to several empirical therapies (antibiotics, shampoos).

Physical examination demonstrated a mature bitch that was well fleshed but smaller than breed standards (11.7 kg, body condition score 3/5). There were no abnormal physical findings other than those related to the integument. The coat was dull and brittle. Cream-colored patches of thick, tightly-adherent crusts were present above each eye, within the inner pinnae (**Figure 1**) and overlying the elbows and hocks. All of the footpads were thickened and cracked with "feathers" of adherent keratin extruding from the edges (**Figure 2**).

Results of a complete blood count, serum biochemistry profile and urinalysis were normal. Histopathology of skin biopsy specimens revealed marked parakeratotic hyperkeratosis. Neutrophils infiltrated the superficial dermis with some exocytosis, spongiosus and scattered individual dyskeratotic keratinocytes in the epidermis.

Assess the Food and Feeding Method
The dog had been fed a dry commercial food formulated for puppies for the first 10 months of life and several different dry dog foods formulated for adult maintenance for the next three years.

Therapy Including Feeding Plan
Based on the age at onset, breed, diagnostic results and a lack of response to various therapies, a tentative diagnosis of acrodermatitis of bull terriers was made.

Questions
1. What nutritional therapy should be recommended for this dog?
2. What other information should the owner be given regarding this disease and the prognosis for the dog?

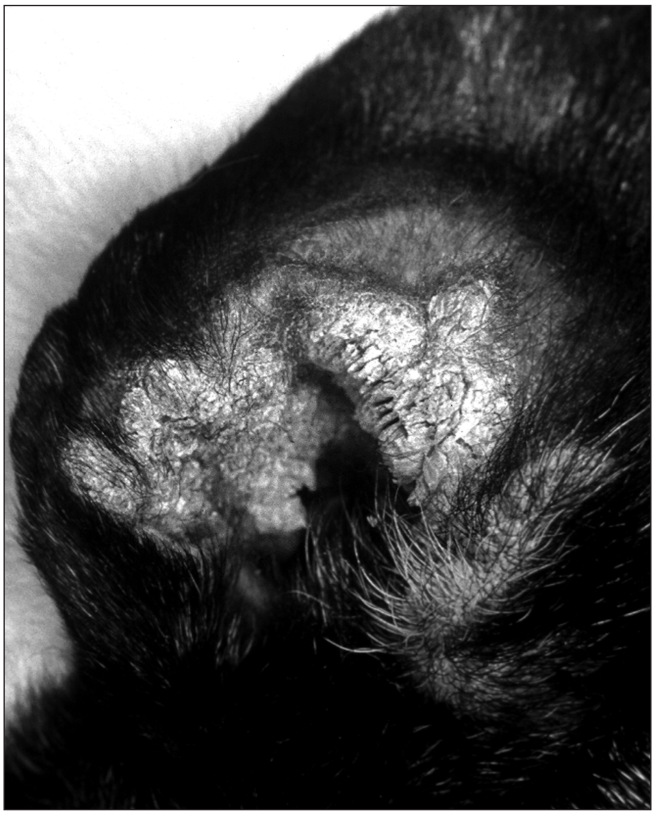

Figure 1. A four-year-old bull terrier with thick crusts in the inner pinna at the ear canal entrance.

Figure 2. The same dog with hyperkeratosis of the footpads.

Answers and Discussion
1. Acrodermatitis develops in bull terriers shortly after birth and is associated with defects in zinc absorption and metabolism. Cutaneous and systemic clinical signs resemble severe zinc deficiency with growth retardation, gastrointestinal disease, chronic bacterial infections and progressive, erythematous, exfoliative, papular to pustular dermatitis of the distal extremities and skin surrounding the mucocutaneous junctions. Surface crusts usually contain numerous bacteria and yeast organisms.

   Supplementation of the food with oral or intravenous zinc usually fails to ameliorate clinical signs. Treatment with systemic antimicrobials, especially for secondary superficial yeast infections, may result in marked improvement, although systemic and cutaneous infections recur. This dog was treated with a zinc methionine supplement (50 mg once daily) and oral cephalexin (250 mg b.i.d.) for secondary pyoderma.
2. Acrodermatitis is an inherited, autosomal recessive metabolic disease reported to occur in bull terriers in the United States, Canada and the United Kingdom. This bitch had already been spayed but further breeding of this dog's parents should be discouraged. The condition has been termed lethal acrodermatitis because homozygously affected dogs rarely live beyond 18 months of age. Some of the apparently normal littermates may develop zinc-responsive dermatitis. Owners of affected dogs usually complain that their pets have skin disease, stunting, difficulty with eating and large, splayed, painful feet. Ulcerated and thick, crusted lesions are prominent on the muzzle and ears. Abnormal keratinization of the footpads, severe nail dystrophy and paronychia are also common. Prognosis is guarded to poor for severely affected dogs.

Progress Notes
After eight weeks of therapy, the crusting shown in the pictures had decreased about 30%. At that point, the dog was lost to further evaluation.

CASE 32-4

Crusting Dermatosis in a Siberian Husky Crossbred Dog

Candace A. Sousa, DVM, Dipl. ABVP and ACVD
Pfizer Animal Health
Sacramento, California, USA

Patient Assessment

A four-month-old male Siberian husky crossbred dog weighing 18 kg was presented for evaluation of an eight-week history of variable but persistent crusting. The lesions were first noticed above the eyes and around the mouth, but now extended to the chin and neck. A fungal culture was negative for dermatophytes. Therapy with topical agents, cephalexin and griseofulvin resulted in no clinical improvement. No history was available for either the parents or related dogs.

Physical examination revealed a bright, active and alert puppy with a body condition score of 3/5 (ideal). The only abnormalities noted were limited to the skin. Thick, tightly adherent white crusts were noted above both eyes. The outer ear pinnae were alopecic and crusty. Scattered, white, tightly adherent crusts 1 to 3 cm in diameter were found around the lip margins (**Figure 1**) and ventral neck.

Histopathology of multiple skin biopsy specimens demonstrated severe irregular acanthosis accompanied by prominent parakeratosis and marked serocellular crusting. The parakeratosis extended into the superficial hair follicles. A mixed inflammatory infiltrate, which included lymphocytes, macrophages, neutrophils, plasma cells and scattered eosinophils, was found beneath the acanthotic and multifocally spongiotic epidermis.

Assess the Food and Feeding Method

The owners fed the dog a combination of commercial moist and dry foods formulated for puppies after they obtained it from a private home at nine weeks of age.

Questions

1. Given the signalment and clinical signs, what diseases should be considered?
2. What are the risk factors for development of zinc-responsive cutaneous disease in dogs?
3. What are the best methods to diagnose zinc-related cutaneous disease in animals?
4. Outline an appropriate feeding plan for this puppy.

Answers and Discussion

1. The list of differential diagnoses for this dog should include demodicosis, dermatophytosis, bacterial pyoderma, primary keratinization defect (e.g., ichthyosis), nutritional dermatosis (vitamin A-responsive or zinc-responsive dermatosis) and autoimmune skin disease (e.g., pemphigus foliaceus, pemphigus erythematosus and lupus erythematosus). The histopathologic changes were most compatible with a zinc-responsive dermatosis and secondary pyoderma.
2. Risk factors for zinc-responsive skin disease in dogs include breed, high mineral or phytate levels in the food, low essential fatty acid levels, supplementation with calcium or other minerals and small intestinal disease resulting in malabsorption or maldigestion. Breeds in which zinc-responsive disease has been reported to occur include Siberian huskies, malamutes, bull terriers, Great Danes, Labrador retrievers and other rapidly growing large- and giant-breed dogs.
3. Diagnosis of zinc-responsive cutaneous disease is based on the history, physical examination and skin biopsy results.

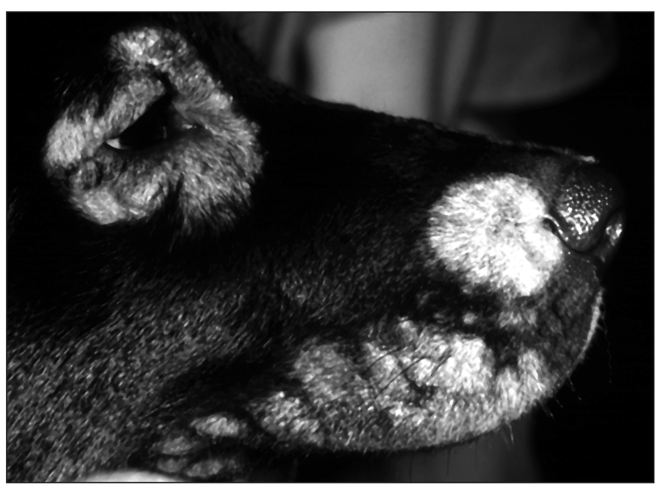

Figure 1. A four-month-old male Siberian husky cross with marked alopecia, lichenification and crusting of the periocular and perioral skin.

Hyperplastic superficial perivascular dermatitis with marked diffuse and follicular parakeratotic hyperkeratosis is suggestive of zinc deficiency. In general, concentrations of zinc in serum, leukocytes and hair are not good indicators of zinc status in dogs.

4. The tentative diagnosis was zinc-responsive dermatosis, which is often seen in Siberian husky dogs. Treatment generally includes changing to a food that avoids excess minerals and contains adequate amounts of zinc and essential fatty acids. Zinc supplementation will be necessary in those breeds in which decreased ability to absorb zinc is suspected. Siberian huskies are one such breed.

Progress Notes
Initial therapy consisted of feeding the moist food supplemented with 50 mg of zinc given orally once daily. Within two months, the lesions disappeared and the dog's coat had returned to normal. When the dog was 10 months old, the owner discontinued the zinc supplement and lesions began to return. Based on this finding, the dog will probably need zinc supplementation for the remainder of its life. Some Siberian huskies do not respond to oral zinc supplementation; however, intravenous injections of zinc sulfate solutions may be effective in these animals.

CASE 32-5

Pruritus and Seborrhea in a Wire-Haired Fox Terrier
Kevin P. Byrne, DVM, Dipl. ACVD
Bensalem, Pennsylvania, USA

Patient Assessment
A four-and-one-half-year-old, castrated male wirehaired fox terrier was examined for a two-year history of pruritus, oily coat and red skin bumps. Initially, the problems had been seasonal (occurring in the summer), but this year they did not clear up during the winter months. The pruritus had been responsive to oral prednisone. Physical examination revealed diffuse mild seborrhea oleosa with moderate erythema and scaling. These lesions were worse on the dorsum. Hypotrichosis with pustules and crusts were also found on the dorsum and in the axillae. Interdigital erythema was also present. The dog weighed 14 kg and had a body condition score of 4/5.

The initial evaluation of these problems included skin scrapings (negative) and interdigital skin cytology (no abnormal findings). Diagnosis was superficial bacterial pyoderma with seborrheic dermatitis and possible underlying allergic disease. Treatment was initiated with an oral antibiotic (cephalexin, 250 mg, t.i.d.), an antiseborrheic/antibacterial shampoo (twice weekly baths), and a six-week dietary elimination trial using a combination of commercial moist and dry therapeutic foods containing venison and potato.[a]

Six weeks later the dog weighed 13.5 kg and the owner reported a 50% improvement in the pruritus. Examination revealed no visible signs of bacterial pyoderma but erythema persisted in the axillary and interdigital areas.

Assess the Food and Feeding Method
The dog was normally fed a mixture of various dry and moist commercial grocery brand foods supplemented with occasional table foods (rice, potatoes, pasta) and various commercial biscuit snacks. The commercial venison and potato veterinary therapeutic foods were used for six weeks as part of a dietary elimination trial. The owners were instructed not to feed any other commercial foods, table foods or snacks during this trial.

Questions
1. What additional diagnostic tests would be helpful in this patient?
2. What dietary changes may help manage the pruritus and dermatitis in this patient?

Answers and Discussion

1. Underlying allergic disease due to atopy, flea allergy or food allergy could cause the pruritus, dermatitis and seborrhea seen in this patient and predispose the dog to secondary pyoderma. Atopy can be ruled out with intradermal and in vitro allergy testing. There was no evidence of flea infestation. The clinical improvement was probably due to elimination of the superficial bacterial pyoderma.
2. Supplementing the current food with fatty acids or changing to another food with higher fatty acid levels may benefit this patient. Fatty acid therapy alone is rarely successful in controlling moderate to severe pruritus in most patients with skin disease, but may be effective when used concurrently with other therapies. A synergistic effect between fatty acid and antihistamine administration has been documented in some clinical trials involving allergic dogs.

Progress Notes

Intradermal skin testing was positive for a few weed antigens. Blood was drawn for in vitro (ELISA) allergy testing. Positive reactions were found to house dust mites, several trees, several grasses and several weeds, including ragweed. The probable diagnosis was atopy with secondary superficial pyoderma and seborrhea. Treatment was initiated with an antihistamine (hydroxyzine, 25 mg, t.i.d.) and a fatty acid supplement[b] (1 capsule twice daily with food) that delivered 500 mg of eicosapentaenoic acid (EPA) daily in addition to the fatty acids in the food. Bathing with the shampoo was continued.

Eight weeks later the owners reported some improvement in the level of pruritus, but evidence of self-induced alopecia persisted (barbered hairs on the dorsal lumbar region). The skin was also erythematous; salivary staining was evident in these areas. The bathing, fatty acid supplementation and hydroxyzine administration were continued. Hyposensitization injections were started using allergens identified by the ELISA performed two months earlier. The veterinary therapeutic foods were fed until they were gone (about two weeks). At that time, the owner began feeding the dry and moist grocery store brand foods fed previously.

The owner reported significant improvement eight weeks later. There were no areas of visible erythema on the skin, but salivary staining persisted on all four feet. There was mild oiliness and scale accumulation on the dorsum. Bathing, hydroxyzine administration, hyposensitization injections and fatty acid supplementation were continued.

Further Discussion

The optimal dose of omega-3 fatty acids and γ-linolenic acid for control of inflammation and pruritus has not been established. The levels of these fatty acids in the grocery brand foods the patient was eating were unknown. The venison and potato veterinary therapeutic foods provided approximately 50 mg of omega-3 fatty acids per day to the patient. The supplement provided an additional 500 mg of EPA, which markedly increased total omega-3 intake. This dosing level may have been enough additional omega-3 fatty acids (36 to 40 mg EPA/kg body weight) to benefit this patient. The clinical improvement was probably attributable to the combination of all therapies used in this dog.

CLINICAL IMPORTANCE

The prevalence of musculoskeletal disorders for all dogs at multicenter referral practices has been reported to be approximately one in four, with 70% of these disorders involving the appendicular skeleton (Johnson et al, 1994; LaFond et al, 2002). Furthermore, the prevalence of musculoskeletal problems in dogs less than one year old in all breeds is about 22%, with 20% possibly having a nutrition-related etiology.[a] Developmental orthopedic disease (DOD) includes a diverse group of musculoskeletal disorders that occur in growing animals (most commonly fast-growing, large- and giant-breed dogs whose adult weight will exceed 25 kg) and that are sometimes related to nutrition. Canine hip dysplasia and osteochondrosis make up the overwhelming majority of the musculoskeletal problems with a possible nutrition-related etiology.[a]

Canine Hip Dysplasia

Canine hip dysplasia is the most frequently encountered orthopedic disease in veterinary medicine with heritability and a potential nutrition-related etiology (Johnson et al, 1994). Canine hip dysplasia is an abnormal development, or growth, of the hip joint (**Figure 33-1**) manifested by varying degrees of laxity of surrounding soft tissues, instability of the joint and malformation of the femoral head and acetabulum with osteoarthrosis (Brinker et al, 1990). The number of cases of canine hip dysplasia is estimated to be in the millions worldwide (Corley and Hogan, 1985).

Osteochondrosis

Osteochondrosis is widespread among people and young, rapidly growing, domesticated species. Generally, osteochondrosis is a disruption in endochondral ossification that results in a focal lesion (Brinker et al, 1990a). Osteochondrosis occurs in the physis and/or epiphysis of growth cartilage, and may be considered a generalized or systemic disease. Clinical signs of osteochondrosis are related to the severity and location of disease.

When osteochondrosis affects physeal cartilage, it may cause growth abnormalities in long bones such as angular limb deformities. Osteochondrosis of articular epiphyseal cartilage

Figure 33-1. Progression of joint disease in a dog with rear-limb lameness due to severe bilateral hip dysplasia. This ventrodorsal radiograph shows degenerative joint disease in both coxofemoral joints. The right hip has advanced osteophyte formation on the femoral neck. The right acetabular cup and femoral head have remodeled to form a pseudoarthrosis. The left femoral neck also has osteophyte formation and the hip is luxated craniodorsally.
.

commonly occurs in the shoulder (proximal humerus, **Figure 33-2**), stifle (distal femur), hock (talus) and elbow (distal humerus). Acute inflammatory joint disease (or degenerative joint disease) may ensue subsequent to development of osteochondrosis when the cartilage surface is disrupted and subchondral bone is exposed to synovial fluid. Inflammatory mediators and cartilage fragments are released into the joint (osteochondritis dissecans), which perpetuates the cycle of degenerative joint disease (Hill et al, 1984) (Chapter 34). Other disease processes such as spondylolisthesis, intra-articular fracture, complete or partial epiphysiolysis and deformed joint surfaces have been associated with osteochondrosis but their etiology is still undetermined.

Elbow Dysplasia

Elbow dysplasia describes the four main developmental dysplastic conditions that are frequently diagnosed in the elbow joint: 1) osteochondrosis of the medial condyle, 2) fragmented medial coronoid process, 3) ununited anconeal process and 4) elbow incongruency, due to a relatively short ulna. These conditions result in severe lameness although the clinical manifestation varies with the breed, the underlying diagnosis, the typical exercise pattern and the amount of osteoarthritis.

Breed specific distribution of the elbow dysplasia types has been recognized and elbow dysplasia has a complex hereditary background. Each of the conditions included may occur independently in the canine population, although they can occur in the same elbow in different combinations.

The frequency and severity of elbow dysplasia are also subject to environmental factors such as nutrition, body weight and exercise. The etiology is similar to what has been described for osteochondrosis-related conditions. It seems that fragmented medial coronoid process is not influenced by nutrition as much as the other three conditions.

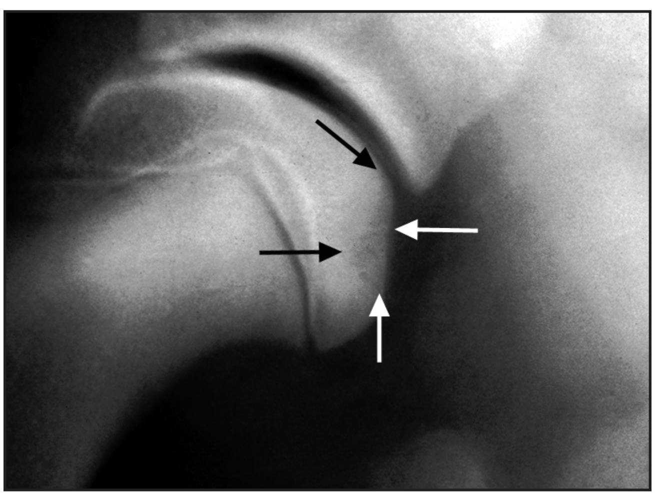

Figure 33-2A. Radiograph of the proximal humerus of a nine-month-old male Labrador retriever examined for forelimb lameness. The radiolucent area (arrows) indicates disrupted endochondral ossification and subchondral bone necrosis associated with osteochondrosis.

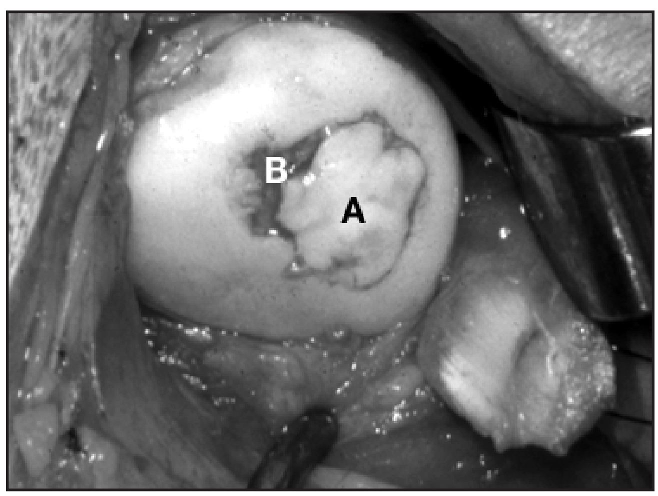

Figure 33-2B. Intraoperative view of an osteochondritis dissecans lesion in the articular epiphyseal cartilage of the proximal cartilage of the same dog. Note the cartilage flap (A) and exposed subchondral bone (B) where a portion of the cartilage flap is missing.

Growth Velocity

Puppy growth can be measured in height/length and body weight. Typically, when discussing growth in people, we assume an increase in height. Rapid growth in children means they reach an above average height at a certain age. Growth curves have been established per population and gender. However, in dogs, growth is usually measured in terms of body weight. When considering rapid growth, the risk is that real growth (increased height/length) becomes confused with the development of relative overweight during growth, resulting from excess food intake. This can become an issue when discussing risk factors for developmental disease conditions of the skeleton. The statement in the literature that overnutrition results in rapid growth is typically supported by body weight data and not by height/length measures. Because osteochondrosis conditions may be related to disturbed height/length growth and not just excessive weight, this discrepancy between human and canine growth references needs to be taken into account when interpreting growth. Some breed standards for popular dogs (including Labrador retrievers) tend to reflect overweight. This has to be taken into account when calculating energy requirements during growth relative to adult body weight.

Box 33-1. Use of DEXA to Assess the Skeleton.

The ability to make repeated, accurate assessments of body composition is crucial to the investigation of many key nutritional issues of cats and dogs. In a research setting, dual energy x-ray absorptiometry (DEXA) allows the body to be viewed as three compartments: bone mineral, fat tissue and lean tissue. The ability to evaluate changes in these three compartments independently greatly benefits the study of growth, obesity and geriatrics.

DEXA uses x-rays of two different energy levels (70 and 140 kVp) to distinguish the nature and amount of each tissue in the part of the body being scanned. The x-ray source below the table and the detector above the table move in concert to measure the amount of radiation passing through the subject. Because x-rays of different energy levels are impeded differently by bone mineral, fat and lean tissue, it is possible to calculate the quantity of each tissue in each area scanned.

The accuracy of DEXA in companion animals is supported by the good correlation between values obtained from DEXA and chemical analysis.

PATIENT ASSESSMENT

History and Physical Examination

Breed and familial history are important predisposing factors for DOD. For mixed-breed dogs, it is useful to know the breed of the stud and bitch as well as historical wellness of offspring. If possible, it may be helpful to gather information pertaining to skeletal abnormalities of previous litters from the same bitch and stud. If it is anticipated that the puppy will have an adult weight of more than 25 kg, it should probably be considered at risk.

Food intake and history should be evaluated as described in Chapter 1. Any treats and supplements fed to the patient should be scrutinized closely, paying special attention to the calcium and energy intake. It is critical to calculate, or closely estimate, metabolizable energy (ME) and calcium and phosphorus intake to provide good advice for feeding growing large- and giant-breed dogs.

Puppies should be weighed during the initial visit and all subsequent visits to help monitor their growth rate. A body condition score (BCS) should be determined and recorded at each visit (Chapter 1). Attention to abnormal changes in weight or BCS will help in assessing and managing growing dogs. In some cases, graphs of body weight and BCS may prove useful in recognizing variances from desired goals. BCS does not always reliably indicate overfeeding, because many young dogs react to higher energy intake with an accelerated growth rate.

Before a physical examination is conducted, historical information should be gathered about the degree, if any, of perceived lameness, the affected limb(s), duration of lameness and any peculiarities regarding the lameness. Following historical evaluation, the patient should be observed at rest for any gross conformational abnormalities. Next, the patient should be observed in motion to ascertain the degree of lameness and location of involvement (Brinker et al, 1990b).

If a locomotor defect is confirmed, the etiology should be determined. To determine the cause, the examination should include: 1) palpation of limbs for asymmetry, swelling, heat and sensitivity, 2) deep palpation of long bones, 3) flexion/extension of joints to determine range of motion, crepitation, instability and sensitivity and 4) neurologic evaluation. Even after a thorough physical examination, the exact cause of the lameness may remain undetermined.

Radiography

Radiographs should be taken to further define the clinical diagnosis. Radiographic identification of lesions aids in confirming the disease. However, inability to identify lesions by survey radiography does not always negate the presence of disease (Henry, 1992) (**Box 33-1**).

Laboratory Information

Diagnostic tests to detect other diseases that may result in skeletal abnormalities should be considered when appropriate. Confounding diseases such as osteomyelitis, septic emboli and mycotic infection should be considered. DOD is usually typified by a lack of abnormal laboratory findings (Hazewinkel, 1994; Nap and Hazewinkel, 1994).

Uncomplicated cases of DOD rarely have altered complete blood counts. Severe elevations or decreases in white blood cell counts usually indicate other disease processes. If anemia is present, classifying the type may give insight to other causes for select skeletal disorders (e.g., copper deficiency) (Zentek et al,

Table 33-1. Parathyroid hormone (PTH), ionized calcium and 1,25-dihydroxyvitamin D_3 concentrations in different physiologic/disease states.*

States	PTH	Ionized calcium	1,25-dihydroxyvitamin D_3
Apocrine gland tumors of the anal sacs	Low	High	Low
Chronic renal failure	High	Low/normal	Normal/low
High calcium intake	Low	High	Normal/low
Hypervitaminosis D	Low	High	Normal/high
Hypoparathyroidism	Low	Low	Low
Lymphosarcoma	Low	High	Low
Primary hyperparathyroidism	High	High	Normal/high

Disease Mechanisms in Small Animal Surgery, 2nd ed. Philadelphia, PA: Lea & Febiger, 1993; 1119-1128. Chastain CB, Ganjam VK, eds. Clinical Endocrinology of Companion Animals. Philadelphia, PA: Lea & Febiger, 1986; 192-217.

1991; NRC, 2006).

Occasionally, serum concentrations of calcium and phosphorus may be elevated or decreased during the genesis of DOD. However, absence of calcium or phosphorus perturbations does not rule out a diagnosis of DOD. Conversely, many other disease processes may result in altered calcium or phosphorus homeostasis, which indicates abnormal values are not pathognomonic for a diagnosis of DOD (Nap and Hazewinkel, 1994).

Increased bone remodeling may result in increased serum alkaline phosphatase activity. This parameter is already high in young, growing animals and may not be a very sensitive indicator of ongoing metabolic bone disease. Other enzyme activities in serum are not very useful for diagnosis of DOD. Biochemical markers of human bone metabolism such as type I collagen propeptides, tartrate-resistant acid phosphatase and osteocalcin are useful in research studies; however, the significance for veterinary diagnostics remains to be proven (Robey and Termine, 1990).

Serum and urinary assays of bone markers are of interest as noninvasive alternatives to bone biopsy. Assays that were developed for people have been shown to cross-react in dogs. Serum bone-specific alkaline phosphatase, urinary deoxypyridinoline and N-terminal telopeptide of collagen were measured in dogs with commercial enzyme immunoassays designed for people. Serum osteocalcin and carboxy-terminal cross-linked telopeptide of type I collagen were measured with commercial radioimmunoassays. Significant diurnal rhythms were identified for osteocalcin, bone-specific alkaline phosphatase, carboxy-terminal cross-linked telopeptide of type I collagen and urinary deoxypyridinoline. No clear rhythm was evident for N-terminal telopeptide of collagen. Due to the variability in marker excretion in individual animals, the most appropriate use for these assays is as a screening tool for cohort studies, rather than as a diagnostic or prognostic tool in individual animals (Ladlow et al, 2002). Breed effects cannot be excluded; however, for serum alkaline phosphatase and carboxyl-terminal cross-linked telopeptide of type I collagen, the concentrations were comparable in giant and toy breeds and in beagles (Breur et al, 2004).

Urinalysis results are usually within normal limits for animals with DOD. Advanced techniques, including measurement of calcium and phosphorus partial clearance ratios, may add insight about calcium and phosphorus nutrition, but repeated measurements may be needed for accurate interpretation. Evaluation of other mineral partial clearances may give some insight into dietary excesses or deficiencies. Analysis of urine for markers of bone turnover such as hydroxylysine glycosides, free pyridinolines or pyridinoline cross-links of collagen may prove useful in the future (Eyre, 1996).

Measuring and Interpreting Specific Laboratory Tests

PARATHYROID HORMONE

Interpretation of serum parathyroid hormone (PTH) concentrations from other species has proven that evaluation must be made in conjunction with presenting signs and other biochemical tests such as concentrations of ionized calcium and 1,25-dihydroxyvitamin D_3 (**Table 33-1**). PTH values may be increased, decreased or normal in DOD depending on the etiology. Increased PTH concentrations may be observed in association with renal disease, vitamin D deficiency and states in which insufficient calcium is present in foods. Decreased PTH concentrations may be observed when excess calcium or vitamin D is present in foods, and in other metabolic diseases.

PTH concentration is most accurately measured by a "two-site" immunoassay. This assay eliminates interference by mid-region or terminal fragments that are abundant in animal serum. Single time-point evaluations of PTH may not prove useful in determining the etiology of DOD. Repeated evaluations may yield more useable information, but are probably not cost effective.

CALCITONIN

Calcitonin, a peptide hormone, is released primarily from C-cells of the thyroid gland in response to sudden increased concentrations of ionized calcium in serum. Calcitonin may also be released in response to other stimuli such as gastrin secretion stimulated by food intake (Azria, 1989). Calcitonin is measured by radioimmunoassay (Hazewinkel et al, 1985, 1999). The test is not commercially available and rational interpretation requires multiple sample evaluations. If calcitonin levels are evaluated to investigate the etiology of DOD, results should be compared to normal values for the laboratory and interpreted in conjunction with results of other tests (e.g., PTH, ionized calcium and vitamin D_3 analyses).

VITAMIN D

Vitamin D_3 may be required in foods for dogs because endogenous synthesis may be limited (Hazewinkel et al, 1987; How et al, 1994). Because commercial foods contain added vitamin D_3, and in light of potentially limited endogenous synthesis, measurement of vitamin D_3 in serum may reflect dietary changes rather than specific disease states. 25-hydroxyvitamin D_3 is produced in the liver from vitamin D_3 and is a good indicator of general vitamin D_3 deficiency (Hazewinkel and Tryfonidou, 2002) or excess (Tryfonidou et al, 2003a). Another useful indicator of vitamin D_3 status is measurement of the most biologically active metabolite of vitamin D_3, 1,25-dihydroxyvitamin D_3, which is produced in the kidneys via the 1-α-hydroxylase enzyme. The concentration of 1,25-dihydroxyvitamin D_3 in serum is not a good indicator of vitamin D_3 toxicity (Tryfonidou et al, 2003a); however, it is a more sensitive indicator of deficiency than serum concentrations of 25-hydroxyvitamin D_3.

All metabolites of vitamin D_3 in serum may be measured by high-pressure liquid chromatography. Concentrations should be compared with reference values from laboratories performing the analysis, preferably derived from healthy dogs fed similar foods (Tenenhouse, 1990). A multitude of factors affect production of 1,25-dihydroxyvitamin D_3 including breed differences (Hazewinkel and Tryfonidou, 2002; Tryfonidou et al, 2003a) and laboratory results should be interpreted in conjunction with other physical and biochemical findings (**Table 33-2**). Generally, high concentrations of 1,25-dihydroxyvitamin D_3 indicate low availability of calcium to animals, normal concentrations indicate adequate calcium availability and low concentrations may indicate vitamin D_3 deficiency.

The amount of growth hormone and IGF-1 (insulin-like growth factor-1) may also directly influence vitamin D metabolism. In puppies, these hormones are inherently associated with growth rate and breed, with large-breed puppies having higher levels of these hormones than small breeds. Therefore, both dietary content and breed may influence metabolism of vitamin D and resultant bone development (Tryfonidou et al, 2003b).

Table 33-2. Factors affecting activity of 25-hydroxyvitamin D_3 renal 1-α-hydroxylase.*

Factors	Changes
Acidosis	Decrease
Alkalosis	Increase
Decreased ionized calcium	Increase
Decreased parathyroid hormone	Decrease
Increased 1,25-dihydroxyvitamin D_3	Decrease
Increased calcitonin	Increase/decrease/ no effect
Increased growth hormone	Increased vitamin D intake
Increased ionized calcium	Decrease
Increased parathyroid hormone	Increase
Increased phosphate (serum)	Decrease
Increasing age	Decrease
Insulin	Increase
Insulin-like growth factor-1	Increase
Pregnancy	Increase
Prolactin	Increase/no effect
Sex steroids	Increase

Table 33-3. Composition of bone.

Bone is composed of a mineral phase, a non-mineral (organic) phase and a cellular phase

Mineral phase
99% of body calcium
85% of body phosphorus
40-60% of body sodium and magnesium
Ca-P ratio 1.67:1 on a molar basis. Ratio is 2.15:1 on a weight basis (hydroxyapatite crystals = [$Ca_{10}(PO_4)_6(OH)_2$])

Organic phase
Type I collagen (90% of bone protein)
Noncollagenous protein (cell attachment proteins, proteoglycans, gamma carboxylated gla proteins, growth-related proteins)

Cellular phase
Osteoclasts
Osteoblasts
Osteocytes

CALCIUM

Bone contains 99% of the calcium in the body with the majority in the form of hydroxyapatite crystals (**Table 33-3** and **Box 33-2**). Bone functions physiologically as a structural material and an ion reservoir. When bone acts as an ion reservoir, it is in equilibrium with ionized calcium in serum and under tight homeostatic control.

Calcium homeostasis is maintained by the sum of physiochemical and calciotropic hormonal processes. Calcium in blood is in equilibrium between the ionized state (45 to 50%), a protein-bound state (40 to 45%) and a complexed or chelated state (5 to 10%). Generally, the concentration of ionized calcium is approximately 45 to 50% of the total concentration of calcium in serum over a wide range of total calcium concentrations. The concentration of ionized calcium is the most important determinant of calciotropic homeostatic regulation initiated by the parathyroid gland and the C-cells of the thyroid gland. Sudden increases in ionized calcium concentrations stimulate release of calcitonin from the thyroid gland, whereas decreases in concentrations of ionized calcium stimulate release of PTH from the parathyroid gland. The total concentration of calcium in serum is affected by the interplay of the homeostatic mechanisms involving influx (gastrointestinal [GI] absorption and bone resorption), efflux (GI and renal loss) and skeletal mineralization of the less labile bone pool as outlined below.

When concentrations of ionized calcium are below the normal range:

1. PTH secretion is stimulated, which in turn stimulates conversion of 25-hydroxyvitamin D_3 to the biologically more potent 1,25-dihydroxyvitamin D_3 in the kidneys.

Table 33-4. Summary of reports delineating risk factors for developmental orthopedic disease in dogs.

Diseases	Key points	Interpretation	Risk factors	References*
Hip dysplasia	Rapid weight gain German shepherd dogs First 60 days of age	Rapid weight gain increased risk of hip dysplasia. Dysplastic parents increased risk	Breed Rapid weight gain	Riser et al, 1964
Hip dysplasia	Pups born by cesarean section-hand reared Vaginally born pups, pair-fed bitch milk at 70% free choice	Free-choice feeding resulted in increased weight gain and increased occurrence of hip dysplasia	Free-choice feeding Rapid weight gain	Lust et al, 1973
Hip dysplasia	Labrador retrievers Rapid growth rate	Early fusion of triradiate growth plate in acetabulum	Breed Rapid weight gain	Lust et al, 1985
Hip dysplasia	Weight gain >breed standards	Increased occurrence of hip dysplasia	Rapid weight gain	Kässtrom, 1975
Hip dysplasia	Restricted feeding Labrador retrievers	Restricted feeding decreased occurrence of hip dysplasia	Breed Rapid weight gain	Kealy et al, 1992
Osteochondrosis	Epidemiologic study	Labrador retrievers, Great Danes, Newfoundlands, rottweilers at greatest risk All large breeds at increased risk	Breed Gender Anatomic location	Slater et al, 1991; Slater et al, 1992
Osteochondrosis	Epidemiologic study	Males at higher risk of OCD in shoulder	Gender Calcium content Well water	Dobenencker et al, 1997; Slater et al, 1991; Slater et al, 1992
Osteochondrosis	Great Danes Rapid growth Overnutrition	Rapid growth increased occurrence of developmental orthopedic disease	Breed Rapid growth	Daemmrich, 1991; Hedhammar et al, 1974; Meyer and Zentek, 1992
Osteochondrosis	Great Danes Excess calcium	Excessive calcium intake increased occurrence of developmental orthopedic disease	Breed Excessive calcium	Hazewinkel et al, 1985
Osteochondrosis	Great Danes Excess calcium and phosphorus intake	Excessive mineral intake at young age leads to hypercalcitoninism	Breed Excess minerals	Schoenmakers et al, 2000
Osteochondrosis	Great Danes Excess vitamin D intake	Imbalance of vitamin D metabolites at chondrocytes	Breed Excess vitamin D	Tryfonidou et al, 2003
Developmental orthopedic disease	Large breeds Rapid growth	Excessive energy intake increased occurrence of developmental orthopedic disease	Breed Rapid growth High energy density food	Richardson and Toll, 1997

2. 1,25-dihydroxyvitamin D_3 stimulates calcium uptake in the gut via receptor-mediated mechanisms.
3. 1,25-dihydroxyvitamin D_3, in conjunction with PTH, stimulates bone resorption and calcium reabsorption in the kidneys.
4. PTH induces phosphaturia.

When concentrations of ionized calcium are above the normal range:

1. Calcitonin secretion is stimulated, PTH secretion is suppressed and 1,25-dihydroxyvitamin D_3 production is not stimulated. Instead, the kidneys produce 24,25-dihydroxyvitamin D_3, which is generally considered biologically inactive.
2. Gut absorption and bone resorption of calcium are not stimulated.
3. Calcitonin decreases osteoclastic activity.
4. Renal calcium excretion is increased.

The equilibrium between the protein-bound and ionized fraction of calcium is affected by a variety of physiologic conditions. Alterations of serum proteins usually do not affect the equilibrium of bound to ionized calcium, but the total calcium may be increased or decreased. Alterations in albumin or total serum protein concentrations should be corrected before calcium values are evaluated (Feldman and Nelson, 1996).

Albumin correction:

Corrected total calcium (mg/dl) = Total calcium (mg/dl) – albumin (g/dl) + 3.5

Total serum protein correction:

Corrected total calcium (mg/dl) – (0.4 x total protein [g/dl]) + 3.3

The percent of total calcium bound to protein may be roughly estimated using differential binding affinities of albumin and globulin (Arnaud and Kolb, 1991).

% protein-bound calcium = 8 x albumin (g/dl) + 2 x globulin (g/dl) + 3

Acidosis shifts the equilibrium toward ionized calcium and is not accounted for by the above equation. Other physiologic perturbations, such as alkalosis, chloride ion concentration and phosphate ion concentration may also affect the equilibrium and are not accounted for by the above equation. Accurate determination of ionized calcium is best performed using ion selective electrodes.

Risk Factors

The genesis of DOD is presumed to be a multifactorial process. The most critical period for development of DOD is during the growth phase, before physeal closure (**Figure 33-3**). Specific factors that are currently thought to increase the risk of DOD in young dogs include: 1) belonging to a large or giant breed (genetics) (>25 kg adult weight), 2) free-choice feeding (management), particularly of high-energy foods (nutrition) and 3) excessive intake of calcium and vitamin D from food, treats and supplements (nutrition) (**Table 33-4**) (Hazewinkel et al, 1985; Daemmrich, 1991; Dobenencker et al, 1997; Hedhammar et al, 1974; Kasström, 1975; Kealy et al, 1992; Lust et al, 1973, 1985; Meyer and Zentek, 1992; Riser et al, 1964; Slater et al, 1991, 1992; Richardson and Toll, 1997; Tryfonidou et al, 2003a).

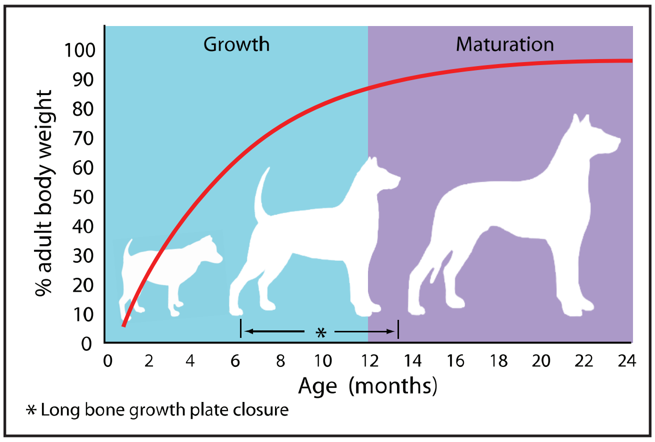

Figure 33-3. Growth phase vs. long bone physeal closure in dogs. Note that weight gain still occurs under the maturation phase although growth plate closure is complete. This is attributable to bone remodeling and especially to the acquisition of adult body mass, with the possible consequence of overweight/obesity.

Box 33-2. Calcium Deposition in Bone.

The actual physical mechanism of calcium deposition in bone is controversial. Evidence suggests the following:

- Calcium and phosphorus exist in metastable equilibrium in solution.
- A nucleation molecule initiates precipitation of solid calcium in collagen.
- Calcium is deposited initially as poorly crystalline type B (carbonate) apatite.
- Initial crystals have brushite properties but as they mature they become more hydroxyapatite in nature.
- Initial nucleation sites are within collagen fibrils.
- Nucleation sites are independent of each other (multicentric).
- Nucleation initiating molecules may include phosphoproteins, proteolipids and complex acidic phospholipids.
- Proteoglycans may inhibit or promote calcification centers.

The Bibliography for **Box 33-2** can be found at www.markmorris.org.

Etiopathogenesis

A variety of mechanisms are plausible in considering the pathogenesis of DOD. No one specific etiology is considered ultimately responsible for all observed clinical manifestations of DOD. Historically, feeding dogs imbalanced foods, especially those deficient in calcium, phosphorus or vitamin D_3, was the main risk factor predisposing them to skeletal diseases such as secondary hyperparathyroidism with subsequent development of osteodystrophia fibrosa (Daemmrich, 1991). Dietary deficiencies are rare in young, growing dogs fed commercial growth foods because most foods are formulated to meet or exceed allowances for specific nutrients (Kallfelz and

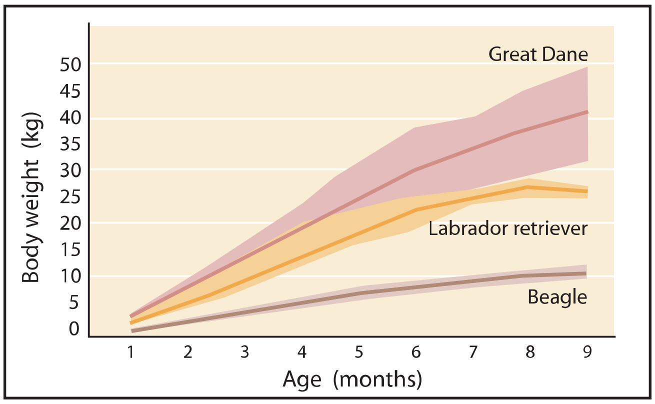

Figure 33-4. Growth curves (weight vs. age) for Great Dane, Labrador retriever and beagle dogs. Note that rapid growth occurs during the first few months in all breeds, but is prolonged in giant-breed dogs such as Great Danes.

Dzanis, 1989). Two popular theories for the pathogenesis of some types of DOD are discussed in the following sections. Specific nutrients are addressed in the Key Nutritional Factors section.

Theory 1: Energy/Growth/Biomechanical Stress

The musculoskeletal system changes constantly throughout life with the most rapid changes occurring during the first few months (**Figure 33-4**) (Hedhammar et al, 1974; Lust et al, 1973; Alexander et al, 1988; Allard et al, 1988; Booles et al, 1991; Booles et al, 1994; Meyer and Zentek, 1989; Romsos et al, 1976; Sheng and Huggins, 1971; Chakraborty et al, 1983; Lavelle, 1989; Rainbird and Kienzle, 1990). The skeletal system apparently is most susceptible to physical, nutritional and metabolic insults during the first 12 months of life because of heightened metabolic activity. Large- and giant-breed dogs are most susceptible to DOD, presumably because of their genetic propensity for rapid growth (Daemmrich, 1991; Meyer and Zentek, 1991).

Present knowledge about energy intake effects on bone growth gives rise to an hypothesis for the etiopathogenesis of growth disorders associated with overfeeding of energy to young, large- and giant-breed dogs. High energy intake directly affects growth velocity via nutrient supply and indirectly through changes in concentrations of growth hormone, IGF-1, triiodothyronine (T_3), thyroxine (T_4) and insulin (Blum et al, 1992; Danforth and Burger, 1989; Eigenmann et al, 1985; Nap, 1993). Dysregulation of these endocrine factors, whether attributable to nutrition, feeding management or genetics, during this critical period of skeletal growth may be responsible for producing an environment in which DOD develops.

Growth hormone and IGF-1 stimulate chondrocyte proliferation and differentiation (Daughaday et al, 1972; Froesch et al, 1985; Glade, 1984; Harris and Heaney, 1969; Hochberg et al, 1989; Isaksson et al, 1987; Eigenmann, 1986). Growth hormone release in non-canids is influenced primarily by energy intake but may also be affected by food protein content, specific amino acids or peptides, exercise and environmental factors (Nap and Hazewinkel, 1994; Blum et al, 1992; Glade, 1984; Eigenmann, 1986). IGF-1 is released systemically primarily from the liver but also locally from chondrocytes in response to growth hormone stimulus. Little is known about dietary influences on growth hormone secretion in dogs; however, young Labrador retrievers had a temporal decrease in concentrations of growth hormone from weaning to 14 weeks of age, followed by an increase in the prepubertal period (Chakraborty et al, 1983). IGF-1 was found in significantly higher concentrations in growing dogs fed free choice compared with animals on restricted feed allowance (Blum et al, 1992), whereas dietary protein intake only weakly influenced IGF-1 levels (Nap et al, 1993).

Free-choice feeding of dogs that results in excess energy intake is also accompanied by higher circulating concentrations of T_3 and T_4 compared with levels in food-restricted controls, reflecting a general stimulation of metabolic processes (Blum et al, 1992). Thyroid hormones are not only general stimuli for metabolic processes, including increasing the rate of bone formation and resorption, but are also important for capillary penetration of degenerating cartilage cells and the final stage of endochondral bone formation (Glade, 1984). In conjunction with the food-hormone relationships summarized here, additional endocrine or autocrine factors are involved in cartilage and bone metabolism (Glade, 1984); unfortunately, relevant data for growing dogs are unavailable. The result of these hormon-

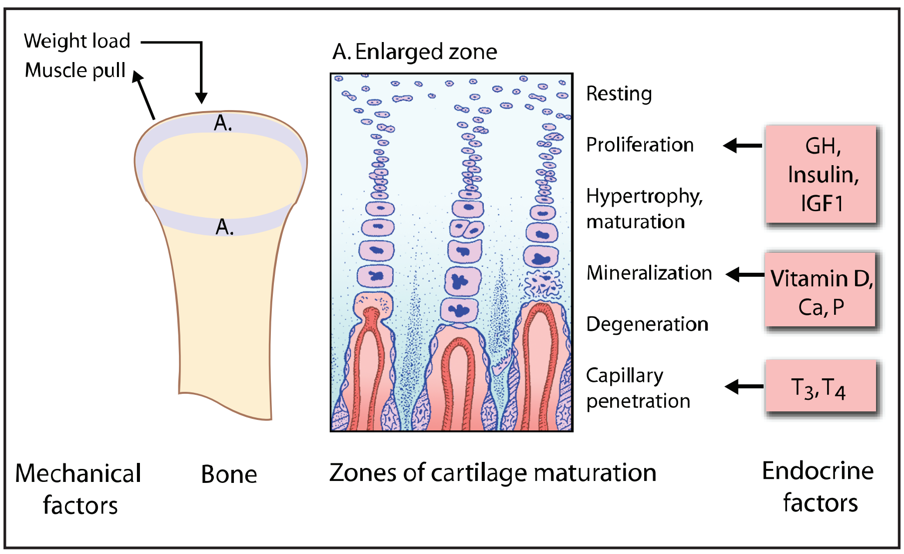

Figure 33-5. Biomechanical and endocrinologic influences on the growing skeleton are depicted. Biomechanically, excessive static (weight load) and dynamic (muscle pull) forces can damage immature skeletons. Note the various zones of cartilage maturation (resting zone, proliferation, hypertrophy and maturation, mineralization, degeneration and capillary penetration) where hormonal influences are thought to occur.

al influences is enhanced mitotic activity of proliferative cartilage cells, which may enlarge the width of the inherently mechanically unstable zone of chondrocyte growth.

Histologic examinations have revealed articular cartilage is less well supported by solid bone plates in rapidly growing dogs, compared with smaller breeds or to littermates fed restricted amounts after weaning (Daemmrich, 1991). The epiphyseal spongiosa of giant-breed dogs is inherently less dense and therefore assumed to be weaker than the spongiosa in small breeds, a tendency that may be exaggerated by overnutrition. Free-choice feeding may lead to a mismatch between bone growth and body growth, resulting in a lower ratio of long bone diaphyseal shaft cross-sectional area to body weight and also a less dense epiphyseal spongiosa.

The biomechanical stress induced by rapid weight gain during growth as discussed above has been cited as an etiology for DOD. It is unknown whether small focal cartilaginous lesions occur first and are then exacerbated by biomechanical stress (Daemmrich, 1991; Carlson et al, 1991), or if biomechanical stress first induces cartilaginous lesions (Hazewinkel et al, 1985; Hedhammar et al, 1974). In either case, increased static forces (weight load) and dynamic forces (muscle pull) may damage immature skeletons, especially in large- and giant-breed dogs. These dysregulations of nutrient supply, bone formation and endocrine regulation may interfere with skeletal maturation, thus increasing the risk for DOD in young animals (**Figure 33-5**).

Theory 2: Excess Calcium and Hypercalcitoninism

A contrasting theory to the preceding theory about high energy intake and rapid growth rate stems from the observation that the rate of DOD is increased in dogs with high calcium intakes (Dobenencker et al, 1997; Slater et al, 1992; Schoenmakers et al, 1997; Voorhout and Hazewinkel, 1987). Young Great Dane puppies fed a food high in energy and minerals free choice (Hedhammar et al, 1974), or high in calcium alone (Hazewinkel et al, 1985), developed osteochondrosis lesions with overt clinical signs of disease (**Figure 33-6**). These lesions appeared at both weight-bearing sites and sites where weight bearing was of no influence, such as the growth plates of ribs.

Feeding high-calcium foods to growing small-breed dogs results in histologic lesions but no clinical manifestations of DOD (Nap et al, 1993a). Large-breed dogs raised on food with a high calcium content or high calcium and phosphorus content had disturbed endochondral ossification (Nunez et al, 1974; Goedegebuure and Hazewinkel, 1986), retained cartilaginous cores in the distal radius and ulna (Schoenmakers et al, 1997; Voorhout and Hazewinkel, 1987) and delayed skeletal

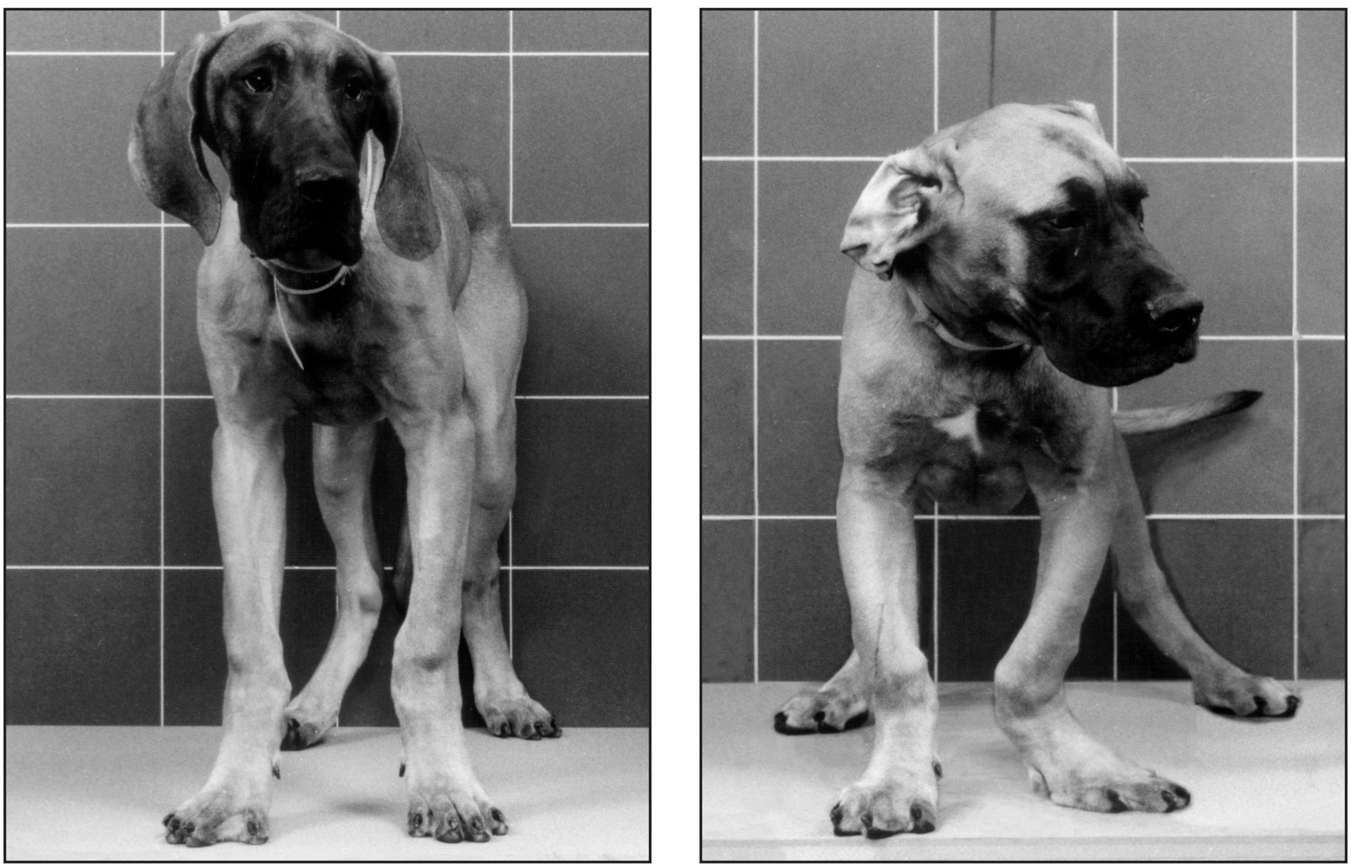

Figure 33-6. Littermate Great Dane puppies fed two different levels of dietary calcium. The puppy on the left was fed a growth food containing 1.1% dry matter calcium. The puppy on the right was fed a similar growth food containing 3.3% dry matter calcium. Note the poor growth and angular limb deformities in the puppy consuming excess calcium.

Table 33-5. Key nutritional factors for foods for growth (postweaning) of large- and giant-breed puppies.*

Factors	Dietary recommendations
Energy density	Energy density = 3.2 to 4.1 kcal/g; recommend the lower end of range if clients use free-choice feeding**
Fat	8.5 to 17%
Docosahexaneoic acid***	$\geq$0.02%
Calcium	0.8 to 1.2% calcium
Phosphorus	Phosphorus amount is based on calcium amount to maintain recommended Ca-P ratio (below)
Ca-P ratio	1.1:1 to 2:1 (the lower end of range is preferred)
Supplements	None recommended if a commercial food is fed

Key: Ca = calcium, P = phosphorus.
*Dry matter basis.
**To convert kcal to kJ, multiply kcal by 4.184. Free-choice feeding is not recommended. Energy intake can be better controlled through food-limited feeding.
***For improved learning.

maturation and growth of bone length (Voorhout and Hazewinkel, 1987). Calcium intake, therefore, seems to be a significant determining factor in DOD. This may occur either directly by calcium competing with other minerals or indirectly by stimulating hormonal effects (PTH or calcitonin) or acid-base balance (**Box 33-3**). Accordingly, hypercalcitoninism may be a contributing factor to DOD in dogs (Hazewinkel et al, 1985; Hedhammar et al, 1974). Dogs ingesting excessive amounts of calcium for a prolonged period exhibited hyperplastic C-cells in their thyroid glands (Goedegebuure and Hazewinkel, 1986; Martin and Moseley, 1990). Great Dane puppies, with access to food with increased calcium content from three to six weeks (i.e., partial weaning), had significantly higher calcitonin release after challenge with calcium infusion, compared with the response of littermates that had access to food containing 1% calcium (Schoenmakers et al, 2000). These same dogs had clinical and radiographic evidence of DOD when compared with controls (Hazewinkel et al, 1985; Goedegebuure and Hazewinkel, 1986; Martin and Moseley, 1990).

Calcitonin is released into blood, where it has a half-life of a few minutes, and reduces concentrations of calcium and phosphorus (Hazewinkel, 1994; Martin and Moseley, 1990). Extrapolation of calcitonin action in other species indicates that increased osteoblastic activity and decreased osteoclastic activity are responsible for shifts in plasma concentrations of calcium and phosphorus, which in turn may affect production of 1,25-dihydroxyvitamin D_3 (**Table 33-2**) (Weisbrode and Capen, 1990). It has been proposed that the physiologic action of calcitonin on bone turnover (decreased skeletal remodeling) and endochondral ossification are inciting causes of DOD in dogs. Commercial foods with increased levels of calcium, calcium and phosphorus or vitamin D are associated with severe disturbances in endochondral ossification, with subsequent osteochondrosis and radius curvus syndrome (Schoenmakers et al, 2000; Tryfonidou et al, 2003).

Key Nutritional Factors

Nutrients must be provided in appropriate amounts and balances for optimal bone development. Excesses of calcium and energy, together with rapid growth, appear to predispose dogs to certain musculoskeletal disorders such as osteochondrosis and hip dysplasia (Hedhammar et al, 1974; Meyer and Zentek, 1991). However, severe excesses, deficits and imbalances of any nutrient may affect bone development. The recommended levels of key nutritional factors are summarized in **Table 33-5**.

Energy and Fat

Energy intake is a major determinant of growth rate. The detrimental influence of excess energy intake on skeletal development during growth has been demonstrated in dogs (Hedhammar et al, 1974; Kealy et al, 1992; Daemmrich et al, 1992; Zentek et al, 1995) and other animals (e.g., chickens, turkeys, pigs) (Carlson et al, 1988; Hester et al, 1990; Nakano and Aherne, 1994; Oviedo-Rondon et al, 2006). Associated lesions appear in physeal and/or articular epiphyseal cartilages as disturbances of endochondral ossification (Daemmrich, 1991). The best method for avoiding excess energy intake is to limit it quantitatively by means of food-limited (food-restricted) feeding.

The risk of DOD appears to be increased in large- and giant-breed puppies fed highly palatable, energy-dense foods, free choice. This is sometimes true even if foods are well balanced (Lavelle, 1989; Daemmrich, 1991; Kealey et al, 1992; Meyer and Zentek, 1992; Hoefling, 1989; Meyer, 1990; Richardson, 1992). However, when large-breed puppies were fed a very low energy density food (3.16 kcal [13.22 kJ]/g ME, 8.0% fat dry matter [DM] basis free choice vs. a food of higher energy density and increased fat (3.98 kcal [16.65 kJ]/g ME, 23.9% DM fat), the puppies eating the low energy density food had less body fat but not slower growth (no difference between groups in radius/ulnar lengths) (Richardson et al, 2000). It should be noted that none of the puppies in either group developed signs of DOD. The results of this report suggest that if free-choice feeding is used, it should only be done in combination with a low energy density food to decrease the risk for DOD and obesity. However, generally, free-choice feeding is risky and is not recommended for large- and giant-breed puppies until they have attained adulthood. Furthermore, commercial foods for large- and giant-breed puppies typically have energy densities of approximately 4 kcal (16.7 kJ) ME/g (DM) and should be food-limited fed.

Dietary fat is an important contributor to the energy density of a food. Dietary fat yields 8.5 kcal ME/g, whereas dietary digestible carbohydrate and protein each yield 3.5 kcal ME/g. Thus, as the fat content of a food is increased, the energy density is also increased (unless sufficient fiber is substituted for either carbohydrate or protein). Furthermore, when the energy density of a food is increased, concentrations of other essential nutrients need to be increased accordingly so that requirements for these nutrients are met at a lower food intake. The minimum recommended allowance for dietary fat in foods for growing puppies is 8.5% (DM) (NRC, 2006). Upper limits for

dietary fat in foods intended for large- and giant-breed puppies have not been established but a dietary fat level of 17% is acceptable as long as the puppies are fed properly (food-limited feeding). The associated energy density range would be between 3.2 and 4.1 kcal ME/g (DM). Besides being an important energy source, dietary fat is necessary for the absorption of fat-soluble vitamins. Dietary fat is also important from the standpoint of its constituent fatty acids and their effects on bone metabolism.

Some dietary fatty acids may play a role in preventing DOD. Metabolism of lipid in bone is thought to be under the same regulatory controls as in other tissues (Gilder and Boskey, 1990). Lipid content of mineralized tissues ranges from 1.7% of dry weight for cartilage to 0.2% for bone and dentin. Although specific studies on long bone growth have not been performed, interesting results have been obtained in studies of dentin formation. Essential fatty acid deficiency leads to abnormal calculus deposition, loosened teeth and poor gingival color in rats (Prout and Tring, 1971). Other lipids may play equally important roles in several metabolic aspects of tissue calcification:

1. Phospholipids form matrix vesicles that may be important in new calcification sites.
2. Calcium-acidic phospholipid phosphate complexes may signal nucleation and apatite formation under appropriate conditions.
3. Proteolipids may help initiate apatite formation and calcification.
4. Prostaglandins may influence calcium resorption similar to PTH, and affect collagen synthesis.
5. Inositol phospholipids may mediate calcium transport in and out of cell organelles via second messenger systems.
6. Glycolipids are important constituents of most cell membranes and are found in high concentrations in epiphyseal cartilage. Their specific function is not understood.
7. Phosphatidylserine may act as an ionophore to mediate calcium translocation.

Although no specific studies have been performed in growing dogs to assess the effect of omega-3 (n-3) or omega-6 (n-6) fatty acids on musculoskeletal growth, studies in other species may prove important. Rats fed foods high in lard (animal fat) compared with those fed foods high in linolenic acid (vegetable fat) had increased weight gain and depressed T_3 concentrations (Takeuchi et al, 1995). Chicks fed four different lipid sources had the highest bone formation rate when fed butter and corn oil as the dietary fat (Watkins et al, 1997). Dietary lipids modulate bone prostaglandin E and IGF-1 production, and bone formation rate in chicks. Changing dietary omega-6 and omega-3 fatty acid concentrations alter eicosanoid production in dogs and help manage osteoarthritis. Omega-3 fatty acids are used to help manage osteoarthritis (Hansen et al, 1990). In a double-blind efficacy study with 36 osteoarthritic dogs, increased omega-3 fatty acid intake increased plasma concentrations of LTB_5 (a less inflammatory leukotriene), although these findings did not coincide with improved ground reaction forces (locomotion) (Hazewinkel et al, 1998) (Chapter 34).

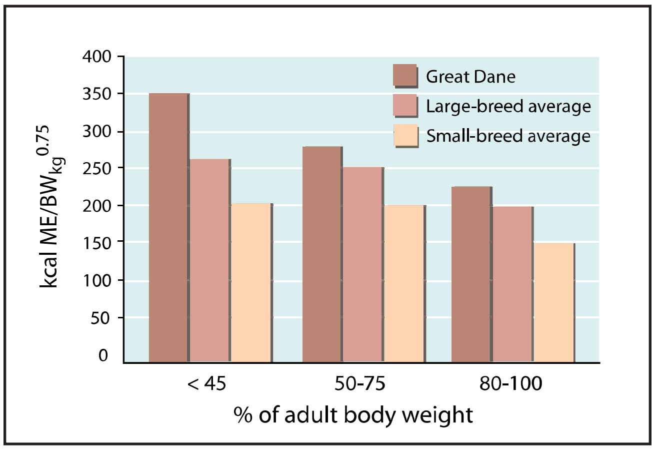

Figure 33-7. Average free-choice energy intake of Great Dane, large-breed and small-breed dogs in kcal metabolizable energy (ME)/$BW_{kg}^{0.75}$ as a percent of adult body weight. Note that energy intake is highest at <45% of adult body weight, which, on an age basis, is between the second and fourth month of life. Great Dane puppies appear to have higher energy requirements for growth than other large-breed dogs. (Adapted from Hedhammar A, Wu F, Krook L, et al. Overnutrition and skeletal disease. An experimental study in growing Great Dane dogs. Cornell Veterinarian 1974; 64 (Suppl. 5): 1-160. Meyer H, Zentek J. Über den Einfluß einer unterschiedlichen Energieversorgung wachsender Doggen auf Körpermasse und Skelettentwicklung. Journal of Veterinary Medicine A 1992; 39: 130-141. Meyer H. In: Ernährung des Hundes, 2nd ed. Stuttgart, Germany: Auflage. Eugen Ulmer, 1990. Rainbird A, Kienzle E. Untersuchungen zum Energiebedarf des Hundes in Abhängigkeit von Rassezugehörigkeit und Alter. Kleintierpraxis 1990; 35: 149-158. Zentek J, Meyer H, Daemmrich K. Untersuchungen einer Unterschiedlichen Energieversorgung auf die Wachstumsintensität und Skelettentwicklung bei Wachsenden Doggen. 3. Mitteilung: Klinisches Bild und chemische Skelettuntersuchungen. Journal of Veterinary Medicine A 1995; 42: 69-80.)

It is difficult to determine the appropriate daily energy requirement (DER) for growing dogs because few well-controlled studies have been conducted. Energy intake reaches a maximum, as related to body weight, in the second to fourth month of life (<45% adult body weight) (**Figure 33-7**). The data used to develop **Figure 33-7** were free-choice energy intakes from several breeds. These average intakes may be used as a crude guideline for determining energy requirements in growing puppies of different breeds.

Breed differences in DER during growth may occur, but it is difficult to give specific recommendations because of the lack of quality data. Based on a small number of observations in dogs over eight months of age, the average ME intake for Great Dane puppies ranged from 311 kcal (1,300 kJ)/$(BW_{kg})^{0.75}$ at weaning to 263 kcal (1,100 kJ)/$(BW_{kg})^{0.75}$ at six months of age. These values are higher than for other large breeds and are consistent with reports of higher energy requirements for Great Dane puppies (Rainbird and Kienzle, 1990; Meyer, 1990; Zentek and Meyer, 1992; Zentek et al, 1995). Marked restriction of ME intake (191 kcal/$(BW_{kg})^{0.75}$ [800 kJ/$(BW_{kg})^{0.75}$]) for Great Dane puppies may lead to unacceptable body composition (Zentek and Meyer, 1992).

Unrelated to DOD, but considered important for all grow-

Box 33-3. Dietary Cation-Anion Balance.

Alteration of dietary cation-anion balance (DCAB) has been reported to influence skeletal development in several species. The DCAB of a food can be described, most simply, by the equation ([Na] + [K] – [Cl] mEq)/100 g dry matter (DM). As the DCAB increases, the net physiologic effect is alkalinization. Conversely, as it decreases an acidification effect is observed and calcium excretion in urine is increased. Acidification will be buffered by carbonate liberated from bone by increased osteoclasia, thus increasing osteoporosis in adult and bone remodeling in young animals. The mechanism for these effects on skeletal development is unclear. In addition, regulation of body acid-base balance, calcium homeostasis and osmolality of the synovial fluid compartment may be influenced.

The role of electrolyte balance in canine nutrition appears to be most relevant to preventing canine hip dysplasia. Investigators have associated the DCAB with the radiographic changes of subluxation in the coxofemoral joints in several canine breeds. A food with a DCAB ([Na] + [K] – [Cl]) <23 mEq/100 g DM fed to large-breed puppies was associated with less severe femoral head subluxation, on average, when the puppies reached six months of age. The slowed progression of subluxation was also observed in dogs fed a food with a reduced DCAB from 33 to 45 weeks of age. Hip joint laxity was determined using Norberg hip scores computed from radiographs. Significant correlation between radiographic findings (e.g., Norberg hip scores) and progression of canine hip dysplasia, either radiographic or clinical, was not proved. The authors proposed the balance of anions and cations in the food (specifically Na, K, Cl) influenced the electrolytes and osmolality in joint fluid. The joint fluid of dysplastic dogs has higher osmolality and is increased in volume when compared with that of disease-free hips from dogs of the same breed. The changes in osmolality and fluid volume could be a result rather than a cause of canine hip dysplasia. These studies suggest an association between DCAB and joint laxity without proving a mechanism of action. Most commercial growth foods encompass a very small range of DCAB and probably do not vary greatly in risk.

In commercial dog foods, the relation between cations and anions is 22 to 46 mEq/100 g DM. The balance of only the electrolytes Na, K, Cl, calculated as equivalents, will be between 15 to 42 mEq/100 g DM. Feeding foods with a dietary anion gap of 8 mEq/100 g DM lowered the severity of subluxation of the femoral head in growing dogs of different breeds. Increasing this relation to 41 mEq/100 g food was accompanied by a higher degree of subluxation as determined by the Norberg angle on radiography. Because the knowledge and experimental databases are very small in dogs, mineral salts should not be added in large amounts to nutritionally balanced foods. Problems may arise not only from the addition of anions, but also from increasing the amounts of cations. Further research is needed in this field but it seems prudent to avoid excessive acidifying foods or acidifying agents in growing puppies.

The Bibliography for **Box 33-3** can be found at www.markmorris.org.

ing puppies, are the effects of specific fatty acids on trainability and the development of special senses. Studies indicate that docosahexaneoic acid (DHA) is essential for normal neural, retinal and auditory development in puppies (Pawlosky et al, 1997). Similar results have been found in other species (Pawlosky et al, 1997; Birch et al, 2002; Diau et al, 2003; Hoffman et al, 2003). The inclusion of fish oil as a source of DHA in puppy foods improved trainability (Kelley et al, 2004). The conversion of short-chain polyunsaturated fatty acids to DHA is an inefficient process in puppies (Bauer et al, 2005). Thus, the essentiality of adding a source of DHA should be considered for this growth phase. The minimum recommended allowance for DHA plus eicosapentaenoic acid (EPA) is 0.05% (DM) with EPA not exceeding 60% of the total (NRC, 2006). Thus, DHA needs to be at least 40% of the total DHA plus EPA, or 0.02% (DM).

Calcium, Phosphorus and the Ca-P Ratio

The amount of true calcium absorption in dogs ranges from 25 to 90% depending on the amount of intake and the age of the animal (Nap and Hazewinkel, 1994; Hazewinkel et al, 1991). Calcium is absorbed via three mechanisms: 1) active absorption, 2) facilitated absorption and 3) passive diffusion. Passive diffusion is especially important in young animals. Active absorption is most important in the proximal GI tract. Passive diffusion and facilitated absorption, however, are important in the distal GI tract, primarily because of prolonged transit time and increased calcium concentration through that section. Vitamin D_3 metabolites, especially 1,25-dihydroxyvitamin D_3, are the most important hormonal regulators of GI calcium absorption (Birge and Avioli, 1990). Analysis of 90 dogs revealed that active calcium absorption decreases with increasing age, whereas passive absorption remains constant during the period of rapid growth. When calcium intake is high, active absorption becomes negligible and passive absorption accounts for up to 53% of total absorption of the amount eaten. There is no difference between breeds (Tryfonidou et al, 2002). Previous studies showed serious consequences for skeletal development in large-breed dogs (Hazewinkel et al, 1985) but not for small breeds (Nap et al, 1991). PTH, vitamin D_3 and dietary cation-anion balance modulate renal handling of calcium (**Box 33-3**), whereas calcitonin does not play a significant role in this aspect in dogs.

In the face of adequate levels of calcium in the food, the absolute level of calcium, rather than an imbalance in the calcium-phosphorus ratio, influences skeletal development (Hazewinkel et al, 1985; Hazewinkel et al, 1991) (**Boxes 33-4** and **33-5**). In one study, the prevalence of DOD was significantly increased in young, giant-breed dogs fed a food containing excess DM calcium (3.3%) with either normal DM phosphorus (0.9%) or high DM phosphorus (3%, to maintain a normal calcium-phosphorus ratio) (Hazewinkel et al, 1991). These puppies apparently were unable to protect themselves against the negative effects of long-term calcium excess (Hazewinkel et al, 1985; Tryfonidou et al, 2002). Furthermore, long-term calcium intake increases the frequency and severity of osteochondrosis (Nap and Hazewinkel, 1994). The minimum calcium

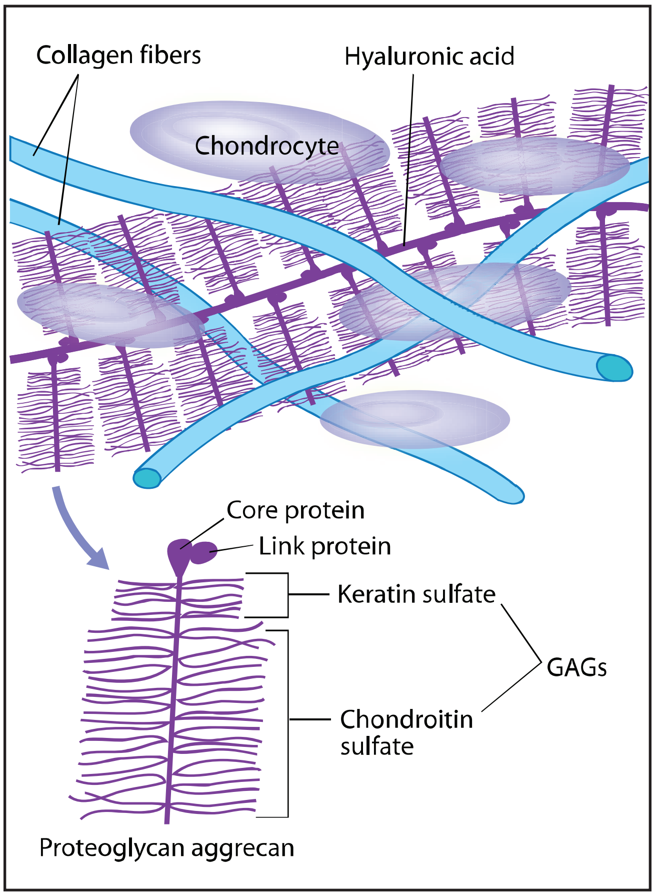

Figure 34-3. Microstructure of cartilage. Key: GAGs = glycosaminoglycans. (Adapted from White GW. DVM Best Practices. Nov. 2003.)

ly affect early diagnosis, development of therapeutics and ultimately clinical care.

Risk Factors

Dogs

Risk factors for developing osteoarthritis include age, breed (large or giant breeds), genetics, developmental orthopedic disease, trauma and obesity. Breeds with the greatest risk tend to be large and fast growing with genetic predispositions for developmental orthopedic diseases. These breeds include German shepherd dogs, rottweilers, Labrador retrievers and golden retrievers (Smith et al, 2001). Developmental orthopedic diseases are a heterogenous group of musculoskeletal disorders of growing dogs that can be affected by nutrition (Chapter 33). CHD, osteochondrosis, elbow dysplasia, fragmented medial coronoid process and ununited anconeal process are common developmental orthopedic diseases that can lead to osteoarthritis. The radiographic prevalence of CHD has been reported to be as high as 70% in golden retrievers and rottweilers (Paster et al, 2005). However, because CHD is a polygenic disease with complex inheritance, environmental factors such as nutrition and lifestyle can have a meaningful influence on its incidence and severity (Smith et al, 2006). Rupture of the cranial cruciate ligament is the most common cause of lameness in dogs and even with surgical correction, the most common traumatic cause of osteoarthritis in dogs (Hayashi et al, 2004; Wilke et al, 2005).

One long-term study documented that the prevalence and severity of osteoarthritis is greater in dogs with body condition scores above normal (Kealy et al, 2000). The mean age at which 50% of the dogs in this study required long-term treatment for clinical signs attributable to osteoarthritis was significantly younger (10.3 years, $p < 0.01$) for the overweight dogs compared to dogs with normal body condition scores (13.3 years) (Kealy et al, 2000). Traditionally, the mechanical stress of excess weight has been thought to be the primary perpetrator of the pathophysiology and progression of osteoarthritis. However, recent studies have documented metabolic activity in adipose tissue that may be of equal or greater importance. Adipocytes secrete several hormones including leptin and adiponectin and produce a diverse range of proteins termed adipokines. Among the currently recognized adipokines are a growing list of mediators of inflammation: tumor necrosis factor-α, interleukin-6, interleukin-8 and interleukin-10. These adipokines are found in human and canine adipocytes (Eisele et al, 2005; Trayhurn and Wood, 2004). Production of these proteins is increased in obesity, suggesting that obesity is a state of chronic low-grade inflammation. Low-grade inflammation may contribute to the pathophysiology of a number of diseases commonly associated with obesity including osteoarthritis. This might explain why relatively small reductions in body weight can result in significant improvement in clinical signs (Burkholder et al, 2000; Impellizeri et al, 2000).

Cats

Overweight cats are reported to be 2.9 times more likely to present for lameness not associated with cat bite abscesses (Scarlett and Donoghue, 1998). In one study, cats older than 12 years were examined for reasons other than lameness. Ninety percent of the radiographs taken documented at least one area of degenerative joint disease (Hardie et al, 2002). Radiographic evidence of osteoarthritis was found in 22% of the general population of cats, greater than one year of age, evaluated at primary care cat clinics in the United Kingdom over a four-year period. The highest incidence of osteoarthritis was found in cats older than 10 years (Godfrey, 2005). In both of these studies, the highest frequency of disease occurred in the elbow, with the vertebral column and stifle being the next most common sites, respectively. One prospective study of osteoarthritis in cats documented the elbow and hip as most commonly affected joints (Clarke and Bennett, 2006). Additional risk factors for osteoarthritis in cats include age-related cartilage degeneration, developmental and traumatic causes of joint instability, chondro-osseous dysplasia of Scottish fold cats, the storage disease mucopolysaccharidosis, nutritional imbalances (hypervitaminosis A), neuropathic diseases (diabetes mellitus) and immune-mediated polyarthritides (Allan, 2000).

Etiopathogenesis

The normal joint is composed of articular cartilage, subchon-

dral bone, joint capsule and supporting ligaments and tendons. The normal joint provides low friction motion and transfer of body weight across the articular surface during movement. Articular cartilage is made up of chondrocytes and extracellular matrix. Chondrocytes are terminally differentiated cells that are highly metabolically active throughout life (Roush et al, 2002). Normal cartilage is dynamic and is replaced over a one- to two-year period by the balance of the catabolic action of degradative enzymes on the extracellular matrix with the anabolic synthesis of matrix components by chondrocytes.

The extracellular matrix is composed of collagen, proteoglycans and water (**Figure 34-3**). Chondrocytes produce and maintain the extracellular matrix. Collagen fibrils (primarily collagen type II) provide structural support for the cartilage matrix. Proteoglycans are composed of glycosaminoglycan (GAG) chains attached to a central core protein. Chondroitin sulfate, keratin sulfate and dermatan sulfate are the most common GAGs in articular cartilage. Aggrecan is the shortened name for the large aggregating chondroitin sulfate proteoglycan. Aggrecan is the most common and well-defined proteoglycan in articular cartilage and is comprised of a core protein to which as many as 100 GAG chains are attached (Lepine and Hayek, 2001). Because GAGs are anionic and hydrophilic, they attract and hold water in a gel-like consistency. Aggrecans, with their hydrophilic GAGs, are normally contained within the framework of collagen fibrils, which limit their expansion when hydrated.

In the normal joint, cartilage must withstand both compressive and shearing forces. The unique relationship between collagen and proteoglycans provides the biomechanical properties necessary to withstand these forces. Collagen fibrils alone cannot resist compressive forces without collapse but tolerate tensile forces well, whereas hydrated aggrecan complexes weakly resist shear forces but withstand compressive forces (Johnston, 2005). When the normal distribution of collagen, proteoglycans and water is disturbed, the function of articular cartilage is altered, leading to changes typically associated with osteoarthritis.

Normal cartilage metabolism is a highly regulated balance between synthesis and degradation of the various matrix components. Osteoarthritis can be initiated by a variety of physical stresses that damage chondrocytes such as trauma, obesity or developmental orthopedic diseases. Despite the variety of initiating events, there seems to be common pathways that lead to the destruction of articular cartilage (Johnston, 1997). Once initiated, these molecular and cellular pathways interact to form a self-perpetuating cycle.

The instigating event of this cycle is thought to be loss of proteoglycans (aggrecans) (Caterson et al, 2000; Hegemann et al, 2002). Damage to chondrocytes causes up-regulation of catabolic enzymes, particularly aggrecanases (enzymes that cleave aggrecans at specific peptide bonds). This shift from anabolic to catabolic pathways is responsible for the loss of proteoglycans. Damaged chondrocytes also produce inflammatory mediators. Inflammatory cytokines contribute to the perpetuation and progression of arthritis by sustaining catabolic processes (Curtis et al, 2002). Initially, damaged chondrocytes attempt to compensate for this imbalance by producing increased quantities of proteoglycans and collagen. This may lead to an initial thickening of the articular cartilage; however, the quantity and quality of the proteoglycans and collagen produced are abnormal (Renberg, 2005). Eventually aggrecanases destroy proteoglycans faster than new ones can be formed. This imbalance escalates the deterioration of the extracellular matrix and cartilage's normal physiologic properties.

Without a healthy extracellular matrix, cartilage is unable to withstand the compressive forces of weight bearing. The net result is cartilage with decreased load bearing capacity and localized areas of softening (Vaughan-Scott and Taylor, 1997). Fibrillations and microfractures are early histopathologic changes. With progression of osteoarthritis, gross evidence of damage to articular cartilage becomes obvious. The normally smooth glistening surface becomes dull and rough. Fissures become evident and ultimately areas of cartilage erosion develop (**Figure 34-4**) (Renberg, 2005). Osteoarthritis affects not only the articular cartilage, but also the underlying bone and adjacent joint structures. Stiffening of the subchondral bone occurs concurrently with changes in the articular cartilage matrix. Osteoblasts in the trabecular portion of underlying bone begin to form new bone and the subchondral region is often thickened and sclerotic. Although changes in subchondral bone may not be necessary for the development of osteoarthritis, these changes may play an important role in the progression of the disease (Johnston, 1997).

Osteophytes are commonly associated with osteoarthritis. Generally, they develop at the periphery of the joint and are thought to form as a result of joint instability. Although they normally form over weeks to months, experimental models have demonstrated formation as early as three days after creation of instability (Johnston, 1997). However, osteophytes have been documented to develop in the presence of inflammation without instability, suggesting that synovial membrane inflammation may play a role (Johnston, 1997). Osteoarthritis and the accompanying inflammation also cause changes in the joint capsule. These changes may include thickening of the synovium and increased vascularity. Conversely, synoviocytes contribute to the progression of osteoarthritis by producing cytokines and leukotrienes, which attract inflammatory cells and the release of prostaglandins and other inflammatory mediators. This inflammation of the synovium contributes to decreased elasticity and viscosity of synovial fluid. Synovitis can either precede or follow observable cartilage changes and is likely secondary to exposure of neoantigens on the cartilage or release of inflammatory mediators by damaged synovium or chondrocytes (Renberg, 2005).

Key Nutritional Factors

Besides supplying age-appropriate nutrition, foods designed for companion animals with osteoarthritis need to provide specific nutrients that may help reduce inflammation and pain, enhance cartilage repair, slow the degradative process, complement prescribed medications and provide tangible improvement in clinical signs. Because foods for osteoarthritis are fed in place of

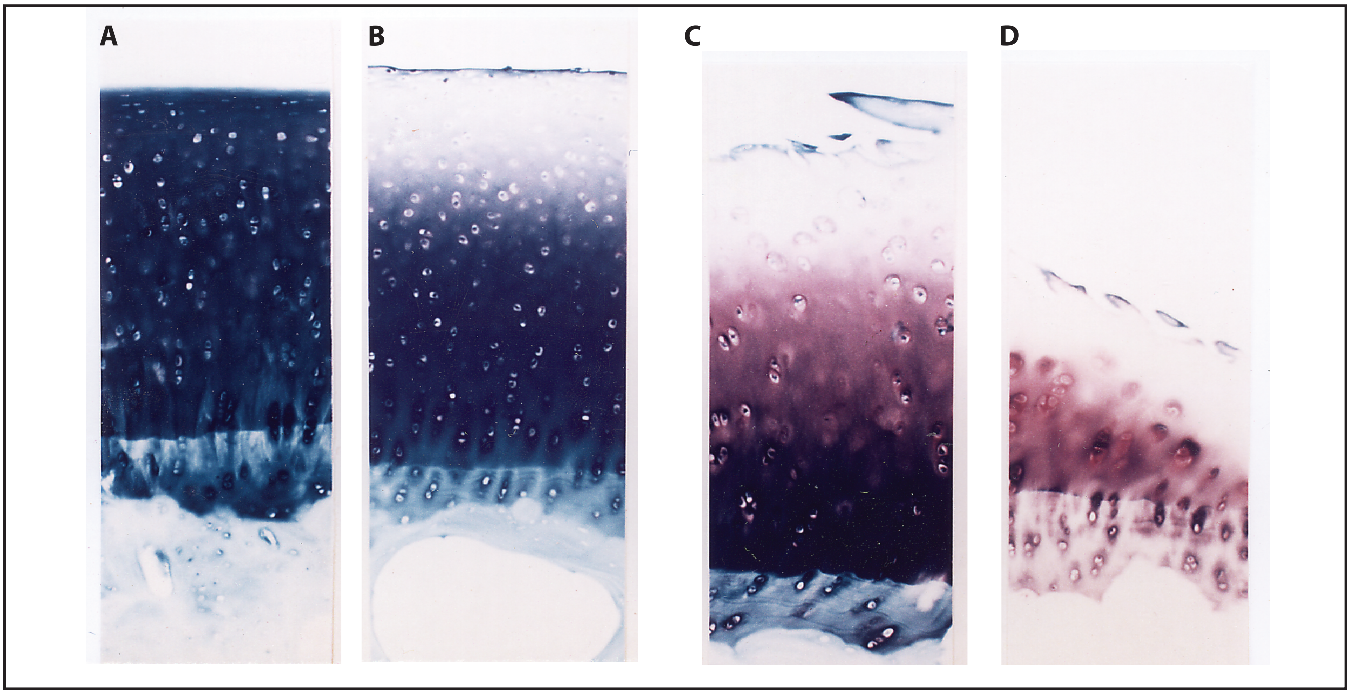

Figure 34-4. Toluidine blue-stained sections of canine articular cartilage from normal joints (A) and joints with early- (B), mid- (C) or late- (D) stage osteoarthritis (OA); the articular surface is at the top of each picture and subchondral bone is at the bottom. In the normal cartilage (A), the articular surface is smooth, the matrix (proteoglycans, collagen and water) is darkly stained and chondrocytes are visible in their lacunae. In early OA (B), proteoglycans and water are lost from the superficial layers (indicated by reduced stain uptake). As OA progresses (C, D), there is further loss of matrix accompanied by articular cartilage surface fibrillation and erosion due to collagen degradation and mechanical disruption of the tissue. (Used with permission from Caterson B, Flannery CR, Hughes CE, et al. Mechanisms involved in cartilage proteoglycan catabolism. Matrix Biology 2000; 19(4): 333-344.)

regular maintenance foods, several key nutritional factors are included due to their relationship to general health rather than specific benefits for osteoarthritis. Nutraceutical, or functional food additives, may also contribute to the management of osteoarthritis. **Table 34-2** summarizes key nutritional factors.

Omega-3 Fatty Acids

All mammals synthesize fatty acids de novo up to palmitic acid, which may be elongated to stearic acid and converted into oleic acid. Plants, unlike mammals, can insert additional double bonds into oleic acid and produce the polyunsaturated fatty acids linoleic acid (LA, 18:2n-6) and α-linolenic acid (ALA, 18:3n-3). Linoleic acid and α-linolenic acid are considered essential fatty acids because animals cannot synthesize them from other fatty acids; therefore, they must be supplied by food.

In most animals, linoleic acid can be converted into arachidonic acid (AA, 20:4n-6) via desaturation and elongation. However, in cats, these conversions are greatly limited because of low Δ–6 desaturase activity (Bauer, 2006). As a result, cats are unable to synthesize other physiologically important long-chain polyunsaturated fatty acids, such as arachidonic acid and docosahexaenoic acid (DHA, 22:6n-3), in amounts sufficient for certain lifestages or processes. For cats, marine fish oils, rather than plant oils, are a more appropriate source of these fatty acids. Many marine plants, especially algae in phytoplankton, carry out chain elongation and desaturation of α-linolenic acid to yield omega-3 (n-3) fatty acids with 20 and 22 carbon atoms and five or six double bonds. Formation of these long-chain omega-3 fatty acids by marine algae and their transfer through the food chain to fish accounts for the abundance of eicosapentaenoic acid (EPA, 20:5n-3) and DHA in certain marine fish oils.

Arachidonic acid and EPA act as precursors for the synthesis of eicosanoids, a significant group of immunoregulatory molecules that functions as local hormones and mediators of inflammation. The amounts and types of eicosanoids synthesized are determined by the availability of the fatty acid precursor and by the activities of the enzyme systems that synthesize them. In most conditions, the principal precursor for these compounds is arachidonic acid, although EPA competes with arachidonic acid for the same enzyme systems. The eicosanoids produced from arachidonic acid are proinflammatory and when produced in excess amounts may result in pathologic conditions. In contrast, eicosanoids derived from EPA promote minimal to no inflammatory activity. Ingestion of oils containing omega-3 fatty acids results in a decrease in membrane arachidonic acid levels because omega-3 fatty acids replace arachidonic acid in the substrate pool. This produces an accompanying decrease in the capacity to synthesize eicosanoids from arachidonic acid (**Figure 34-5**). Studies have documented that inflammatory eicosanoids produced from arachidonic acid are depressed when dogs consume foods with high levels of omega-3 fatty acids (Wander et al, 1997).

The effect of dietary fish oil on the expression and activity of matrix metalloproteinases (MMP), tissue inhibitors of MMP-2 and urokinase plasminogen activator in synovial fluid from

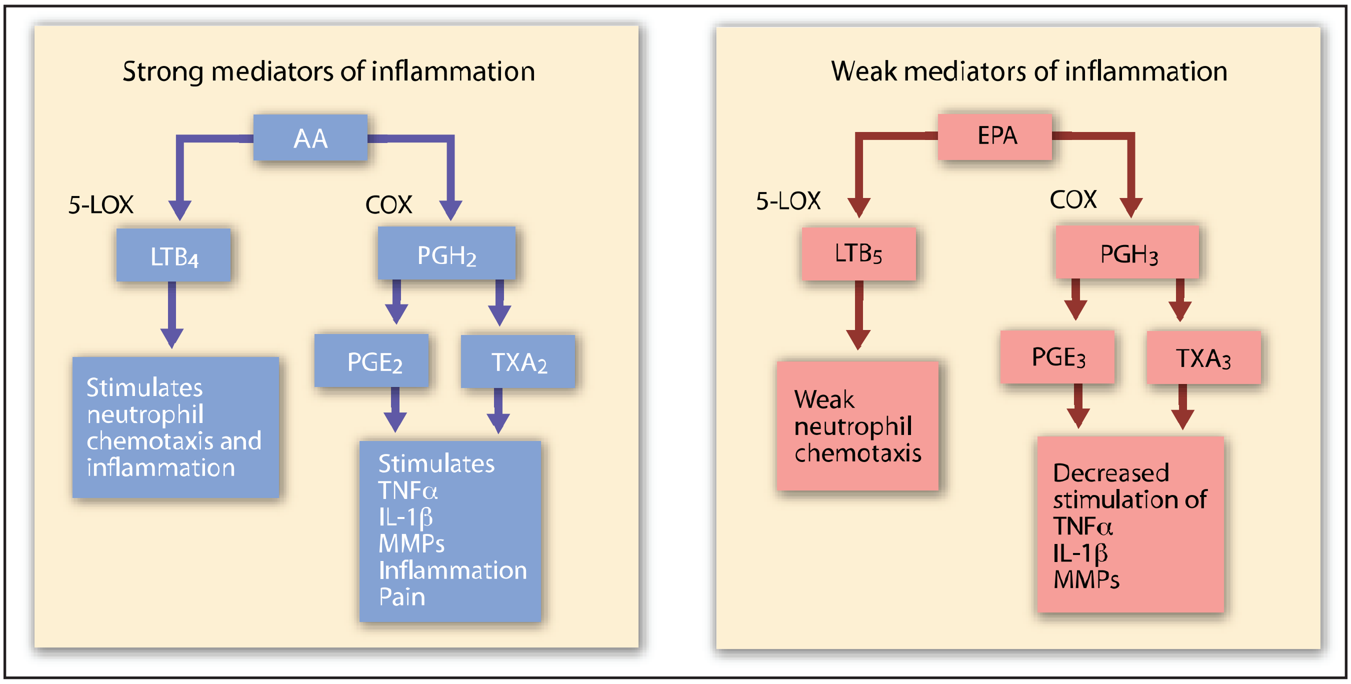

Figure 34-5. Eicosapentaenoic acid (EPA) competes with arachidonic acid (AA) for cyclooxygenase (COX) and lipoxygenase (5-LOX) pathways. Eicosanoids produced from AA are strong mediators of inflammation whereas those derived from EPA promote minimal to no inflammatory activity (sometimes referred to as antiinflammatory). Key: AA = arachidonic acid, LOX = lipoxygenase, COX = cyclooxygenase, LTB = leukotrienes, PGH/PGE = prostaglandins, TXA = thromboxanes, TNF = tumor necrosis factor, MMP = matrix metalloproteinase.

dogs with acute cranial cruciate ligament injury has been evaluated (Hansen et al, 2008). Two groups of 12 dogs with spontaneous cranial cruciate ligament injury were randomized to receive either a fish oil-supplemented food or control food from one week before surgery on the affected knee to 56 days post-surgery. The fish oil and control foods provided 90 and 4.5 mg of combined EPA and DHA/kg body weight per day, respectively. There were no changes in these biomarkers in the synovial fluid from the surgical joint at any time during the study. The authors suggested that the severe inflammation from cranial cruciate ligament injury and subsequent surgery was too great to be affected by the combined levels of EPA/DHA provided in the test food. However, dogs randomized to the fish oil food group had episodic but significantly ($p < 0.05$) decreased pro-matrix metalloproteinases and urokinase plasminogen activator and increased tissue inhibitors of MMP-2 in the synovial fluid from the nonsurgical knee. The fish oil food may have moderated the mild to moderate inflammation in the nonsurgical knee through suppression of inflammatory cytokines by EPA and DHA.

Reducing the production of proinflammatory mediators is only one mechanism by which omega-3 fatty acids promote the termination of inflammation and the return to homeostasis. Although it is true that the inflammatory response is essential to health and disease, sustained inflammatory responses are generally detrimental to the host. In people, in modern western civilization, unresolved inflammation has emerged as a central component of many diseases (e.g., arthritis, periodontal disease, cardiovascular disease, cancer and Alzheimer's disease) (Schwab and Serhan, 2006). Research has demonstrated that resolution of inflammation is an active, endogenous process aimed at protecting the individual from an excessive inflammatory response. The first endogenous local counter-regulatory mediators recognized were the lipoxins, which are derived from arachidonic acid (Serhan, 2005). Subsequently, two new families of lipid mediators derived from omega-3 fatty acids, resolvins and protectins, have been identified. Resolvins derived from EPA are denoted as resolvins of the E series (RvEs) and those derived from DHA acid are resolvins of the D series (RvDs) and protectins. These bioactive mediators have potent antiinflammatory, neuroprotective and pro-resolving properties (Schwab and Serhan, 2006). Further elucidation of the molec-

Table 34-2. Key nutritional factors for foods for canine osteoarthritis patients.*

Factors	Dietary recommendations
Total omega-3 fatty acids	3.5 to 4.0%
Eicosapentaenoic acid	0.4 to1.1%
Omega-6:omega-3 fatty acid ratio	<1:1
L-carnitine	≥300 mg/kg

Antioxidants	
Vitamin E	≥400 IU/kg
Vitamin C	≥100 mg/kg
Selenium	0.5 to 1.3 mg/kg
Phosphorus**	0.3 to 0.7%
Sodium**	0.2 to 0.4%

*All values are expressed on a dry matter basis unless otherwise stated.
**Dogs with osteoarthritis are often in age groups at risk for kidney and/or heart disease.

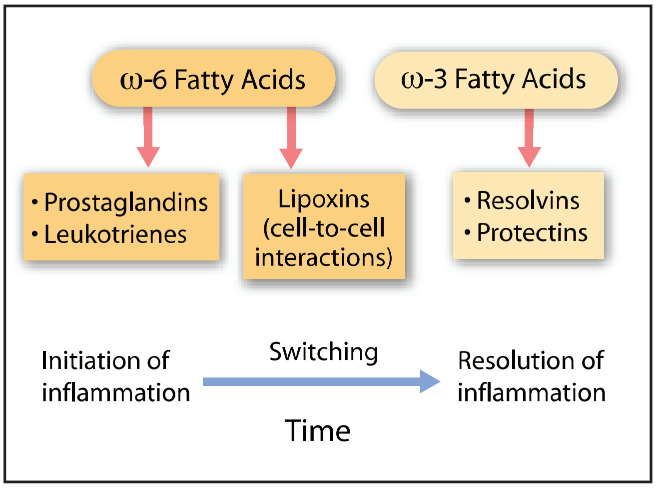

Figure 34-6. The role of omega-6 and omega-3 fatty acids in the initiation and resolution of inflammation over time. Resolution of inflammation is a progressive process involving a switch in the production of lipid-derived mediators over time. Pro-inflammatory products of omega-6 fatty acid metabolism (PGE2, PGE12, LTB4) are thought to initiate this sequence. Arachidonic acid-derived mediators foster the extravasation and homing of inflammatory cells at the site of the lesion. Cell-to-cell interactions exemplified by platelet-leukocytes within the vasculature and/or PMN-mucosal interactions enhance generation of lipoxins. With time, a class shift occurs towards domination by pro-resolving omega-3 derived mediators (resolvins, protectins). These mediators serve as endogenous stop signals by preventing inflammatory cell recruitment and stopping "cell entry" and promoting resolution by removing inflammatory cells from the lesion site through phagocytosis of PMNs and promotion of "cell exit." Key: PGE = prostaglandin, LTB = leukotriene. (Adapted from Schwab JM, Serhan CN. Lipoxins and new lipid mediators in the resolution of inflammation. Current Opinion in Pharmacology 2006; 6: 414-420.)

ular actions of these previously unappreciated families of lipid-derived mediators may shed light on the clinically recognized beneficial effects of omega-3 fatty acids (**Figure 34-6**).

The interaction between nutrients found in certain foods and the expression of genes responsible for certain disease conditions is known as nutrigenomics (Chapter 4). Progression from a healthy to a disease state occurs through changes in gene expression, which can be influenced through ingestion of specific nutrients. The capacity of specific omega-3 fatty acids (EPA in dogs) to alter the expression of genes responsible for progression of cartilage degradation is an example of one application of nutrigenomics to pet foods.

Mechanisms of cartilage metabolism in canine osteoarthritis and the potential role of omega-3 fatty acids to ameliorate the early events in the disease have been investigated using in vitro models. These studies identified some similarities and distinct differences between cartilage from dogs and other species in the response to catabolic agents and omega-3 fatty acids. Numerous catabolic agents significantly decreased canine cartilage proteoglycan synthesis. However, proteolysis and loss of aggrecan could only be stimulated by oncostatin M, leukemia inhibitory factor and retinoic acid. Stimulated aggrecan loss was associated with increased cleavage by aggrecanases and not matrix metalloproteinases. EPA was the only omega-3 fatty acid able to significantly decrease the oncostatin M-stimulated loss of aggrecan in the canine cartilage in vitro model (Caterson, 2005; Caterson et al, 2000; Curtis et al, 2002). In canine cartilage, EPA inhibits the up regulation of aggrecanases by blocking the signal at the level of messenger RNA (Curtis et al, 2000). Altering the expression of this messenger RNA signal by EPA is an example of how nutrigenomics can aid in the management of disease.

The application of nutrigenomic concepts can be applied to foods designed to aid in the nutritional management of osteoarthritis. Ideally, these foods should control clinical signs and moderate the progression of the disease and their efficacy should be demonstrated in well-controlled clinical studies. One veterinary therapeutic food[c] designed to aid in the management of osteoarthritis in dogs has been evaluated in multiple clinical studies. Specifically, four randomized, double-masked, controlled studies were completed in arthritic dogs fed either a control or test food. The foods had similar nutrient content with the exception of total levels of omega-3 fatty acids: 0.09% (dry matter [DM]) control vs. 3.48% DM test food and levels of EPA less than 0.01% DM vs. 0.38% DM, respectively. The ratio of omega-6 to omega-3 fatty acids was also markedly different in the two foods: 22.8:1 in the control vs. 0.7:1 in the test food (**Table 34-3**). Pet owners were given the option of feeding dry or a combination of moist and dry foods. One six-month and two three-month prospective studies were conducted in veterinary hospitals across the United States.[d-f] A fourth study was conducted as a three-month prospective study in two academic specialty practices in the United States.[g]

In all studies, osteoarthritis was diagnosed based on compatible history, clinical signs and radiographic evidence of arthritis in one or more joints of the clinically affected limb. To be eligible for inclusion, dogs had to be at least one year of age, weigh 12.5 kg or more, consume at least some dry dog food and be free of systemic disease as determined by history, physical examination, complete blood count, serum biochemistry analysis and urinalysis. Exclusion criteria included acute traumatic injuries, complicating disease conditions, preexisting conditions for which corrective surgery was anticipated during the feeding period and recent intraarticular injection or arthrocentesis.

Change in arthritic condition over time was evaluated in these studies and was based on owner observations of clinical signs and veterinary clinical evaluations. Variables were assessed at the beginning of the study and at set time intervals after onset of feeding the control or therapeutic food. Additionally, veterinary clinical evaluations were conducted at each time interval. These consisted of an orthopedic examination with a specific emphasis on lameness and pain, limitation in weight-bearing ability, range of motion of the affected joint(s) and willingness to bear weight on the most affected limb when the contralateral limb was elevated.

Investigators in the three studies conducted in veterinary hospitals[d-f] reported that the animals fed the EPA-supplemented food improved in several parameters throughout the studies. Veterinarians reported improvement in range of

motion and ability to bear weight, along with a decrease in pain (upon palpation of the affected joint) and lameness as compared to evaluations of these dogs before they participated in the studies. Dogs fed the EPA-supplemented food had significantly ($p < 0.05$) improved ability to rise from a resting position, in running and playing at six weeks and improvements in walking at 12 and 24 weeks compared to dogs fed the control food.

In the academic specialty practice clinical study,[g] variables were assessed at the beginning of the study and at 45 and 90 days after onset of feeding the control or test food. Additionally, gait analyses using a computerized biomechanical force plate were conducted at the same time intervals. For each dog, five valid force-plate trials were obtained during each test period for the most severely affected and ipsilateral limbs. Orthogonal ground reaction forces of peak vertical force, vertical impulse, braking and propulsion peak force and braking and propulsive force were measured and recorded. All forces were normalized with respect to body weight in kg. Data from valid trials for each limb were averaged to obtain a mean value at each time period.

On clinical orthopedic examination, a significantly ($p < 0.05$) greater percent of dogs consuming the test food were evaluated as "improved" vs. those consuming the control food. In addition, more dogs in the test group had a reduction in pain at the end of the 90-day trial when the affected joint was palpated. Vertical peak force was the key parameter measured to determine weight bearing of affected limbs. There was no significant change in mean peak force over the duration of the 90-day feeding trial for the control group. The mean vertical peak force increased significantly ($p = 0.01$) for the test group over the same time interval. The percent mean change in vertical peak force was also significantly ($p = 0.04$) different between groups, indicating that the test group increased weight bearing on the affected limb over the course of the study. Additionally, only 31% of dogs in the control group had improved weight bearing after the 90-day feeding trial, whereas 82% of dogs in the test group increased weight bearing; this difference was also statistically significant ($p = 0.003$).

These clinical studies indicate that nutritional management using a veterinary therapeutic food supplemented with omega-3 fatty acids helped improve the clinical signs of osteoarthritis in dogs as noted by pet owners, clinical orthopedic examination and gait analysis of ground reaction forces. Based on these studies, a food designed to aid in the management of osteoarthritis in dogs should provide levels of total omega-3 fatty acids between 3.5 to 4.0% DM and specifically 0.4 to 1.1% DM EPA. The omega-6 to omega-3 fatty acid ratio should be less than 1:1. Dogs consuming the therapeutic food should receive an average of 50 to 100 mg EPA/kg body weight/day.

Supplements have traditionally been used to provide a source of omega-3 fatty acids to pets. However, using supplements to provide levels of EPA documented to have a clinical effect may prove cumbersome. Many supplements designed to provide omega-3 and omega-6 fatty acids are available in both human and veterinary formulations. Concentrations in these supplements range from 50 to 375 mg of EPA per dose. To achieve EPA concentrations of 50 mg/kg body weight/day, a 27-kg dog would require four to 27 doses of a supplement (**Table 34-4**). Long-term compliance with this dosing regimen is likely to be poor. Providing a food with the recommended levels of EPA and total omega-3 fatty acids is preferable and likely improves compliance.

One study in osteoarthritic geriatric cats evaluated the effects of feeding an omega-3 fatty acid-supplemented food on cartilage protection (Yamka et al, 2006). Increased levels of EPA (3.2% DM), DHA (0.23% DM), methionine (1.32% DM) and manganese (104 mg/kg DM) and no synthetic glucosamine or chondroitin sulfate were associated with decreased values for arthritic biomarkers in these cats. Changes in clinical signs were not noted during the 60-day study.

Anecdotally, radiographic signs of osteoarthritis in cats have been managed with a combination of calorie restriction plus supplementation of the food with omega-3 fatty acids (75 to 110 mg/kg body weight/day). Over eight weeks of evaluation, there were no changes in radiographic appearance, but therapy resulted in a more natural gait and increased voluntary activity

Table 34-3. Nutrient comparison of control and test foods.*

Nutrients	Control food	Test food**
Protein (%)	23.2	20.0

(Saker, 2006). This treatment is similar to protocols recommended for management of dogs with osteoarthritis. Adverse effects on platelet function have been reported in cats fed a food with a 1.3:1 omega-6 to omega-3 ratio (1.03 g omega-3 fatty acids/kg food), but not in cats fed a food with 12:1 omega-6 to omega-3 ratio (0.07 g omega-3 fatty acids/kg food) (Saker et al, 1998). More studies are needed to confirm these findings; however, based on results in other species, providing enhanced levels of omega-3 fatty acids to cats with osteoarthritis seems promising.

L-Carnitine

Maintaining a healthy weight throughout life will delay the onset and minimize clinical signs of osteoarthritis. Achieving an ideal body weight in dogs diagnosed with osteoarthritis will improve clinical signs and long-term management. Paradoxically, many dogs diagnosed with osteoarthritis are either overweight or obese prone as a result of breed, age and/or decreased activity. One key nutrient in weight loss and weight maintenance foods is L-carnitine. It plays a vital role in a variety of physiologic processes related to fat metabolism and energy production; specifically L-carnitine mediates the transfer of long-chain fatty acids into mitochondria. This action promotes oxidation of fatty acids as an energy source. Perhaps more importantly, weight-loss foods with appropriate levels of L-carnitine (≥300 mg/kg DM) aid in the retention of lean body mass during weight loss in dogs (Allen, 1998). Additionally, L-carnitine supplementation of obese-prone dogs led to a reduction in fat mass and increase in lean body mass through an extended feeding period (Gross, 1998). Obese cats supplemented with L-carnitine have been reported to lose weight faster and have less ketogenesis (Center et al, 2000), suggesting that increasing the L-carnitine level of foods for cats at risk for becoming overweight, such as after neutering, could be beneficial. Because lean tissue uses more calories than fat, increased lean body mass is desirable for long-term maintenance of an ideal body weight in dogs and cats. Achieving and maintaining a healthy weight is critical to the successful management of osteoarthritis.

Because many patients with osteoarthritis need support to achieve or maintain a healthy body weight and L-carnitine supports both weight loss and maintenance of weight after weight loss, foods intended for the dietary management of osteoarthritis should contain at least 300 mg of L-carnitine/kg DM.

Chondroitin Sulfate and Glucosamine Hydrochloride

Chondroitin sulfate is a GAG consisting of repeating disaccharide subunits of glucuronic acid and N-acetylgalactosamine sulfate (Schoenherr, 2005). Commercially available chondroitin sulfate is generally derived from bovine cartilage. However, porcine and chicken cartilage and chondroitin from perna mussels and algae have also been used. Chondroitin sulfate decreases interleukin-1 production, blocks complement activation, inhibits metalloproteinases, inhibits histamine-mediated inflammation and stimulates GAG production and collagen synthesis (Beale, 2004). Both the molecular weight and species of derivation affect the bioavailability of chondroitin sulfate products. The low molecular weight form appears to be absorbed more readily. Some sources such as perna mussels contain only trace amounts of high molecular weight chondroitin sulfate and avian sources have not proven any more effective than placebo (Millis, 2006). **Box 34-1** contains additional information about commercially available glucosamine and chondroitin sulfate products.

Glucosamine hydrochloride is one of the basic sugar component precursors of the disaccharide units that make up all of the glycosaminoglycans in cartilage. Proposed mechanisms of action of glucosamine include a reduction of proteoglycan degradation and inhibition of the synthesis and activity of degradative enzymes (aggrecanases/matrix metalloproteinases) and inflammatory mediators (nitric oxide and prostaglandin E_2). Anabolic effects include stimulation of GAG and proteoglycan production (Neil et al, 2005). Glucosamine hydrochloride and glucosamine sulfate appear to be more efficacious than N-acetylglucosamine.

Glucosamine hydrochloride and chondroitin sulfate, taken in appropriate doses, are considered safe for dogs and cats. Safety studies of one proprietary formulation using oral administration in excess of the recommended daily dose for 30 days documented no clinically important alterations in hematologic indices or biochemistry and clotting profiles in dogs and cats (McNamara et al, 1996; McNamara et al, 2000). Although no coagulation abnormalities were recognized, because of the structural similarities of glycosaminoglycans and heparin, the concurrent use of other platelet inhibitors, such as phenylbutazone or aspirin, may be contraindicated. Some dogs and cats may experience mild gastrointestinal upset, which can be managed by offering the product with a meal.

Meta-analysis of randomized, double-blind, placebo-controlled studies evaluating the effectiveness of glucosamine and chondroitin sulfate supplements in people demonstrated moderate to large reductions of pain and disability in osteoarthritis compared with placebo; however, these effects may have been exaggerated as a result of publication bias. Greater effects have been detected for chondroitin sulfate than glucosamine (McAlindon et al, 2000). The Glucosamine/Chondroitin Arthritis Intervention Trial (GAIT) evaluated over 1,500 human participants with osteoarthritis of the knee who were randomly assigned to one of five treatment groups: 1) glucosamine alone, 2) chondroitin sulfate alone, 3) glucosamine and chondroitin sulfate in combination, 4) celecoxib or 5) a placebo. Patients were assessed at intervals over six months. Patients taking the positive control (i.e., celecoxib) experienced statistically significant pain relief vs. placebo. Overall, there were no significant differences between the other treatments tested and placebo. For a subset of participants with moderate-to-severe pain, glucosamine combined with chondroitin sulfate provided statistically significant ($p = 0.002$) pain relief compared to placebo. According to the researchers, because of the small size of this subgroup, these findings should be considered preliminary and need to be confirmed in further studies. For participants in the mild pain subset, glucosamine and chondroitin sulfate together or alone did not provide statistically sig-

Box 34-1. All Nutraceutical "Chondroprotective Agents" Are Not Created Equal.

Veterinary nutraceuticals have been defined as "a non-drug substance that is produced in a purified or extracted form and administered orally to a patient to provide agents required for normal body structure and function and administered with the intent of improving the health and well-being of animals." Because the term nutraceutical has no regulatory definition and is not recognized by the FDA, these products are not subject to a pre-market approval process. As a result the safety, efficacy and manufacturing quality of these products cannot be ensured and there is evidence that this lack of regulatory oversight should be of concern to consumers.

In the United States, although there is no mandatory regulatory oversight, manufacturers of nutraceuticals can voluntarily submit their products for quality assurance. A variety of independent groups such as Consumer Laboratory (www.consumerlab.com) and the Institute for Nutraceutical Advancement (www.nsf.org) or trade associations such as the National Animal Supplement Council (www.nasc.cc) provide independent quality assurance testing and certification programs. The two substances most commonly used for treatment of osteoarthritis in veterinary medicine are glucosamine HCl and chondroitin sulfate either alone or in combination. Chondroitin sulfate is an expensive ingredient of many "joint" targeted products and serves as an example of the need for careful evaluation of these unregulated products.

A 1999 study partially funded by Nutramax Laboratories found that 26 of 32 (81%) commercially available human products contained less than 90% of the chondroitin sulfate stated on the label and 17 (53%) of those products contained less than 40% of label claim. This study documented that products costing ≤$1/1,200 mg chondroitin sulfate were critically deficient; on average less than 10% of the label claim. Interestingly, expense did not guarantee content because several of the most expensive products also contained less than 10% of label claim (**Figure 1**). ConsumerLab.com (accessed 11/16/06) found similar problems with glucosamine HCl/chondroitin sulfate combination products. Initially, on November 2, 2003, two of three veterinary combination products evaluated were found to have no chondroitin sulfate despite each displaying a "guaranteed analysis." One of these companies has since produced a re-formulated product that did pass Consumer Lab testing. Glucosamine hydrochloride, unlike chondroitin sulfate, is much more likely to be present in the amounts indicated on product labels. Information about specific products and testing procedures can be accessed at the Consumer Lab website for a fee. Because of these inconsistencies, consumers are cautioned against extrapolating results from clinical and experimental studies comparing one product to other similar products. Based on this information, when prescribing nutraceuticals, preference should be given to those products whose quality assurance and efficacy can be verified.

The Bibliography for **Box 34-1** can be found at www.markmorris.org.

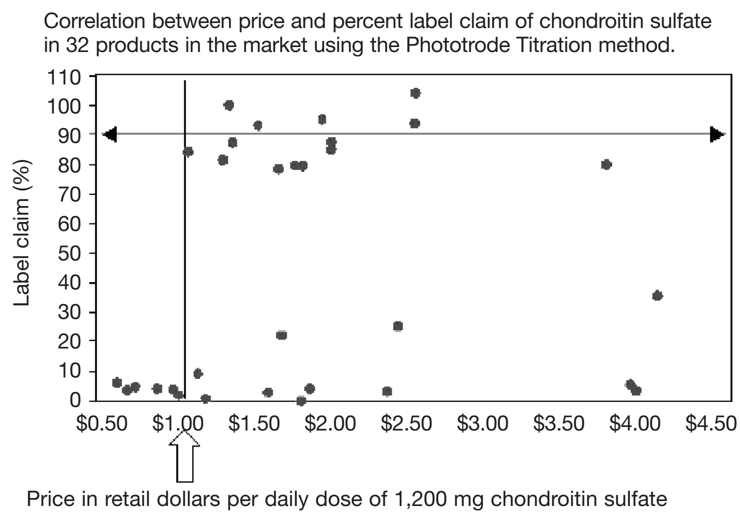

Figure 1. Relationship between products' label claims and standard retail prices. (Adapted from Adebowale AO, Cox DS, Liang Z, et al. Analysis of glucosamine and chondroitin sulfate content in marketed products and the Caco-2 permeability of chondroitin sulfate raw materials. Journal of the American Nutraceutical Association 2000; 3(1): 37-44.)

nificant pain relief (Clegg et al, 2006). The authors also noted that the elevated placebo response seen in this study may have dampened the ability to differentiate among the treatments (60% of patients receiving placebos had at least a 20% decrease in pain scores after 24 weeks) (Clegg et al, 2006). These studies suggest that glucosamine and chondroitin sulfate may offer clinically relevant reductions in pain for some patients with osteoarthritis. However, despite a large number of clinical trails in human medicine, there is still no consensus about the effectiveness of these compounds. In veterinary medicine, there is a lack of consensus and a lack of clinical trials to evaluate.

In veterinary medicine, claims of efficacy for glucosamine/chondroitin sulfate supplements are often based on subjective methods of assessment, in vitro testing or testimonials. Two studies evaluated the efficacy of supplements containing the combination of glucosamine/chondroitin sulfate in client-owned dogs with naturally occurring osteoarthritis compared to positive controls. These two trials evaluated 106 dogs with confirmed osteoarthritis. Nonsteroidal antiinflammatory drugs (carprofen and meloxicam) were used for positive controls. One study evaluated ground reaction forces and subjective owner and veterinary evaluations in 71 dogs randomized to receive meloxicam, carprofen, a combination glucosamine/chondroitin sulfate product or placebo (Moreau et al, 2003). After 60 days, dogs in the meloxicam and carprofen groups had improved ground reaction forces and clinical improvement. Owners

Elizabeth Head

"Dogs' lives are too short. Their only fault, really."
Agnes Sligh Turnbull

CLINICAL IMPORTANCE

Current estimates suggest that approximately 20 to 30 million dogs over the age of seven years live in the United States, representing 30 to 40% of the total canine population (AVMA, 2002). Behavioral changes, the development of new behavioral problems and the exacerbation of previous behavioral problems occur commonly with increasing age. At one animal behavior referral clinic, the most common complaints cited by pet owners included increased incidence of separation anxiety, house soiling, phobias, waking at night and excessive vocalization (Chapman and Voith, 1990). In addition, memory impairments, symbolic recognition and object permanence were associated with aging in dogs (Dehasse, 2005).

Canine cognitive dysfunction syndrome (CDS) is the name proposed to describe behavioral changes noted in client-owned aged dogs (Ruehl et al, 1995). Numerous owner-based observational studies have assessed the prevalence of CDS. For example, 180 dogs that had been determined to be healthy at their annual visit were reevaluated by client telephone followup; 28% of owners of 11- to 12-year-old dogs and 68% of owners of 15- to 16-year-old dogs reported at least one sign of CDS (Neilson et al, 2001). (See disorientation, alterations in interactions with people and other pets, alterations in sleep-wake cycles and house soiling [DISH] below.) In another study of 102 dogs eight years old and older, in which underlying medical problems had been ruled out, 41% had alterations in one category, whereas 32% had alterations in two or more categories of DISHA (See definition below) (Osella et al, 2007).

PATIENT ASSESSMENT

History, Screening Questionnaires and Other Clinical Information

Behavioral signs reported by pet owners are the primary criterion upon which to base a diagnosis of cognitive dysfunction (**Table 35-1**). However, the diagnosis can only be made after exclusion of all other medical problems that may cause similar clinical signs. For example, any change in personality or mood, inability to recognize or respond appropriately to stimuli or loss of previously learned behavior may indicate diseases of the forebrain or may arise from sensory system deficits. Diseases of virtually any other organ system can also affect behavior and these are discussed in more detail elsewhere (Landsberg and Araujo, 2005; Landsberg et al, 2003). Chronic or recurrent stress and anxiety can also affect health and behavior, in part by affecting the hypothalamic-pituitary axis and possibly by overstimulation of the noradrenergic system. Therefore, reporting any change in behavior is essential for the health and well-being of all pets, and, in particular, for senior pets, in which degenerative diseases, tumors, pain and discomfort are increasingly common.

In 2005, the American Animal Hospital Association senior care task force published guidelines that recommend yearly

Table 35-1. Behaviors evaluated in dogs to assess age-related cognitive decline.*

1. Confusion, awareness, spatial orientation
Gets lost in familiar locations
Goes to wrong side of doors (e.g., hinge side)
Gets stuck and cannot navigate around or over obstacles
Less responsive to stimuli
Decreased recognition of familiar people, pets or places
2. Relationships and social behavior
Decreased interest in petting or contact
Decreased greeting behavior
Alterations or problems with social hierarchy
In need of constant contact (e.g., over dependent or "clingy")
3. Activity: Increased, decreased or repetitive
Decreased daytime sleep/increased wandering or pacing
Decreased exploration (apathy)
Staring, fixation or snapping at objects
Licking owners or household objects
4. Agitation or anxiety
Inappropriate vocalization
Restless sleep
Increased irritability/aggression
Aimless pacing and wandering
Increased/new fears or phobias
Separation anxiety
5. Appetite
Increased interest (volume eaten or speed of eating)
Decreased interest
Anxiety–conflict behaviors at food bowl
6. Decreased responsiveness to stimuli
May seem to have a decline in vision, hearing or odor perception
7. Decreased self-care
8. Sleep-wake cycle
Restless sleep or awake at night
Increased daytime sleep
9. Learning and memory
a) House soiling: Indoor elimination at random sites or in view of owners
Decreased or no signaling
Goes outdoors, eliminates indoors upon return
Elimination in crate or sleeping area
Incontinence
b) Works, tasks, commands
Impaired working ability
Impaired responsiveness to known commands or tricks
Decreased ability to perform tasks
Inability or slow to learn new tasks (must retrain)
*Adapted with permission from Landsberg G, Hunthausen W, Ackerman L. The effects of aging on behavior in senior pets. Handbook of Behavior Problems of the Dog and Cat. Edinburgh, Scotland: Elsevier Health Sciences, 2003.

wellness screening for healthy middle-aged pets and twice yearly screening for senior pets (i.e., last 25% of predicted lifespan). At each visit, the pet should receive a physical examination and laboratory tests and the owner should be extensively questioned about changes in behavior and health (Epstein et al, 2005). Most of these changes would not be detected during a veterinary visit because they can be intermittent, subtle in onset and only noticeable in other environments. Therefore a senior care program should include use of a screening questionnaire (**Table 35-1**). (Landsberg and Araujo, 2005; Landsberg et al, 2003; Pfizer Animal Health) and/or allow sufficient time for interactive history taking. If problems are identified, early intervention may improve quality of life and longevity.

The reliability and usefulness of brain imaging for detection of CDS has not been systematically examined. However, in some cases, a magnetic resonance imaging (MRI) scan might be useful for differential diagnosis. Imaging might allow practitioners to rule out alternative explanations for changes in behavior, such as the presence of gliomas, tumors or damage due to stroke. Note that a normal MRI scan cannot be used to rule out CDS. However, with increased age, there is a tendency toward ventricular dilatation and neuronal loss. (See macroscopic changes below.) Although these changes might be expected to correlate with increasing cognitive dysfunction, this has not been validated. Traditionally, the signs of canine CDS, hypothesized to be caused by brain aging, were described by the acronym DISH. (See above.) Alterations in activity levels including increased restlessness and pacing have also been identified; therefore, an "A" for activity has more recently been added to the acronym (Landsberg and Araujo, 2005; Landsberg et al, 2003; Neilson et al, 2001; Osella et al, 2007). These signs, however, do not necessarily reflect all of those associated with CDS and brain aging.

In a review of 50 recent Veterinary Information Network (VIN) postings of behavioral signs in senior dogs (aged nine to 17), many of the reported problems were related to agitation and anxiety including fear, excessive vocalization, salivation, destructiveness, hypervigilance, over-attachment, separation anxiety, night-time waking and anxiety, restlessness, wandering, pacing, confusion, noise phobias, increased sensitivity to sound, compulsive licking and aggression (sometimes concurrent with and sometimes independent of other signs of DISH). Each case received the guidance of one or more of the VIN specialists in neurology, internal medicine or behavior. Seizures, hypertension, sensory decline, arthritis, pituitary-dependent hyperadrenocorticism and cerebral disease were the most commonly suggested rule outs. There was no identifiable medical cause in 24 of the 50 cases, and medical problems were deemed unlikely to have contributed to the behavioral signs in another nine cases. Of the remaining cases, arthritis, hearing loss, renal insufficiency, lymphadenopathy, mild anemia and pharmaceutical therapy such as phenylpropanolamine and prednisone were considered as possible contributing factors. This underscores the importance of ruling out medical problems that might cause clinical signs, and the fact that anxiety and agitation are commonly reported signs in senior pets.

A number of cognitive disorders have been described in the French literature including confusional syndrome, dysthymic disorder and involutive depression (which may be associated with compulsive and stereotypical behavior, hyper-attachment, vocalization and anxiety) (Landsberg and Araujo, 2005). In addition, laboratory studies indicate that there is a measurable decline in learning and memory associated with brain aging. Laboratory-based systematic studies of changes in behavior and cognition also provide evidence that behavioral changes in senior dogs observed clinically have a neurobiological basis. Thus the acronym DISHA may not sufficiently and accurately reflect all of the clinical signs associated with brain aging and cognitive dysfunction in older pets. Because these signs are generally noticed by pet owners and seldom in the veterinary clin-

ic, pet owners should be counseled to immediately report any changes in behavior or health in older pets. In turn, veterinarians should use these signs, along with results of physical and neurologic examinations and results of other diagnostic testing to diagnose or rule out possible systemic causes, and to determine if the signs may be associated with brain aging. The use of a cognitive assessment questionnaire may help facilitate the process (**Table 35-1**).

Although feline data are much more preliminary, **Box 35-1** describes clinical observations of CDS, age-related neuropathology and treatment of CDS in cats.

Relationship Between Age, Cognitive Dysfunction and Pathology: Laboratory Studies

Changes in Cognitive and Non-Cognitive Behaviors with Age

Although owner-based survey studies are informative for assessing global brain function, using laboratory-based neuropsychological tests represents a more systematic approach to detect subtle and early changes in learning and memory with age that might go unreported in the clinic. By contrast, owner assessment is generally unable to detect changes in learning or memory, because house soiling and the level and extent of commands that the pet has learned are the only values that can be assessed, except perhaps in performance, working or assistance dogs in which a higher degree of training and learning has been attained. A modified Wisconsin General Testing Apparatus (**Box 35-2**) is one laboratory-based method used to detect early changes and systematically characterize changes in cognition in aging beagles (Milgram et al, 1994). An array of tasks has been developed to measure specific cognitive abilities in dogs. These tests include assessment of associative learning in which a dog must learn that only one of two objects hides a food reward based on shape (Head et al, 1998), size (Head et al, 1998; Tapp et al, 2003) or spatial location (Christie et al, 2005; Milgram et al, 1999) of the object. There are also tasks that assess how long a dog can remember if it has seen a particular object (Callahan et al, 2000) or spatial location (Adams et al, 2000; Chan et al, 2002) and tests of executive function that assess how readily it can learn a particular rule or strategy for solving a task (Tapp et al, 2003a, 2004a).

Cross-sectional and longitudinal studies using these tests indicate that cognition declines with age in dogs, but that the decline is selective to certain cognitive abilities and tasks. Procedural learning, or the ability to remember particular skills or habits necessary for success in the Toronto General Testing Apparatus, remains relatively intact in old dogs (Milgram et al, 1994), whereas tests of executive function and working memory are highly sensitive to aging (Christie et al, 2005; Tapp et al, 2003, 2004). For example, young and old dogs are easily trained to associate one object in a pair of stimuli with a food reward when the object pair is presented repeatedly over several test trials (Adams et al, 2000; Christie et al, 2005; Milgram et al, 1994). At this stage, no age differences in learning are found, suggesting that simple visual processing remains intact in aged animals. If, however, the reward contingency is reversed such that the opposite stimulus becomes associated with food reward, some senior dogs are unable to change their response pattern (Christie et al, 2005; Head et al, 1998; Tapp et al, 2003, 2004). This indicates that age affects cognitive flexibility, or the ability to modify previously formed associations, which suggests changes in frontal lobe function in aged dogs (Tapp et al, 2004).

Table 35-2. Laboratory deficits and tentative clinical correlates in age-related cognitive dysfunction syndrome in dogs.

Laboratory deficit	Clinical signs
Impaired spatial learning	Disorientation in space, time
Impaired spatial memory	Disorientation in familiar surroundings
Impaired oddity and discrimination learning	Impaired symbolic recognition, object permanence
Executive dysfunction	Deterioration of social skills, increased house soiling
Disrupted sleep-wake cycle	Wandering at night
Altered locomotion in open field	Altered activity levels

Aged dogs also have impaired ability to acquire and remember an oddity discrimination task (Milgram et al, 2002). In this paradigm, the animal is presented with three objects; two are identical but one differs in size, shape and color. The dog must learn that the odd object hides a food reward and remember to choose the odd object when tested at a later occasion on other oddity discrimination levels. There are four levels to the oddity task and each successive level becomes more difficult by increasing the similarity of the odd object to the identical pair of objects. Old dogs learn all oddity levels more slowly than young dogs. Furthermore, this age effect is particularly pronounced as the task increases in difficulty (Milgram et al, 2002).

The precise link between clinical measures of CDS and systematic laboratory cognitive tests is unknown. Currently, we can only speculate as to which laboratory-based deficits might correspond to clinical signs reported to occur in dogs with CDS (**Table 35-2**). For example, the owner-observed disorientation in space and time might correspond most closely with neuropsychological tests of spatial learning and memory. More research is needed to determine if results from the laboratory translate directly to the clinic and if tests of cognitive function in laboratory-based tasks involve the same brain circuits that are compromised in CDS. This would be accomplished, in part, by conducting both neuropsychological tests and in-home behavioral questionnaires on the same group of dogs. Currently, this is not a practical option because home tests would need to be developed and standardized.

Laboratory studies provide evidence that aged dogs develop changes in overall activity and in cognition. Studies identify differences in young and aged beagles in exploration (as measured by response to novel toys) and social responsiveness to a passive human subject. Although aged dogs with minimal evidence of cognitive impairment may have decreased activity, cognitively impaired aged dogs show increased sporadic activity levels, but decreased social responsiveness and exploratory behavior (Siwak et al, 2001, 2003). This may correlate with the initial decline in activity and increased sleep reported clinically in

Box 35-1. Clinical Observation of Cognitive Dysfunction Syndrome in Cats.

The presenting complaints of 83 senior cats referred to veterinary behaviorists were house soiling (73%), intraspecies aggression (10%), aggression toward people (6%), excessive vocalization (6%), restlessness (6%) and excessive grooming (4%). However, there is a much wider range of subtler and more frequent behavioral changes seen by owners that may not be reported and are unlikely to require referral.

A second study was intended to evaluate the prevalence of clinical signs in a population of otherwise healthy cats that were presented for annual examination or other routine care. Owners of 154 cats aged 11 and older were asked, using a questionnaire (similar to the canine questionnaire in **Table 35-1**), about whether their cats showed any behavioral signs such as altered activity levels, increased anxiety, night waking, increased vocalization, house soiling, altered responsiveness to stimuli, alterations in interactions with people or other cats and evidence of confusion or disorientation. After removing cats with medical problems, 50% of those aged 15 years or older were diagnosed with cognitive dysfunction syndrome (CDS); altered activity levels, aimless activity and excessive vocalization were reported most commonly. Additionally, 28% of cats aged 11 to 15 years had signs of CDS; altered social interactions were reported most commonly.

In an attempt to further determine some of the more common behavioral problems for which owners seek veterinary advice, 100 recent Veterinary Information Network (VIN) postings about senior cat (aged 12 to 22 years) behavioral problems were reviewed. The most common complaints were vocalization, altered sleep-wake cycles, night-time anxiety, nighttime restlessness, inappropriate elimination including spraying, confusion, disorientation, wandering, pacing, anxiousness, restlessness, irritability, aggression, fear/hiding, increased attachment/"clingy" behavior and decreased interaction with owners. A few problems were reported in only single cats. These included departure anxiety, pica (cardboard) and scratching. Pain (e.g., arthritis, dental), decreased mobility, metabolic problems including hyperthyroidism, renal and hepatic disease, hypertension, concurrent drug therapy, vision or hearing loss and forebrain lesions (particularly meningiomas) were the primary rule outs suggested by VIN specialists. Although many of these cases had sufficient workups to rule out all possible medical causes including physical and neurologic examinations, urinalyses, blood tests (including thyroxine measurement), radiographs and blood pressure evaluation, few cats had magnetic resonance imaging. Furthermore, the effects of arthritis and hearing and vision loss were difficult to assess. In 11 cases, a recent change in the household including the death of another pet may also have contributed to anxiety. In comparison to the canine data (See text.), there were far more feline cases in which concurrent medical conditions could not be entirely ruled out. Thus, although signs of anxiety are common in aging cats, age-related brain pathology (CDS), environmental changes and medical problems might be factors. Conversely, the diagnosis of a medical problem does not exclude CDS because both could exist concurrently.

To date, few systematic laboratory studies have looked at changes in cognition across the lifespan of cats. As described above, however, owners of senior cats report age-related behavioral problems. It is also known that cats develop age-related neuropathology that theoretically underlies cognitive decline (described in detail below). For example, one study found that development of diffuse senile plaques in the brains of three aged cats was correlated with behavioral changes including wandering, confusion and inappropriate vocalization. In a more recent study, a range of cognitive deficits from mild to severe, including wandering, inappropriate vocalization, confusion/getting lost, decreased grooming, lethargy, loss of housetraining and decreased affection and recognition of owners, was reported in four out of five cats aged 16 years and older. Development of laboratory-based tests for cats will allow the correlation of age-related behavioral problems with neuropathological changes and may allow detection of cognitive decline in younger cats, as has been found in dogs.

AGE-RELATED NEUROPATHOLOGY IN CATS

Beta-amyloid (Aβ) has also been studied in the brains of cats although not as extensively as in dogs. The first study to look at Aβ pathology in cats consisted of immunohistochemical staining of the brain of three family cats aged 15, 16 and 20 years old. According to their owners, all cats exhibited abnormal behavior within the final years of life including wandering, confusion and night-time howling. The 20-year-old cat was specifically described as having behavior "suggestive of Alzheimer's Disease." Pathologic analyses revealed that all three cats displayed age-dependent increases in Aβ pathology very similar to that found in aged dogs, with diffuse deposits (sometimes spanning the entire cortical depth) and smaller, denser deposits in various cortical layers. Senile plaques were also assessed in seven aged cats of various breeds (12 to 20 years old) that had no abnormal behavioral reports when they were alive. In this study, only three aged cats, two 18 year olds and one 20 year old, had senile plaques that were immunoreactive for Aβ in the temporal and occipital cortex. In another study in which the brains of seven Siamese and seven domestic shorthair cats (aged 7.5 to 21 years old) were examined, Aβ deposition was detected by various antibodies in different brain structures of all 14

aging dogs, which then progresses to repetitive behaviors, restless pacing and compulsive disorders.

Risk Factors

Age is a risk factor for CDS. Behavioral disturbances are reported with increasing frequency in dogs around 11 years of age (Bain et al, 2001; Landsberg et al, 2003; Neilson et al, 2001). Initially, these changes might be subtle and seem innocuous to the client; however, in many cases they progress to include more clinical signs and/or signs of increasing severity that affect the pet's quality of life and the owner's ability to care for the pet. For example, in one study, 22% of senior dogs that had no impairments at an initial interview developed at least one sign of CDS at a followup interview 12 to 18 months later. In the same study, 48% of dogs that initially displayed one behavioral disturbance had impairments in two or more categories at followup (Bain et al, 2001).

To date, age is the only risk factor for CDS that has been systematically studied in the clinic and laboratory, although other risk factors are possible, such as breed (larger breeds might have an earlier age of onset), previous head trauma or occurrence of microvascular accidents. Consistent breed differences in susceptibility to CDS have not been reported; however, a potential genetic predisposition for development of CDS can be inferred

cats. One 12-year-old Siamese cat had a notable amount of Aβ plaques in the hippocampus, but diffuse Aβ plaque pathology was most likely to occur after 17 years of age. A study looking at very young and very old cats found that Aβ abnormalities were not observed in very young cats (<4 years old), but diffuse plaques were common in the brains of aged cats (16 to 21 years old). A more comprehensive study involving 19 cats (aged 16 weeks to 14 years old) found that 17 cats had clinical signs of neurologic dysfunction. Diffuse Aβ plaque deposition was observed beginning at 10 years of age and increased with age. Collectively, the Aβ neuropathological findings in cats show that, in comparison to dogs, which have Aβ deposition beginning at middle age, feline Aβ plaques appeared towards the end of the lifespan.

TREATMENT OF CDS IN CATS

Although no food is commercially available for cats with cognitive dysfunction, it is not unreasonable to believe that many of the same therapeutic options may be effective because cats have many of the same brain changes and behavioral signs associated with age as dogs and people. However, care must be taken when recommending off-label inclusion of some supplements such as α-lipoic acid because it is not metabolized as quickly in cats as in dogs. Therefore, although there is only anecdotal evidence of efficacy, some dietary supplements such as Senilife[a] are marketed for use in cats. There are no drugs licensed for treatment of cognitive dysfunction in cats, but selegiline, propentofylline and nicergoline have been used in cats with varying degrees of success.

As in dogs, treatment of clinical signs associated with brain aging such as vocalization, night waking or an increase in anxiety may also necessitate the use of anxiolytics drugs such as buspirone, benzodiazepines that have the least potential for hepatotoxicity such as oxazepam and antidepressants with no anticholinergic effects such as fluoxetine or pheromones such as Feliway.[b] It would be prudent to evaluate the effects of possible feline therapies either in the laboratory or clinic because aged cats may have compromised function and dose response data are limited.

from reports of increased concordance rates of beta-amyloid plaque pathology (discussed in detail below) in littermates. In one study of aged dogs, the authors reported significant familial influence on plaque development by observing congruence in 15 of the 16 litters examined (Russell et al, 1992). Previous head trauma or occurrence of microvascular accidents may predispose animals to CDS by affecting the integrity of the blood-brain barrier (BBB), although no clinical data are available for definitive conclusions. In laboratory beagles, increases in BBB permeability with age in conjunction with the presence of vascular amyloid pathology suggest that disruptions to vascular integrity may be a risk factor for development of CDS (Su et al, 1998).

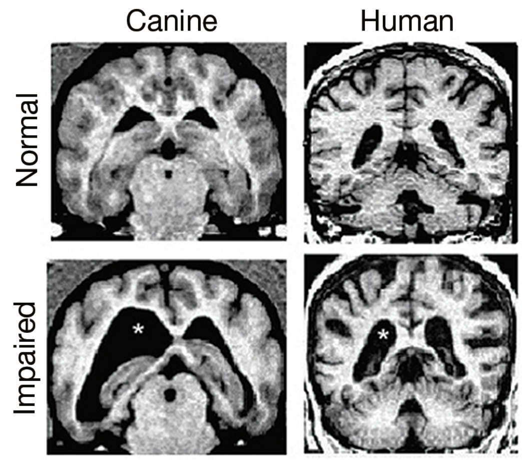

Figure 35-1. Magnetic resonance imaging of canine and human brain. Coronal sections of a cognitively normal beagle and person reveal structural similarities and a well-developed cortex. However, cognitive impairments are associated with enlarged ventricles (*) and general cortical atrophy of the gray and white matter, resulting in deep gyri and widened sulci. (Courtesy Dr. Min-Ying Su, University of California-Irvine.)

Etiopathogenesis

Cognitive changes in learning and memory often coincide with neuropathological changes in the brain. Despite the concomitant and statistically significant occurrence of various pathologic changes with deficits in cognition, to date, these studies remain largely correlative rather than directly causative. The following sections describe macroscopic and microscopic changes in the brains of dogs with cognitive dysfunction. See **Box 35-1** for information about age-related development of neuropathology in cats.

Macroscopic Changes in the Aging Brain

Changes in overall brain structure and volume can be seen using noninvasive techniques such as MRI. MRI studies in dogs reveal decreased brain volume, increased ventricular volume, increased perivascular space, lesions and cortical atrophy of the gray and white matter that often correlate with increasing age and cognitive decline (Su et al, 1998, 2005) (**Figure 35-1**). In 18 beagles (four to 15 years old), ventricular size increased slowly until 10 years of age and progressed very rapidly thereafter. In a longitudinal study using 47 beagles (eight to 11 years old at the first MRI), serial MRIs over four years revealed yearly increases in ventricular volume. Furthermore, different regions of the canine brain may have differing vulnerabilities to the aging process. An MRI study of 66 beagles (three months to 15 years) revealed decreases in total brain volume in dogs 12 years and older, whereas frontal lobe atrophy began much earlier, at eight years of age and correlated with impaired cognitive functions thought to be mediated by the frontal cortex (Tapp et al, 2004).

Lesions in aged beagles can be detected visually by MRI or by postmortem analysis of the brain. The cause and effect of these apparently spontaneous lesions is unclear; however, they have the morphologic appearance of lacunar infarcts or cysts

Box 35-2. The Toronto General Testing Apparatus.

The Toronto General Testing Apparatus (TGTA) is a canine-modified version of the Wisconsin General Testing Apparatus used for nonhuman primates. During testing, this wooden apparatus (**Figure 1**) houses the dog in a space (A) that contains no distinguishing features that a dog can use as cues for solving tasks. The experimenter is separated from the dog by a screen with a one-way mirror and a hinged door (B) that is opened for presentation of a sliding stimulus tray (C). The front of the TGTA is equipped with height- and width-adjustable bars (D) through which the dog accesses the stimulus tray, which contains one medial and two lateral food wells. The dog uses its nose to displace a stimulus and retrieves a highly-palatable cube of wet dog food when it makes a correct response. No food reward is given for an incorrect response. All stimuli used in tasks are baited with the same food in such a way that the dog can smell it but not see or eat it. This has the effect of masking any odor from the reward food cube so that it cannot be used as a cue to locate the correct stimulus.

Dogs first undergo a pretraining period during which they are exposed to the testing room and TGTA. They are encouraged to climb the stairs, enter the apparatus and eat food from the wells of the stimulus tray. After the pretraining phase is complete, a battery of cognitive tasks ranging from simple two-choice discrimination tasks to complex tests of executive function can be employed to provide objective and quantifiable measures of learning, memory and cognition. In addition, the TGTA can be used to assess attention, sensory and motor function, and recently, a paradigm was developed for evaluating dog food palatability. Cross-sectional studies using dogs of various ages are used to determine how learning is affected by age, and longitudinal studies are used to assess task retention across the lifespan.

and may be related to cerebrovascular changes in the aging brain. MRI lesions in beagles appear as hypointense cavities distributed throughout the brain, but are found most commonly in the frontal cortex and caudate nucleus (Su et al, 2005). In a group of 47 beagles imaged longitudinally over four years, lesions were observed starting at 11 years of age and became increasingly common by the time dogs were 14 years old (Su et al, 2005). Currently, the exact implications of these lesions are unknown and they may be clinically "silent."

Microscopic Changes in the Aging Brain

Microscopic signs of brain pathology can be observed in aged beagles with cognitive dysfunction. One type of pathology of significant interest is the accumulation of a protein fragment called beta-amyloid (Aβ). Aβ contains 39 to 43 amino acids and is the primary constituent of amyloid plaques in the brains of people with Alzheimer's disease (**Box 35-3**). Aβ is toxic to neurons in the brain and accumulates in diffuse proteinaceous plaques that are thought to play a causative role in the development of Alzheimer's disease in people (Selkoe, 2000).

Aged dogs naturally accumulate Aβ protein, with the exact same amino acid sequence, and with a similar extracellular pattern of deposition as occurs in people (Head et al, 2000; Johnstone et al, 1991). The brains of 40 beagles (two to 18 years old) were assayed for Aβ deposition; it was found that cortical Aβ is deposited in a specific spatial and temporal pattern. The earliest and most consistent area of Aβ, deposition was in the frontal cortex beginning at eight years of age, spreading caudally into the parietal and temporal/entorhinal regions by age 10 to 12 years, with the occipital cortex being the last to develop deposition at 13 years of age (Head et al, 2000). Other studies involving larger cohorts (more than 100 dogs) confirm that Aβ deposition is an accumulative and age-dependent process (Russell et al, 1996; Czasch et al, 2006). The Czasch et al 2006 study involving 130 dogs (one month to 18 years) revealed only one dog with pathology in the one month to seven years of age category, whereas 47% had Aβ deposition between the ages of eight to 10 years, 79% between 11 to 13 years and 91% between 14 to 18 years. Other studies involving dogs of different breeds (i.e., German shepherd dog, sheepdog, schnauzer, Doberman pinscher, poodle, Pekingese, fox terrier, beagle, caniche, boxer, Labrador retriever, collie, cocker spaniel, Irish setter, husky, mixed breed, etc.) also confirmed that Aβ deposition increases with age and severity of cognitive deficits (Anderson et al, 2000; Borras et al, 1999; Colle et al, 2000; Cummings et al, 1996; Hou et al, 1997; Pugliese et al, 2006, 2006a).

Aβ deposition has been studied more thoroughly in beagles than in other dogs. In this breed there are significant correlations with increased age and cognitive dysfunction (Cummings et al, 1996; Head et al, 1998; Tapp et al, 2004) and with decreased brain volume as determined by MRI (Tapp et al, 2004). Investigators selected 20 dogs (11 beagles) in one study and all dogs received a battery of six cognitive tasks (i.e., reward and object approach learning, discrimination and reversal learning, object recognition and spatial learning and memory). In this study, increased Aβ deposition was strongly associated with

Box 35-3. Similarities Between Neurologic Diseases in People and Those Found in Dogs.

The original rationale for conducting laboratory-based studies on canine cognition was to develop a model of human age-related cognitive dysfunction. The population of aged dogs tested to date display many similar characteristics to those observed in the aged human population. Like people, dogs show age-related individual variability in their learning, memory and cognitive abilities, and these impairments vary as a function of task. Some old dogs perform neuropsychological tests quite well for their age (successful agers), others are mildly impaired (similar to age-associated memory impairments in people) and still others are severely impaired (similar to dementia in people). Furthermore, neuropsychological tests developed for use in dogs have been adapted to test people. Preliminary evidence suggests that these adapted canine tasks are successful in discriminating healthy and cognitively impaired subpopulations of people.

Aged dogs develop similar neuropathological features to those in both successfully aging people and patients with Alzheimer's disease. As in people, beta-amyloid (Aβ) protein is deposited in the aging dog brain, and shows a selective distribution that changes as a function of age. Immunostaining of the frontal cortex with an anti-Aβ marker reveals morphologic similarities between Aβ plaques in the brains of normal and cognitively impaired people and beagles, making it very difficult to distinguish one species from another based on plaque deposition (**Figure 1**). Furthermore, the extent to which they possess these biologic markers is correlated with their cognitive abilities across the lifespan. For instance, results from a recent study show that decreased brain volume and increased Aβ load accumulation in the frontal cortex of aged dogs are correlated with deficits in complex discrimination and reversal learning.

Taken together, these findings suggest that the canine model can be used effectively for studying the etiology of age-related cognitive decline and dementia and their prevention and treatment in people. There are many research endeavors currently underway to determine if similar positive effects on cognition with antioxidant dietary intervention will be evident in people. This research represents a unique and exciting approach in translating what we know in dogs to aged and diseased human populations.

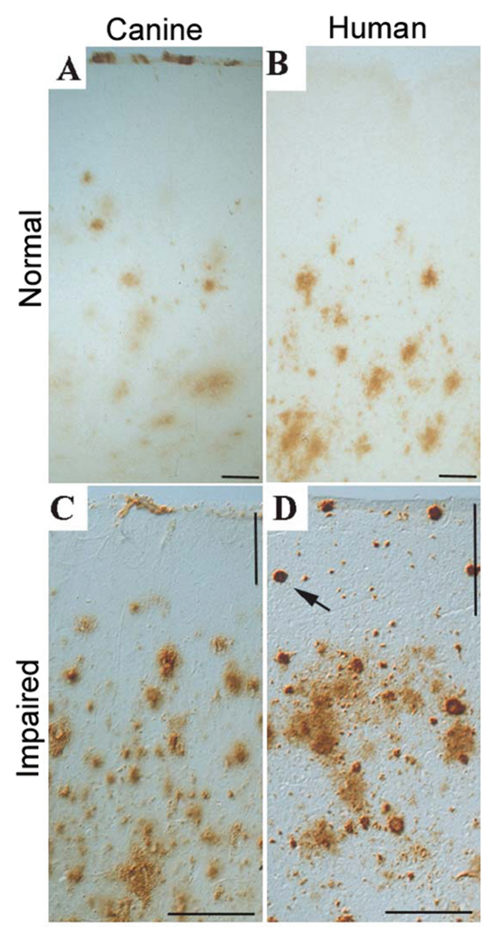

Figure 1. Comparable beta-amyloid (Aβ) immunostaining in the canine and human brain. The frontal cortex of a cognitively normal 13-year-old beagle (A) and 90-year-old female (B) illustrates a similar pattern of senile Aβ plaque deposition in the deeper cortical layers. Frontal cortex sections of a severely impaired 12-year-old beagle (C) and 86-year-old individual (D) with Alzheimer's disease show extensive Aβ pathology throughout all layers of cortex, whereas the molecular layer is largely spared (vertical line = molecular layer, arrow = compact plaque, all bars = 200 mm). New York, NY: Academic Press, 2001; 457-468.)

increased error scores across all tasks (Cummings et al, 1996) (**Figure 35-2**).

Functional Changes in the Aging Brain

In addition to macroscopic and microscopic morphologic changes in the aging canine brain, there is also evidence of functional change.

CHANGES IN THE BLOOD-BRAIN BARRIER WITH AGE

The BBB is a collective term for the complex vascular system of endothelial cells, astrocytes, pericytes and basement membranes surrounding the brain. The BBB allows for selective transport of nutrients from the blood to neuronal cells (Khan, 2005). An MRI study involving 18 beagles (four to 15 years old) showed a non-significant increase in BBB permeability with age; surprisingly, one six-year-old beagle, in which no pathology was expected, had severe BBB leakage and dysfunction, enlarged ventricles, Aβ deposition and cognitive dysfunction (Su et al, 1998). Another study reported a direct link between vascular Aβ deposition and vessel wall integrity; leptomeninges obtained from old dogs affected by cerebral amy-

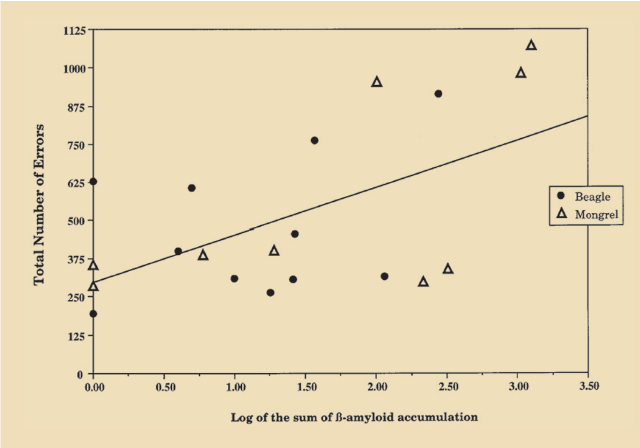

Figure 35-2. Correlations between cognitive task errors and beta-amyloid (Aβ) accumulation in beagles and mixed-breed dogs. The y-axis represents the summed error scores for a series of cognitive tasks and the x-axis represents the overall log scores of the Aβ load measurements from the frontal cortex, entorhinal cortex and cerebellum for each individual animal. Increased cognitive error scores were significantly correlated with increased Aβ measurements ($r = 0.66$, $p \leq 0.01$). (Reproduced with permission from: Cummings BJ, Head E, Afagh AJ, et al. Beta-amyloid accumulation correlates with cognitive dysfunction in the aged canine. Neurobiology of Learning and Memory 1996; 66: 11-23.)

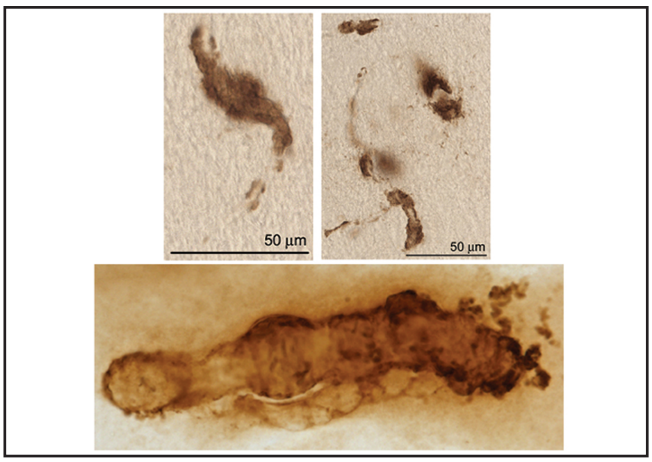

Figure 35-3. Amyloid angiopathy in the canine brain. All three panels illustrate immunostaining with beta-amyloid (Aβ) antibodies in the aged (~10 years old) canine cortex with vessels that are severely affected by Aβ deposition. Angiopathy can impair vascular function and damage the blood-brain barrier, leading to increased permeability of substances in and out of brain cells. (Courtesy Viorela Pop, University of California-Irvine.)

loid angiopathy showed segmental loss of vessel integrity at sites of Aβ deposition, suggesting that the presence of Aβ in old dogs disrupts the BBB (Prior et al, 1996). A study investigating the white matter of 31 dogs of various breeds (six months to 18 years old) found that age-related morphologic changes in the capillaries were associated with BBB permeability dysfunction. Specifically, aging dogs had degeneration of axons, perivascular infiltration of macrophages and iron and sometimes small foci of hemorrhages and infarction (Morita et al, 2005).

Recently, BBB permeability studies involving aged beagles treated with a food containing enhanced levels of antioxidants and/or behavioral enrichment found that, overall, there was a higher permeability index in the occipital lobe compared to the frontal and parietal regions (Su et al, 2006). In this same analysis, the occipital cortex had the highest amount of vascular Aβ pathology (**Figure 35-3**), which may have contributed to the increased BBB index in this region. Furthermore, yearly increases and worsening of BBB permeability were slowed in groups given antioxidant and/or enrichment treatment. Another study involving 25 dogs of various breeds (three to 19 years of age) found that scores on cognitive status questionnaires (Age-Related Cognitive and Affective Disorders) correlated with increased vascular Aβ deposition (Colle et al, 2000). More studies are underway to better understand BBB changes with increased age; interventions may prevent or delay BBB dysfunction and reduce the secretion of serum containing harmful substances that may further induce tissue damage and oxidative stress.

INCREASED OXIDATIVE DAMAGE WITH AGE

Oxidative damage is one possible mechanism that contributes to neuronal dysfunction and the progression of neuropathology with age. Normal metabolic processes in the brain lead to the production of oxidants, or reactive oxygen species (ROS). The free radical theory of aging (Harman, 1956) was the first to propose that excessive production of ROS leads to cell damage and that this damage accumulates over time and inevitably leads to age-dependent pathology in multiple tissues. ROS are the byproducts of mitochondrial aerobic respiration (Beckman and Ames, 1998), and include any atoms or molecules that contain one or more unpaired electrons. ROS are unstable because their unpaired electrons thermodynamically seek to pair with other electrons. This increases unregulated/nonspecific reactions that have enhanced potential for interaction, damage and dysfunction inside cells. Overproduction of ROS results in oxidative damage to proteins, lipids and nucleotides, which, in the brain, lead to neuronal dysfunction and untimely neuronal death. Therefore, the aging process might be mitigated by appropriate reduction of excessive ROS (Chapter 7).

Normal aerobic metabolism in mitochondria generates the superoxide ion, the ROS molecule of central interest. An appropriate balance between superoxide production and detoxification systems is essential to cellular health and intracellular metabolic signaling. Under normal circumstances, cells have a variety of mechanisms to detoxify superoxide (Head and Zicker, 2004). As mitochondria age or become dysfunctional from disease, defense mechanisms are compromised and/or overwhelmed and superoxide is produced in excess leading to uncontrolled reactions in cells (Ames et al, 1993; Cottrell and Turnbull, 2000).

In dogs, at least one defense system declines with age. Superoxide dismutase is present normally in the brain and acts to convert reactive superoxide ions to hydrogen peroxide, thereby decreasing oxidative damage to surrounding tissues. In fact,

one approved treatment for cognitive dysfunction, selegiline, has been shown to increase levels of superoxide dismutase in the brain (Carillo et al, 1994). This compensatory mechanism appears to be compromised in older dogs (Kiatipattanasakul et al, 1997). It has also been shown that oxidative damage to proteins (Head et al, 2002) and lipids (Rofina et al, 2004) accumulates in older dogs. These findings, in combination with age-related cognitive dysfunction and pathologic changes, suggest that decreasing oxidative damage in the brain might improve cognitive function in older dogs. Thus, dietary interventions that decrease specific types of oxidative damage may slow the progression of age-related cognitive decline in dogs.

Key Nutritional Factors

A longitudinal laboratory-based study and a randomized, controlled clinical field trial of the effects of a food enriched in a broad spectrum of antioxidants were conducted as described below. Subjects were assigned to receive either an enriched food (test food) or an extruded senior food (control food). The enriched food was supplemented with vitamins C and E, selenium, L-carnitine, α-lipoic acid, omega-3 fatty acids and a mixture of fruits and vegetables. Key nutritional factors for cognitive dysfunction are listed in **Table 35-3** and discussed in more detail below.

Antioxidants and Mitochondrial Cofactors

Antioxidants are substances that scavenge ROS and decrease the overall number of oxidants in a system (Ames et al, 1993; De Ruvo et al, 2000). Many antioxidant compounds such as vitamin E, vitamin C and trace minerals (e.g., selenium) are derived from food sources. Vitamin C is a water-soluble vitamin that helps replenish vitamin E. Mitochondrial cofactors (α-lipoic acid and L-carnitine) act to enhance the function of aged mitochondria so that fewer ROS are produced during aerobic respiration (i.e., they work to increase mitochondrial efficiency). L-carnitine is involved in lipid metabolism within mitochondria; α-lipoic acid participates in redox reactions and increases intracellular concentrations of glutathione, a primary water-soluble antioxidant within cells. Fruits and vegetables contain flavonoids and carotenoids, which have antioxidant activities as well.

One hypothesis is that adding increased amounts of these components to a food would reduce the amount of oxidative damage in two ways, by: 1) decreasing the production of ROS and 2) increasing the capacity to clear ROS, and that this would slow the progression of age-related pathologic changes and cognitive decline by reducing overall oxidative damage.

A longitudinal laboratory-based study and a blinded veterinary clinical field trial were conducted to assess the effectiveness of a food supplemented with antioxidants and mitochondrial cofactors in ameliorating cognitive decline in older dogs (Dodd et al, 2003). Results were used as grade 1 evidence-based nutritional research for the development of a commercial, antioxidant-enriched food.[a]

Investigators conducting the clinical field trial recruited dogs over seven years of age that had clinical signs in two or more

Table 35-3. Key nutritional factors for foods for dogs with brain aging and associated behavioral changes (cognitive dysfunction).*

Factors	Dietary recommendation
Vitamin E	Increase dietary antioxidants Provide foods with ≥750 mg/kg
Vitamin C	Increase dietary antioxidants Provide foods with ≥150 mg/kg
Selenium	Increase dietary antioxidants Provide foods with 0.5 to 1.3 mg/kg
L-carnitine	Increase mitochondrial cofactors Provide foods with 250 to 750 IU/kg
α-lipoic acid	Increase mitochondrial cofactors Provide foods with ≥100 mg/kg
Omega-3 fatty acids (docosahexaenoic and eicosapentaenoic acids)	Total omegas-3 >1%
Fruits and vegetables	1% of each of five vegetable and fruit ingredients

*Dry matter basis.

DISH categories. The dogs were randomly assigned to two groups: one that was fed a commercial control food (n = 64) and one that was fed an antioxidant fortified test dog food[a] (n = 61). Owners rated their pet's behaviors before and on Days 30 and 60 of the dietary intervention. After 30 days of dietary intervention, owners reported significant improvements in the following categories: disorientation, interactive changes, sleep patterns and house soiling. By Day 60, owners reported that dogs receiving the test food improved in all four DISH categories (plus activity) whereas those fed the control food improved in only two categories. Dogs receiving the fortified food had improvements in awareness of their surroundings, family and animal recognition and interaction, enthusiasm in greeting and agility, and were reported to circle and house soil less frequently. Overall, the test food was better than the control food; dogs receiving it improved in 13 of 15 behaviors (87%) compared to four of 15 behaviors (27%) for dogs in the control group (Dodd et al, 2003; Zicker, 2005).

The laboratory-based study included 48 aged beagles (10 to 13 years old) and 17 young dogs (three to five years). Each age group was divided into an enriched food group (antioxidant) and a control food group; both groups were balanced for age and initial cognitive performance. The enriched food consisted of a variety of antioxidants, mitochondrial cofactors and dried fruits and vegetables. The control food was an identical base food adequate for senior dogs; however, it was not fortified with additional antioxidants and mitochondrial cofactors. Dogs were tested at several time points over two years after initiation of dietary intervention. Old dogs receiving the antioxidant food had improved learning and memory as measured by several cognitive tasks. The oddity discrimination task was administered, as described above, six months after the dietary intervention began (Milgram et al, 2002). Both age and food effects were observed (**Figure 35-4**); old dogs made more errors at learning all levels of the task compared to young dogs. However, old dogs fed the antioxidant food made significantly

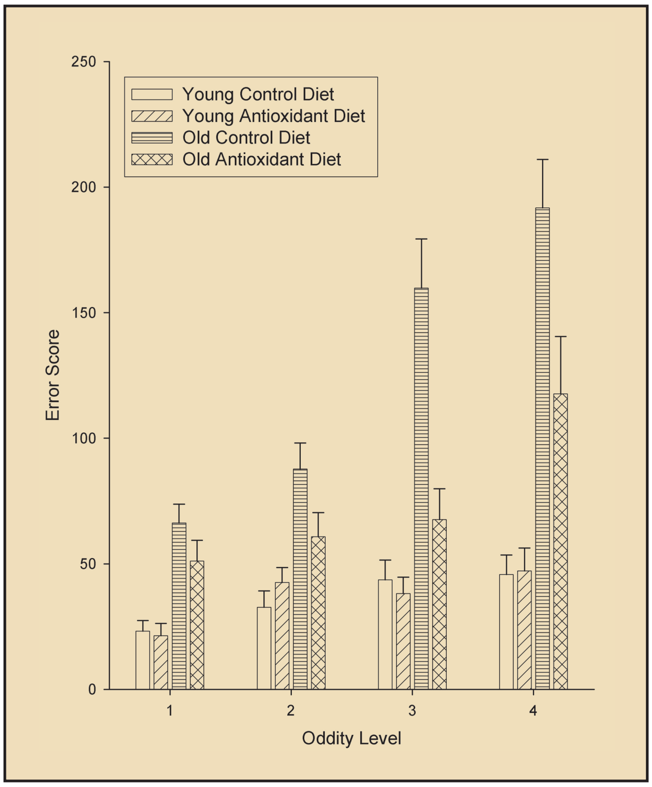

Figure 35-4. Effect of age, food and task difficulty on acquisition of an oddity discrimination learning task. Overall, the number of errors made to achieve the criterion increased with increasing oddity level; old dogs made more errors compared to young dogs on all levels. A food with enhanced levels of antioxidants and mitochondrial cofactors significantly reduced the number of errors made by old dogs to acquire the task. (Courtesy Dr. Elizabeth Head, University of California-Irvine.)

fewer errors than old dogs fed the control food. This effect was particularly pronounced at the most difficult oddity levels. Furthermore, the beneficial effect of the antioxidant food on oddity discrimination learning was not observed in young dogs, presumably because they did not have significant oxidative damage that could be reduced by dietary intervention like the older dogs (Head and Zicker, 2004; Milgram et al, 2002).

Positive antioxidant food effects were also observed selectively in old dog's reversal learning performance (Milgram et al, 2004, 2005). Dogs were first taught to respond to one of two stimuli to receive a food reward, as described above. There was no significant effect of diet at this stage of learning, which was anticipated given that simple discrimination learning, in general, remains intact in old animals (Milgram et al, 2005). However, when the reward contingencies for the task were reversed so that dogs had to suppress their tendency to respond to the previously rewarded stimulus and learn to choose the opposite stimulus, old dogs receiving the antioxidant food had improved learning compared to old dogs fed the control food. This effect of the antioxidant food on reversal learning was found when stimuli differed in size after one year of treatment and when they differed in intensity (e.g., black/white discrimination) after two years of treatment, indicating that the improvement in cognitive function was maintained over time (Milgram et al, 2005). Similar beneficial effects of the antioxidant food in old dogs have been observed with other cognitive tests, including a landmark spatial discrimination task as early as two months after the start of the trial (Ikeda-Douglas et al, 2004; Milgram et al, 2002), a complex size concept task (Siwak et al, 2005) and in contrast sensitivity discrimination (de Rivera et al, 2005).

Overall, the results demonstrate that the rate of cognitive decline observed in old dogs can be slowed by dietary intervention, and that the positive effects on cognition occur relatively rapidly. The findings also suggest that feeding a food containing a mixture of specific antioxidants and mitochondrial cofactors may act synergistically to reduce oxidative damage and increase mitochondrial efficiency, and that oxidative damage and mitochondrial function are fundamental mechanisms contributing to age-associated cognitive dysfunction in older dogs. More studies are currently underway to determine the specific combinations of ingredients that are most effective at ameliorating cognitive dysfunction in older dogs.

In the same laboratory-based intervention study in beagles described above, analyses of Aβ plaque deposition revealed that only dogs given the antioxidant food had less Aβ in the parietal and entorhinal cortex, but not in the prefrontal cortex (Pop et al, 2003). The food may prevent production of Aβ from its larger parent protein, Aβ precursor protein (APP), by increasing the activity of the alpha-secretase enzyme responsible for non-amyloidogenic APP cleavage (Pop et al, 2005). The results of the antioxidant study suggest that food can slow or prevent Aβ, deposition in regions actively accumulating Aβ (e.g., parietal and entorhinal), but cannot reverse existing deposits (e.g., those in the prefrontal cortex).

Appropriate levels of antioxidants and mitochondrial cofactors should be: vitamin E = ≥750 mg/kg; vitamin C = ≥150 mg/kg; selenium = 0.5 to 1.3 mg/kg; L-carnitine = 250 to 750 IU/kg; α-lipoic acid = ≥100 mg/kg; total omega-3 fatty acids = 1% added for docosahexaenoic and eicosapentaenoic acids; fruits and vegetables = 5% added for flavonoids and polyphenols, all on a dry matter basis. No minimum or maximum effective levels for fruits and vegetables have been established. The test food contained 1% of each of five vegetable and fruit ingredients as a substitute for corn.

A careful and detailed analysis of the concentrations of carotenoids, flavonoids and oxygen radical absorbance capacity of individual ingredients was necessary to develop the test food (Zicker, 2005). Studies of commodities with naturally occurring and synthetic antioxidants were conducted to ensure stability through processing, absorption from the gastrointestinal tract, safety and potential antioxidant biologic benefit. The results of these analyses highlighted that the mere presence of a fruit or vegetable on a label was not always indicative of high antioxidant content, an observation that practitioners and pet owners should take into account when choosing food for their senior pets.

Besides their apparent value in the dietary management of

CDS, antioxidants have been shown to play a role in the prevention of certain cancers through various mechanisms (Chapter 30). As in people, increasing age is a general risk factor for cancer in dogs.

Other Nutritional Factors

Older dogs are at increased risk for other diseases, including chronic periodontitis and osteoarthritis. Therefore, the clinician must choose the food based on which medical condition is of greatest priority for the pet. For example, cardiovascular and chronic renal failure may become more of a priority than cognitive dysfunction, necessitating reduced levels of sodium and phosphorus in the food. When the pet's health necessitates the use of a food other than one designed to promote optimal cognitive function, then specific supplements may need to be considered. However, the clinician should evaluate the evidence supporting the efficacy of any supplements that might be added to the feeding plan regimen and ensure there is no contraindication to their use.

FEEDING PLAN

The dietary goals are to provide a food that meets the patient's nutrient requirements and blunts the vulnerability of nervous tissue to ROS as the brain ages. Free radical damage can be manifested by behavioral changes or CDS. The food selected should contain levels of nutrients that protect against free radical damage and improve learning ability and alertness of older pets. Antioxidants and mitochondrial cofactors have demonstrated efficacy when fed in amounts as described in the Key Nutritional Factors section and shown in **Table 35-3**. Behavioral enrichment and medical therapy as described below may augment treatment.

Assess and Select the Food

Levels of key nutritional factors in foods currently fed to patients with cognitive dysfunction should be evaluated and compared with recommended levels. Information from this aspect of assessment is essential for making any changes to foods currently provided. Changing to a more appropriate food is indicated if key nutritional factors in the current food do not match recommended levels. **Table 35-4** provides the key nutritional factors recommended for foods for dogs with CDS and compares them to the key nutritional factor content of a commercial food developed specifically for dogs with CDS.[a]

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods. Evidence Grade 1 (the highest level) exists for at least one food used for dogs with CDS.[a]

Assess and Determine the Feeding Method

A thorough assessment should include verification of the feeding method currently being used. Items to consider include feeding frequency, amount fed, how the food is offered, access to other food and who feeds the animal. All of this information should have been gathered when the history of the animal was obtained. If the animal has a normal body condition score (2.5/5 to 3.5/5), the amount of food previously fed (energy basis) was probably appropriate.

Adjunct Therapy

Behavioral Enrichment

Environmental enrichment (EE) also appears to play an important role in preserving cognitive abilities in old age. In dogs, there is laboratory-based evidence suggesting that an enriched environment acts synergistically with an antioxidant food to slow cognitive decline in older animals (Milgram et al, 2004, 2005). In the same study in which the fortified food was administered (described above), dogs in each of the food groups were further divided to include one group that received EE and one that did not. The EE program consisted of increased activity (i.e., exercise twice weekly), enriched kennel environments (i.e., toys and housing with kennelmates) and regular cognitive testing (i.e., neuropsychological testing five or six times weekly). In combination with the antioxidant food, positive effects of EE were observed after one year in the old dogs; size discrimination and reversal learning were improved. After two

years of EE, the enrichment alone was sufficient to detect improved performance on the intensity discrimination and reversal tasks. On both of these tasks, the investigators found that combined antioxidant dietary and EE intervention were more effective than either treatment alone. The authors concluded that a prolonged period of EE has substantial effects on cognitive performance in older beagles, and like the antioxidant food, appears to slow development of age-related cognitive decline in old dogs (Milgram et al, 2004, 2005).

Supplements

A number of complementary therapies are marketed as treatments for cognitive dysfunction. These products may contain mixtures of herbal extracts, vitamins, phospholipids, fatty acids, antioxidants and mitochondrial cofactors believed to act in a synergistic or potentiating manner to slow the progression of or improve clinical signs associated with brain aging. Although there is little evidence to support the efficacy of most of these products, three clinical trials have recently reported improvements in clinical signs of CDS in pets given dietary supplements containing phosphatidylserine (Osella et al, 2007; Cena et al, 2005; Heath et al, 2007). Phosphatidylserine, *Gingko biloba*, pyridoxine and vitamin E are distributed in Italy as a neuroprotective dietary supplement for senior dogs and cats.[b] In a preliminary laboratory evaluation, dogs were tested after administration of a placebo or the product for 60 days, in a crossover design using spatial memory assessments (Araujo et al, 2006). Performance accuracy was significantly improved in the treated group compared to the baseline group. In addition, dogs receiving the supplement in the first portion of the study maintained their improved performance (Araujo et al, 2006). This product was recently reformulated and now contains resveratrol.

Other commercially available supplements contain docosahexaenoic acid, eicosapentaenoic acid and acetylcysteine, which is a primary precursor to glutathione and coenzyme Q10. Fatty acids and glutathione may be beneficial in slowing brain aging in people (Horrocks and Yeo, 1999; Pocernich et al, 2000). Preliminary work also showed an improvement in memory and health status in dogs receiving a docosahexaenoic acid supplement (Araujo et al, 2005). S-adenosyl-methionine (SAMe) may be useful in elderly pets because it has been shown to be helpful for treating cognitive dysfunction in people. Furthermore, in a preliminary open label clinical trial, SAMe improved activity levels, sleep-wake cycles, playfulness and fecal elimination disorders in elderly depressed or confused pets[c] (Arnold, 2005).

Drug Therapy

Selegiline is licensed for treatment of cognitive dysfunction in dogs in North America.[d] Selegiline is a selective and irreversible inhibitor of MOA-B in dogs (Milgram et al, 1993). It increases 2-phenylethylamine in the canine brain. This drug is a neuromodulator; therefore, the primary mode of action may be to enhance dopamine and catecholamine function in the cortex and hippocampus to improve cognitive function (Milgram et al, 1993; Knoll, 1998). Selegiline may also contribute to a decrease in ROS in the brain by decreasing production of free radicals, scavenging oxygen free radicals and enhancing the scavenging action of enzymes such as catalase and superoxide dismutase (Carillo et al, 1994; Heinonen and Lammintausta, 1991). Selegiline is given at a dose of 0.5 to 1 mg/kg per os each morning. Although selegiline can be used concurrently with most veterinary therapeutic foods and supplements, it should not be combined with narcotics, antidepressants or monoamine oxidase inhibitors. Therefore, it should probably not be used with supplements containing tryptophan, St. John's wort or *Ginkgo biloba*.

Propentofylline and nicergoline, which may enhance cerebrovascular transmission, are licensed in some European countries and Australia for signs of brain aging in senior pets (Penaliggon, 1991; Kapl and Rudolphi, 1998). The efficacy of nicergoline has been demonstrated in at least one clinical trial (Penaliggon, 1991). It was recently determined that senior dogs display a greater sensitivity to the memory impairment effects of scopolamine (an anticholinergic drug) than younger dogs and show a positive response to experimental cholinomimetics (Araujo et al, 2005a). A major focus of drug therapy for Alzheimer's disease in people is to enhance cholinergic transmission. Therefore, drugs that act to augment cholinergic transmission might have application for clinical use in dogs with cognitive decline; however, no available drugs have been sufficiently investigated (Araujo et al, 2005a). This may, however, explain why some of the natural supplements (e.g., those containing phosphatidylserine) are effective by enhancing cholinergic transmission or helping protect cholinergic neurons (Vannucchi et al, 1990; Gelbann and Mullet, 1992).

In addition to preventive therapy, it may be necessary to consider medications to treat specific signs such as anxiety, restlessness, night waking and agitation. Selection of the appropriate medication should consider the pet's health and any concurrent medications. In general, anxiolytics that are less likely to cause hepatic complications (e.g., clonazepam, oxazepam, lorazepam or buspirone), natural products such as DAP, and antidepressants that have little or no anticholinergic effects, such as fluoxetine might be the most appropriate options.

REASSESSMENT

Improvements in abnormal behavior associated with brain aging may be noted within six to 12 weeks after making a dietary change. If improvements are not noted with 12 weeks, then it is unlikely that nutritional management alone will result in significant improvement. Therapy with supplements and drugs appears to be safe to use in conjunction with nutritional management. Reassessment of behavioral changes can also occur during routine health maintenance protocols established for mature or geriatric pets in each hospital.

As mentioned above, in 2005, the American Animal Hospital Association senior care task force published guidelines that recommended yearly wellness screening for healthy mid-

dle-aged pets and twice yearly screening for senior pets (i.e., last 25% of predicted lifespan). At each visit, the pet should receive a physical examination and laboratory tests and the owner should be extensively questioned about changes in behavior and health (Epstein et al, 2005). However, patients with health problems and those receiving drugs or medications may need to be assessed more frequently or have more extensive testing (e.g., blood pressure measurement, radiographs). For example, semiannual visits may be adequate for dogs with CDS; however, if signs worsen or new signs arise, the owners should schedule a more immediate reassessment to ensure that new diseases are not emerging and to assess whether additional therapeutics might be needed. When drugs are dispensed, followup visits should be scheduled based on the specific drug and disease. For example, dogs receiving selegiline should be reassessed after the first month, whereas dogs receiving most nonsteroidal antiinflammatory drugs should be reassessed within a few weeks to establish therapeutic effect and reassess liver enzyme activity.

CASE 35-1

Behavioral Changes in an Older Beagle

Philip Roudebush, DVM, Dipl. ACVIM (Small Animal Internal Medicine)
Hill's Scientific Affairs
Topeka, Kansas, USA

Patient Assessment

A 13-year-old intact female beagle was admitted for routine health maintenance procedures. The owners reported no obvious health problems with the dog other than halitosis and masses under the skin of the ventral abdomen. As part of the geriatric health maintenance program administered at this hospital, the owners were asked to complete a behavioral questionnaire and checklist (**Table 35-1**). On this questionnaire, the owners noted that the dog had shown decreased greeting behavior when they returned home, had less interest in being petted by the owners or their children, paced aimlessly in the fenced backyard at times, often refused to play with the younger dog at home and occasionally woke up at night and paced in their bedroom. The owners attributed these changes to aging and did not consider them major problems.

Physical examination revealed a geriatric dog with a body weight of 12.0 kg and an ideal body condition score of 3 on a 5-point scale. Abnormalities include moderate periodontal disease with extensive bilateral calculus formation on the premolars and molars and reddening and mild swelling of the gingival margins, a small, soft 2 x 2 cm subcutaneous mass at the left sternal border and a small, firm mammary tumor in the third right gland.

Routine preventive health testing included a complete blood count, serum biochemistry profile, heartworm check, urinalysis, fecal examination and fine-needle aspiration of the two masses for cytologic evaluation. Results of blood work, parasite exams and urinalysis were normal. Fine-needle aspiration cytology was consistent with a lipoma and benign mixed mammary tumor.

Assess the Food and Feeding Method

The dog was fed a combination of dry and moist commercial grocery brand dog foods supplemented with occasional table scraps.

Questions

1. What are potential causes and ways to evaluate the behavioral problems noted in this dog?
2. Outline a comprehensive medical and nutritional management plan for this patient.

Answers

1. Aged dogs are susceptible to a number of neurologic disorders with a wide variety of clinical presentations. Behavioral changes, alterations in mental status, seizures, loss of vision or hearing, pain, tremors, stiffness, weakness, gait abnormalities and motor dysfunction are associated with a variety of neurologic diseases. A screening neurologic examination that evaluates mental status, cranial nerve function and gait often can detect neurologic deficits. When deficits are present, a complete neurologic examination

Chapter 36

Cardiovascular Disease

Philip Roudebush

Bruce W. Keene

"Give neither advice nor salt, until you are asked for it."
English Proverb

CLINICAL IMPORTANCE

Cardiovascular disease and congestive heart failure (CHF) are common conditions in dogs and cats. The types and prevalence of heart disease in dogs in the United States were characterized more than 40 years ago in a survey of 5,000 dogs at the University of Pennsylvania (Detweiler and Patterson, 1965). Eleven percent of dogs had reliable signs of heart disease and another 9% had possible heart disease. Congenital heart disease has been recognized in 0.56 to 0.85% of dogs and 0.2% of cats (Detweiler and Patterson, 1965; Harpster and Zook, 1987; Buchanan, 1992). These results predominantly reflect the prevalence of congenital disease in the necropsy populations of referral institutions, and may significantly underestimate the prevalence of heart diseases in the general pet population.

The overall prevalence of heart disease appears to be similar today, but comparable epidemiologic data for acquired heart disease in the U.S. are not available (Buchanan, 1992). A clinical review in Italy found heart disease in 11% of 7,148 dogs (Fioretti et al, 1988). One informal survey identified heart problems as the third leading cause of nonaccidental death of dogs (MAF, 1991). The results of a more recent informal survey of veterinary clinics performed by a pharmaceutical company also suggest that the prevalence of cardiovascular disease among dogs has probably not changed dramatically from these earlier estimates.[a]

Chronic mitral valvular disease (endocardiosis) is by far the most common acquired cardiac abnormality in dogs, affecting more than one-third of patients over 10 years of age (Buchanan, 1992, 1977). The tricuspid valve is also frequently involved (in approximately 30% of cases), but disease of the tricuspid valve is usually less severe. Chronic valvular disease occurs with relatively greater frequency in small dogs, especially poodles, miniature schnauzers, Chihuahuas, cocker spaniels, fox terriers, Boston terriers, dachshunds, Pekingese, miniature pinschers and whippets (Buchanan, 1977; Thrusfield et al, 1985). Mitral valvular disease has been identified in more than 50% of cavalier King Charles spaniels in the United Kingdom, Sweden and the U.S. (Darke, 1995; Beardrow and Buchanan, 1993). Acquired valvular disease in cats is rare.

Since 1987, the prevalence of dilated (congestive) cardiomyopathy in cats has decreased markedly following the discovery that taurine deficiency was the principal cause (Pion et al, 1987, 1989), and the subsequent supplementation of most commercial feline foods with taurine. One study documented that the prevalence of dilated cardiomyopathy as a cause of myocardial failure in cats decreased from 28% in 1986 to only 6% in 1989, whereas the occurrence of hypertrophic cardiomyopathy did not change (Skiles et al, 1990). Referral institutions continue to observe several individual cases of dilated cardiomyopathy in cats each year, only a few of which are now associated with taurine deficiency. Hypertrophic and restrictive cardiomyopathies are now the most common causes of myocardial failure in cats.

Various types of myocardial disease that were not recognized 40 years ago are now seen relatively commonly in dogs (Buchanan, 1992). Large-breed dogs, especially males, are predisposed to dilated cardiomyopathy. Doberman pinscher dogs are particularly susceptible. Hypertrophic cardiomyopathy occurs rarely in dogs. Arrhythmogenic right ventricular cardiomyopathy is common among boxer dogs (Meurs and Spier, 2009).

Pulmonary vascular disease with secondary cor pulmonale is most commonly associated with *Dirofilaria immitis* infection (heartworm disease). The prevalence of this disease is high in endemic areas in those dogs that do not receive appropriate preventive medication. Pulmonary hypertension unrelated to heartworm disease appears to be more common than previously believed and the frequency of diagnosis has increased because of heightened awareness about the condition (Henik, 2009) and the more widespread application of Doppler echocardiography. Pulmonary thromboembolism is most commonly associated with renal disease, hyperadrenocorticism, corticosteroid therapy, neoplasia, nephrotic syndrome, pancreatitis and immune-mediated hemolytic anemia. Primary systemic vascular disease is uncommon, but atherosclerosis and aortic or coronary thrombosis are occasionally recognized, particularly in dogs with hypothyroidism and elevated serum cholesterol concentrations. Secondary aortic thromboembolism in cats may occur with any of the forms of cardiomyopathy and is the most frequently acquired feline vascular abnormality.

Systemic hypertension in dogs and cats appears to be more common than studies indicated 40 years ago (Brown et al, 2007). Because blood pressure measurement in dogs and cats is technically challenging compared to measurement in people, and because of the prominent “white coat effect” in animals (elevations in measured blood pressure associated with the stress of the clinical visit) the actual prevalence of systemic hypertension in dogs and cats is still unknown. Spontaneous essential hypertension occurs in dogs, but hypertension most commonly develops secondary to chronic kidney disease in dogs and cats, hyperadrenocorticism in dogs and hyperthyroidism in cats (Littman and Drobatz, 1995). The demographic characteristics of dogs and cats at risk for the diseases that predispose to systemic hypertension overlap with those of dogs and cats with acquired heart disease. Although hypertensive dogs and cats may present at any age, most often they are middle-aged to geriatric (mean age: dogs nine years; cats 15 years, Littman and Drobatz, 1995). The strength of the peripheral pulses does not help detect systemic hypertension; absolute blood pressure numbers need to be determined. Retinal hemorrhages and detachments are common end-organ changes in patients with moderate to severe hypertension. These ocular signs are often the first evidence of hypertensive disease, which suggests that a fundic examination should be included in the routine evaluation of all dogs and cats. Other clinical signs of hypertension are most often related to the underlying disease that causes systemic hypertension.

The effects of long-term or severe systemic hypertension may cause significant heart disease (e.g. left ventricular concentric hypertrophy), and hypertension may complicate the treatment of chronic mitral valvular disease in dogs by worsening valvular regurgitation. It makes good clinical sense to screen dogs and cats with significant heart disease for the presence of systemic hypertension (by repeated blood pressure measurements), and also makes sense to search for underlying heart disease in patients with known hypertension, especially those exhibiting clinical signs that may be referable to heart disease.

The most frequently encountered problems associated with cardiovascular disease that require nutritional modification are fluid retention states associated with chronic CHF, primary or secondary hypertension, obesity, cachexia and myocardial diseases related to a specific nutrient deficiency (taurine- and carnitine-associated cardiomyopathy and electrolyte disorders that may predispose to cardiac dysrhythmias.

PATIENT ASSESSMENT

History and Physical Examination

Heart failure is a condition characterized by inadequate cardiac output and insufficient delivery of nutrients relative to tissue metabolic needs. Heart failure is not a specific disease, but a clinical syndrome caused by a variety of structural and functional disorders of the heart or great vessels. Clinical manifestations of heart failure are due to reduced cardiac output (weakness, exercise intolerance, syncope), pulmonary congestion (dyspnea, orthopnea, cough, abnormal breath sounds with crackles and wheezes), systemic fluid retention (jugular venous distention, hepatomegaly, ascites, pleural effusion) or a combination of these conditions.

In general, the clinical manifestations of heart failure are similar irrespective of the underlying cause, although the onset may vary. Occasionally, for example, heart failure may occur abruptly and lead to acute pulmonary edema (e.g., ruptured mitral valve chorda tendineae). Diagnosis of this fulminant form of heart failure is based on the history and overt, acute clinical signs. In many instances, however, heart failure becomes evident gradually; a long asymptomatic period (years) following the diagnosis of chronic valvular heart disease based on the presence of the typical murmur of mitral valve insufficiency is typical–this period may be followed by the onset of mild clinical signs that worsen gradually, or by the sudden onset of severe pulmonary edema. Most of the clinical signs used as the basis for diagnosing chronic heart failure may also occur as a result of other conditions.

Validity of a clinical diagnosis of heart failure in human patients was studied in a primary health care setting (Remes et al, 1991). One-third of human patients who were initially diagnosed with heart failure were subsequently found to have other conditions that caused their clinical problems. Obesity and pulmonary diseases were the most important conditions leading to false-positive diagnoses of heart failure in this population of human patients. Obesity and chronic bronchitis often occur in dogs and cats with heart disease and cause clinical manifestations similar to those of heart failure, thereby complicating the

diagnosis. As an example, a small-breed dog may be admitted with moderate obesity, cough, tachypnea, exercise intolerance, abnormal breath sounds with crackles and a holosystolic murmur loudest over the mitral valve. It is important that this patient be evaluated thoroughly to determine whether the cause of the clinical signs is: 1) chronic bronchitis, 2) early heart failure, 3) obesity or 4) a combination of these conditions.

Human patients with heart disease and failure are categorized according to functional and structural schemes. The functional scheme is based on the clinical signs and symptoms evident at rest and during exercise (New York Heart Association functional classes). Members of the International Small Animal Cardiac Health Council popularized a functional classification scheme that is applicable to veterinary patients (**Table 36-1**) (ISACHC, 1994). Although patients with heart disease may follow an orderly progression though a functional classification, animals may change classifications in both directions–e.g., from Class III or IV to Class II or III following therapy, or from Class I to Class III or IV following a salty meal.

In 2001, the American College of Cardiology (ACC) and the American Heart Association (AHA) developed a staging scheme for heart failure patients emphasizing the progressive nature of the diseases that cause heart failure. This scheme has been adapted as follows for veterinary use (Keene and Bonagura, 2009):

- Stage A–patients at high risk for the development of heart failure, but without currently apparent structural heart abnormalities (e.g., cavalier King Charles spaniels, boxers, Doberman pinschers and other animals belonging to breeds, families or demographic groups known to be predisposed to heart disease).
- Stage B–patients with a structural heart abnormality, but without past or current symptoms of heart failure (e.g., patients with an asymptomatic murmur of mitral regurgitation).
- Stage C–patients with a structural abnormality and current or previous clinical signs of heart failure (this stage includes all patients that have experienced clinical signs of heart failure, and they stay in this stage despite resolution of their clinical signs with standard therapy).
- Stage D–patients with clinical signs of heart failure that have become refractory to standard treatment (defined practically as standard doses of furosemide, angiotensin-converting enzyme [ACE] inhibitor and pimobendan).

The ACC/AHA staging system emphasizes that progressive structural abnormalities of the heart underlie the pathogenesis of heart failure. This scheme is meant to encourage a program of client education and heart failure management that supports early screening for heart disease and provides a loosely defined plan for therapeutic intensification, including nutritional intervention, as heart disease progresses. This staging system further departs from functional classifications in that while a patient can still progress suddenly from Stage B to Stage C (or D, for example, if a previously asymptomatic dog with chronic valvular heart disease experiences a ruptured mitral valvular chorda tendineae), that path cannot be traveled in reverse.

Table 36-1. Functional classes of heart failure.*

Class I. The asymptomatic patient
Heart disease is detectable (cardiac murmur, dysrhythmia), but the patient is not overtly affected and does not demonstrate clinical signs of heart failure.
a. Heart disease is detectable but no signs of compensation are evident, such as volume or pressure overload ventricular hypertrophy.
b. Heart disease is detectable in conjunction with radiographic or echocardiographic evidence of compensation, such as volume or pressure overload ventricular hypertrophy.

Class II. Mild to moderate heart failure
Clinical signs of heart failure are evident at rest or with mild exercise and adversely affect the quality of life. Typical clinical signs include exercise intolerance, cough, tachypnea, mild respiratory distress and mild to moderate ascites. Hypoperfusion at rest is generally not present.

Class III. Advanced heart failure
Clinical signs of CHF are immediately evident. These clinical signs include respiratory distress (dyspnea), marked ascites, profound exercise intolerance and hypoperfusion at rest. In the most severe cases, the patient is moribund and suffers from cardiogenic shock.

*Adapted from International Small Animal Cardiac Health Council. In: Recommendations for the Diagnosis of Heart Disease and the Treatment of Heart Failure in Small Animals. Academy of Veterinary Cardiology, 1994.

The ACC/AHA scheme provides a framework for thinking about heart disease that is more analogous to the clinical approach to cancer, i.e., the identification of patients who are known to be at risk for cancer and who might benefit from more intensive screening to identify disease at an early stage (Stage A); the identification and treatment of patients with in-situ disease (Stage B); and the identification and treatment of patients with established (Stage C) or widespread (Stage D) disease. As our knowledge of the pathophysiology of heart disease and the progression of heart disease to heart failure expands, there is hope that early pharmacologic and/or nutritional intervention (often possible before the onset of clinical signs in heart disease) might significantly affect the eventual course of disease and survival in an individual patient. Currently, however, there are essentially no well-defined, effective therapies that prevent or delay the onset of heart disease or failure in either dogs or cats.

In assessing the nutritional status of patients with cardiovascular disease, overall body condition is the most important indicator of nutritional status and it appears to be an important, independent prognostic indicator. As will be discussed later, obesity causes cardiovascular changes that can complicate the management of cardiovascular disease, but in dogs and cats, significant weight loss is a far more common problem after the onset of heart failure. Although treatment of obesity is occasionally necessary in the management of patients with significant cardiovascular disease, it is relatively uncommon that clinically significant obesity coexists with life-threatening cardiovascular disease in dogs and cats. Cachexia is a syndrome of severe wasting seen clinically in a variety of diseases, especially chronic heart failure, cancer and acquired immunodeficiency syndrome. Cachexia is an additional risk factor in people with heart failure; loss of lean

body mass is a negative predictor of survival (Freeman and Roubenoff, 1994). Systems for accurately assessing and scoring body condition are available for dogs and cats (Chapter 1). The body condition of dogs and cats with cardiovascular disease should be followed closely as part of reassessment.

Laboratory and Other Clinical Information

Measurement of Systemic Blood Pressure

Hypertension is often defined as that blood pressure two standard deviations above the mean for the population (Littman and Drobatz, 1995). Most investigators agree that the systemic systolic/diastolic blood pressure in awake, untrained dogs and cats normally should not exceed 180/100 millimeters of mercury (mm Hg), with values up to 200/110 mm Hg considered borderline or mild hypertension (Littman and Drobatz, 1995), especially in cats.

Direct blood pressure measurement is obtained by inserting a needle or catheter into an artery. The needle or catheter is connected to a pressure transducer and the result displayed on an oscilloscope/recording device. Anxiety and pain may falsely elevate the blood pressure of awake, restrained or uncooperative patients when measured by direct techniques.

Indirect blood pressure measurement is noninvasive and obtained with a cuff constricting a peripheral artery (leg or tail). An ultrasonic, oscillometric or photoplethysmographic transducer distal to the cuff is used to detect blood flow or arterial wall motion (Hansen, 1995). Blood pressure values obtained by direct and indirect methods generally correlate well, but indirect methods may produce values less than those obtained simultaneously by direct methods. In general, blood pressure measurements obtained routinely during hospital visits are reasonable estimates of a dog's true blood pressure (Remillard et al, 1991). Uncooperative, anxious patients may have elevated blood pressure measurements in the hospital setting that do not reflect normal values. A review of blood pressure measurements describes these techniques (Hansen, 1995). Comprehensive, current guidelines for the diagnosis and management of hypertension have recently been published (Brown et al, 2007).

Screening for Concomitant Disease

Cardiovascular disease is frequently associated with or exacerbated by underlying chronic renal disease in dogs and cats. All patients with cardiovascular disease should be screened for concomitant renal disease. This is best accomplished with a urinalysis and a serum biochemistry profile, which includes urea nitrogen, creatinine, electrolyte, calcium and phosphorus concentrations.

Hyperthyroidism in cats is a risk factor for secondary thyrotoxic cardiomyopathy and systemic hypertension. Cats over the age of seven years with evidence of cardiovascular disease should be screened for hyperthyroidism (Chapter 29).

Measuring and Interpreting Tissue Nutrients and Hormones

ELECTROLYTES AND MAGNESIUM

Serum electrolyte and magnesium concentrations are important factors to assess in patients with cardiovascular disease. Abnormalities in electrolyte and magnesium homeostasis can cause or contribute to the progression or severity of cardiac dysrhythmias, and decreased myocardial contractility associated with severe electrolyte abnormalities may cause profound heart muscle weakness. Electrolyte and magnesium abnormalities can also potentiate adverse effects from cardiac glycosides and other cardiac drugs. Unfortunately, the precise diagnosis of potassium and magnesium depletion can be difficult to make because these are primarily intracellular constituents. Normal serum potassium and magnesium concentrations can occur in the presence of total body depletion of these elements; therefore, serum potassium and magnesium concentrations do not always reflect total body stores.

TAURINE

Plasma and whole blood taurine concentrations are routinely measured to evaluate the taurine status of cats and dogs. Most early experimental and clinical studies used plasma taurine concentration to define taurine status. Values for plasma taurine of less than 20 to 30 nmol/ml (µmol/l) have been associated with deficiency in clinical studies involving client-owned cats (Pion et al, 1987; Sisson et al, 1991) and dogs (Kramer et al, 1995).

Studies involving laboratory cats have shown that plasma, but not whole blood taurine concentrations are affected by meals and food deprivation (Trautwein and Hayes, 1991; Pion et al, 1991). Therefore, whole blood taurine concentration is a more reliable index of taurine status in cats. In general, the whole blood taurine pool is remarkably stable and declines only during prolonged depletion, whereas plasma taurine concentrations fluctuate acutely depending on availability in food. Cats with whole blood taurine concentrations consistently less than 150 nmol/ml should be considered taurine deficient (Pion et al, 1989, 1991). Whole blood taurine concentrations have also been adopted by the Association of American Feed Control Officials (AAFCO) as part of its feeding protocols for cats. To successfully complete an AAFCO feeding protocol, no individual cat, kitten or queen can have a whole blood taurine concentration less than 200 nmol/ml (AAFCO, 2008).

Assessment of urinary taurine excretion has also been advocated as an alternative to measuring plasma or whole blood taurine concentrations (Glass et al, 1992). Urinary taurine excretion may provide vital information in the experimental setting for proper formulation of feline foods, but this assessment is probably not a practical technique for use with client-owned cats.

In North America, several laboratories routinely perform plasma and whole blood taurine assays. These laboratories are most easily accessed through regional veterinary reference laboratories that perform routine diagnostic services.

CARNITINE

Many investigators have reported blood and tissue carnitine concentrations in animals. The lowest levels are usually found in serum; in contrast, heart and skeletal muscle contain very high levels of carnitine, which underscores its importance in these tissues. Normal canine and feline values are similar for

total, free and esterified carnitine concentrations in plasma based on measurements from a small number of healthy dogs and cats fed a standard dry commercial food (Jacobs et al, 1990, 1990a; Keene, 1992; Shelton, 1995). Total carnitine concentrations in plasma are influenced by intake of carnitine in food. Plasma concentrations will be elevated in animals that eat foods high in carnitine (e.g., raw meat or moist foods high in skeletal muscle content). To measure carnitine concentration, approximately 1 ml of heparinized plasma should be immediately separated, frozen and submitted to an appropriate laboratory.[b]

Carnitine concentrations can also be measured in cardiac muscle, skeletal muscle and liver (Jacobs et al, 1990, 1990a; Keene, 1992; Shelton, 1995). Cardiac tissue is obtained by using a modified transvenous endomyocardial biopsy technique (Keene et al, 1990). Skeletal muscle and liver tissue are obtained using standard biopsy techniques. Tissue specimens are blotted dry, immediately frozen in liquid nitrogen and stored at –70°C (–94°F) until the carnitine concentration is measured at an appropriate laboratory.[b] Tissues for carnitine assay should not be placed in formalin. Dogs with confirmed lipid storage myopathy should have plasma and tissue carnitine assays performed in the hope of identifying a potentially treatable cause of an otherwise difficult to manage disease (Shelton, 1995).[c]

BLOOD CONSTITUENTS ASSOCIATED WITH NEUROHUMORAL ACTIVATION

It is well established that activity of several neurohumoral systems is increased in many patients with chronic CHF. Elevated levels of renin, angiotensin, aldosterone and arginine vasopressin (AVP; antidiuretic hormone [ADH]) occur in both spontaneous and experimental canine models of CHF (Watkins et al, 1976; Riegger and Liebau, 1982; Riegger et al, 1988; Maher et al, 1989; Villarreal et al, 1990; Himura et al, 1994). Increased concentrations of renin, aldosterone, norepinephrine and brain or atrial natriuretic peptide or atrial natriuretic factor (BNP, ANP or ANF) occur in dogs with spontaneous heart disease and failure (Knowlen et al, 1983; Ware et al, 1990; Takemura et al, 1991; Vollmar et al, 1991; Buoro et al, 1992; Haggstrom et al, 1994; Pederson et al, 1995). Aldosterone, norepinephrine and ANP concentrations also increase with the severity of heart failure (Knowlen et al, 1983; Ware et al, 1990; Haggstrom et al, 1994). Aldosterone concentrations may offer some prognostic information about the severity of heart failure (Knowlen et al, 1983). Measurement of n-terminal BNP or troponin-I (a calcium regulatory protein that leaks from myocytes in many heart diseases) in the serum of dogs or cats shows significant promise as a means of identifying patients with either clinical or subclinical heart disease; however, the optimal application of these techniques awaits the availability of a reliable point-of-care test with proven positive predictive value in a variety of clinical settings (Prosek et al, 2007; Oyama et al, 2007). Norepinephrine, angiotensin, ANP and AVP analyses are only available through research laboratories. Plasma renin activity and aldosterone measurements are available through several reference laboratories.

Risk Factors

Risk factors for causing or complicating cardiovascular disease include breed, gender, obesity, renal disease, drug therapy, endocrinopathies and heartworm infection. Breed and gender appear to be the most important risk factors for cardiovascular disease in dogs. A number of breeds are at increased risk for several different congenital cardiovascular malformations, including patent ductus arteriosus, portacaval shunts, aortic stenosis, pulmonic stenosis, ventricular septal defects, tricuspid dysplasia and persistent aortic arch and related vascular abnormalities. Estimated relative risks (odds ratios) are listed elsewhere by breed for many of these congenital abnormalities (Buchanan, 1992). Chronic valvular heart disease occurs with relatively greater frequency in small dogs, whereas large dogs, especially males, are predisposed to dilated cardiomyopathy. Certain canine breeds also have characteristic cardiac dysrhythmias that may occur with or without significant cardiomegaly or signs of CHF. Finally, an increased risk of pericardial effusion is noted in golden retrievers, Labrador retrievers, German shepherd dogs, German shorthaired pointers and Akitas (Buchanan, 1992).

Obesity occurs frequently in dogs and cats with cardiovascular disease. Obesity not only produces clinical signs that mimic those of early heart failure (i.e., exercise intolerance, tachypnea, weakness), but also causes cardiovascular changes that can exacerbate underlying cardiovascular disease.

Chronic progressive kidney disease and failure often occur in dogs and cats with cardiovascular disease, especially in older patients. Cardiac disease often exacerbates underlying renal disease because a large proportion of the cardiac output is normally destined for the kidneys. Renal disease influences the types and dosages of medications that are used to treat patients with cardiovascular disease. Chronic kidney disease is also a risk factor for secondary hypertension in dogs and cats.

Therapy for CHF often includes: 1) diuretics and salt restriction to reduce preload and venous congestion, 2) pimobendan to increase contractility and dilate veins and arteries to increase contractility and decrease preload and afterload and 3) ACE inhibitors, which also act as arterial and venous dilators to reduce venous congestion, preload and afterload, but more importantly appear to have long-term survival benefits from inhibiting the activity of the renin-angiotensin-aldosterone (RAA) system. Dehydration, systemic hypotension, renal insufficiency, electrolyte abnormalities, acid-base disturbances, arrhythmias and loss of appetite are all potential complications of combined pharmacologic and nutritional therapy for patients with CHF.

Hyperthyroidism is a risk factor for hypertrophic cardiomyopathy and secondary hypertension in older cats. Hyperadrenocorticism is a risk factor for pulmonary thromboembolism. Heartworm infection is a risk factor for pulmonary vascular disease, cor pulmonale, right-sided CHF and pulmonary thromboembolism.

Table 36-2. Compensatory mechanisms in heart failure.

Autonomic nervous system
Heart
Increased heart rate
Increased myocardial contractile stimulation
Peripheral circulation
Arterial vasoconstriction (increased afterload)
Venous vasoconstriction (increased preload)
Kidney (renin-angiotensin-aldosterone)
Arterial vasoconstriction (increased afterload)
Venous vasoconstriction (increased preload)
Sodium, chloride and water retention (increased preload and afterload)
Increased myocardial contractile stimulation
Endothelin 1 (increased preload and afterload)
Arginine vasopressin (increased preload and afterload)
Atrial natriuretic peptide (decreased afterload)
Prostaglandins
Frank-Starling law of the heart
Increased end-diastolic fiber length, volume and pressure (increased preload)
Hypertrophy
Peripheral oxygen delivery
Redistribution of cardiac output
Altered oxygen-hemoglobin dissociation
Increased oxygen extraction by tissues
Anaerobic metabolism

Etiopathogenesis

Compensatory Mechanisms in Heart Failure

The first priority of the cardiovascular system is to provide oxygen and nutrients to critical organs such as the brain, kidneys and heart. The next priority is to supply nutrients to all other tissues; a final priority is to maintain normal venous pressure. In heart failure, these cardiovascular priorities are often lost in reverse order. The body will sacrifice normal venous pressure to provide nutrients to tissues. Increased venous pressure values above normal often result in clinical signs of CHF. The first and second cardiovascular priorities are maintained through compensatory responses from several neurohumoral mechanisms (**Table 36-2**), including the sympathetic nervous system, AVP secretion and the RAA system (Schlant and Sonnenblick, 1994; Kubo, 1990; Knight, 1995). In some animals, these compensatory changes ultimately result in: 1) sodium and water retention, 2) expanded extracellular fluid volume, 3) increased venous filling pressure and 4) clinical signs of cough, dyspnea, orthopnea, tachypnea, hepatomegaly and ascites.

SYMPATHETIC NERVOUS SYSTEM

The entire myocardium and peripheral vascular system are supplied with sympathetic nerve terminals. When cardiac output falls, the sympathetic nervous system coordinates increases in heart rate, strength of cardiac contraction and selective peripheral vascular vasoconstriction to restore hemodynamic equilibrium. Increased sympathetic discharge causes: 1) vasoconstriction of arterial resistance vessels with increased cardiac afterload, 2) increased renal neural traffic, which stimulates renin release and thus activation of the RAA system, 3) direct stimulation of renal sodium and water reabsorption and 4) splanchnic venoconstriction with central translocation of blood volume and increased cardiac preload (**Figure 36-1**). Sympathetic stimulation also causes the nonosmotic release of AVP. Diminished circulatory perfusion of arterial baroreceptors appears to activate simultaneously the three major vasoconstrictor systems: 1) the sympathetic nervous system, 2) the RAA system and 3) the nonosmotic release of AVP.

Generalized neurohumoral excitation occurs with impaired parasympathetic control of heart rate (Floras, 1993). The pathophysiologic implications of parasympathetic withdrawal in patients with heart failure have not been fully investigated.

Excessive sympathetic drive to the periphery can exacerbate the hemodynamic derangements of heart failure by increasing preload and afterload. Sympathetic activation occurs in dogs with spontaneous heart failure (Ware et al, 1990). Compared with clinically normal dogs, dogs with heart failure due to chronic mitral valvular disease or dilated cardiomyopathy have increased plasma norepinephrine concentrations that correlate positively with the clinical severity of disease (Ware et al, 1990). Dogs with the most severe degree of heart failure have mean norepinephrine concentrations significantly greater than those of dogs with all other functional classes of heart failure.

RENAL-ADRENAL-PITUITARY INTERACTIONS

In normal hearts and in those patients affected with mild disease, sympathoadrenal stimulation is the primary mechanism for adjusting to transient increases in workload (Schlant and Sonnenblick, 1994). However, as cardiovascular disease progresses, it imposes chronic, sustained changes in hemodynamics that require more stable, long-term adaptations. In this regard, the kidney plays a pivotal role in expanding blood volume and facilitating ventricular filling (increased preload).

Blood volume expansion results from renal conservation of sodium, chloride and water brought about by a combination of intrarenal hemodynamic alterations and neurohumoral stimulation. A decrease in cardiac output and blood pressure decreases renal perfusion pressure, which triggers renin release from the adjacent juxtaglomerular cells. Renin release is also stimulated by a decrease in the amount of sodium and chloride delivered to the distal renal tubules and by direct adrenergic stimulation of the juxtaglomerular cells. (See Sympathetic Nervous System above.) Renin acts on the circulating substrate angiotensinogen to produce angiotensin I. This relatively inactive decapeptide is converted by a peptidase enzyme, ACE, to the octapeptide angiotensin II.

Figure 36-1. (Opposite) Mechanisms for generalized sympathetic activation and parasympathetic withdrawal in heart failure. Normally (top figure), inhibitory input from arterial and cardiopulmonary receptors is high and heart rate is controlled by parasympathetic input (heavy lines). With progressing heart failure (bottom figure), sympathetic activity increases with resulting increases in vascular resistance, heart rate and adverse cardiac effects (heavy lines). Key: Ach = acetylcholine, E = epinephrine, NE = norepinephrine, CNS = central nervous system. (Adapted from Floras JS. Journal of the American College of Cardiology 1993; 22 [Suppl. A]: 72A-84A.)

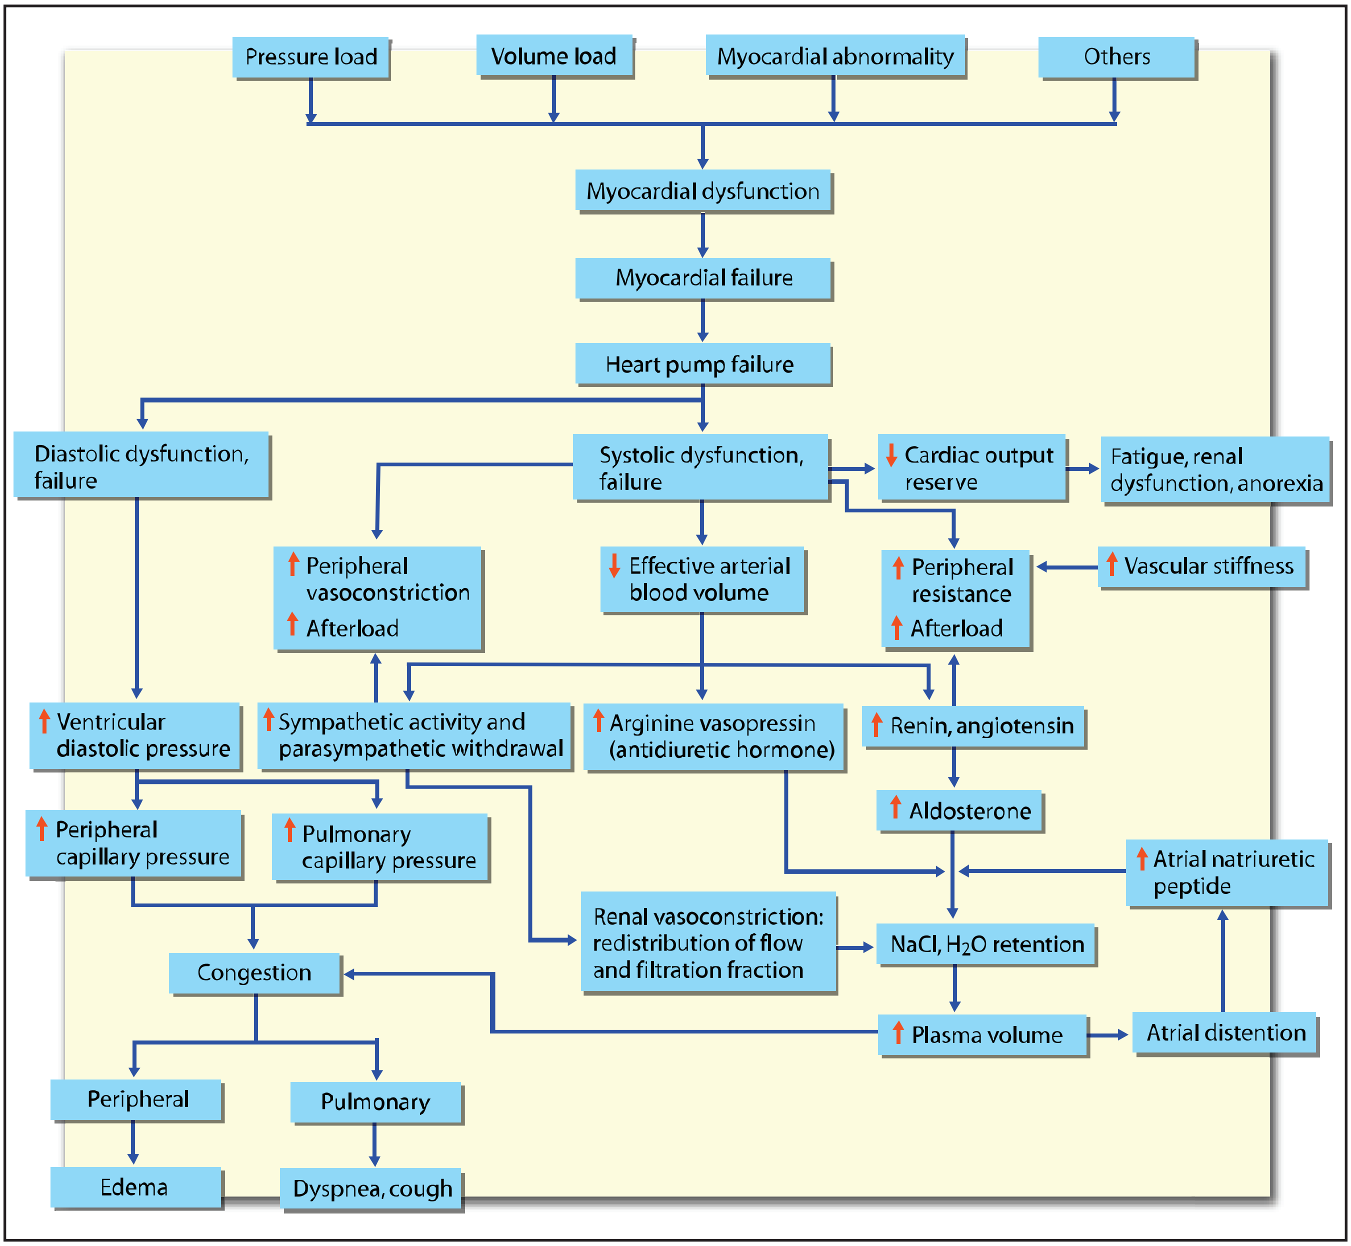

Figure 36-2. Schema of the sequence of events in heart failure. An increased load or myocardial abnormality leads to myocardial failure and eventually to heart failure. This results in increased sympathetic activity, increased levels of renin-angiotensin-aldosterone, pulmonary and peripheral congestion and edema and decreased cardiac output reserve. (Adapted from Schlant RC, Sonnenblick EH. Pathophysiology of heart failure. In: Schlant RC, Alexander RW, eds. The Heart, 8th ed. New York, NY: McGraw-Hill, 1994; 525.)

Angiotensin II counters a decline in effective arterial blood volume by serving as a potent constrictor of veins and arteries, and as a regulator of sodium-potassium homeostasis. Venoconstriction facilitates the return of blood to the heart and increases cardiac preload. Arteriolar vasoconstriction helps maintain systemic blood pressure. Angiotensin II also plays an important role in maintaining blood pressure and volume by stimulating secretion of aldosterone from the adrenal cortex. Aldosterone promotes reabsorption of sodium and chloride, and thus water, from the distal renal tubules and collecting ducts. The effects of aldosterone on sodium excretion may be less important than the direct intrarenal actions of angiotensin II. Studies in dogs support the theory that the intrarenal action of angiotensin II increases sodium and water retention (Hall and Brands, 1992). Angiotensin II also stimulates thirst, which facilitates expansion of blood and interstitial fluid volume. Blood levels of aldosterone tend to parallel those of renin and angiotensin II (Riegger and Liebau, 1982). If effective blood volume is restored, the stimulus for RAA secretion is withdrawn. However, if cardiovascular disease is severe, these hormones continue to stimulate the kidneys and tissue edema ensues or worsens (**Figures 36-2** and **36-3**).

In addition to the RAA system, a locally active paracrine renin-angiotensin system may exist in a number of tissues, par-

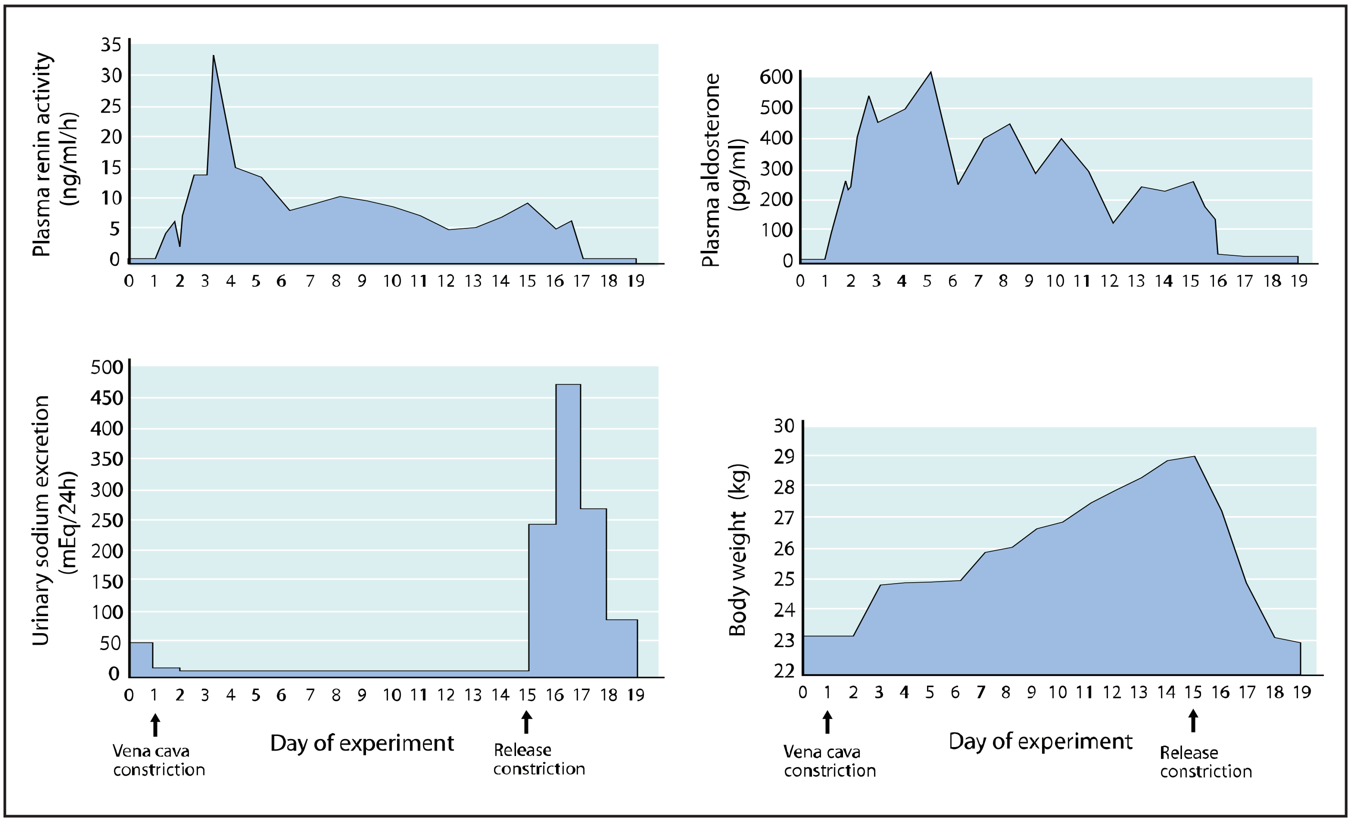

Figure 36-3. The response of a dog to thoracic vena cava constriction and the development of moderate to severe CHF. The first arrow indicates when vena cava constriction was applied. Note the persistent elevation in plasma renin activity (PRA) and plasma aldosterone (PA) concentration with a subsequent decrease in urinary sodium excretion and increase in body weight. The second arrow denotes when vena cava constriction was released. Note the rapid decrease in PRA and PA concentration with marked excretion of excess sodium in the urine and decrease in body weight. (Adapted from Watkins L, et al. Journal of Clinical Investigation 1976; 57: 1606-1617.)

ticularly those associated with cardiovascular homeostasis (MacFadyen, 1993; Straeter-Knowlen et al, 1995). ACE activity, renin substrate and renin-like enzymatic activity have been found in a number of sites including vascular, cardiac, renal, brain and adrenal tissues. Tissue renin-angiotensin activity may contribute to the pathophysiology of heart failure, but this is a topic of considerable debate (Hall and Brands, 1992). Further studies are needed to elucidate the role of extrarenal renin in the development and progression of heart failure.

AVP is secreted by the posterior lobe of the pituitary gland in response to nonosmotic stimuli. (See Sympathetic Nervous System above.) AVP is a potent vasoconstrictor and increases thirst and permeability of cortical and medullary collecting tubules, which allows reabsorption of free water. AVP secretion does not play a major role in the pathogenesis of edema. However, inappropriate AVP secretion probably plays a role in the pathogenesis of the hyponatremia associated with CHF.

Elevated levels of renin, angiotensin, aldosterone and AVP occur in experimental models of CHF in dogs (Watkins et al, 1976; Riegger and Liebau, 1982; Riegger et al, 1988; Maher et al, 1989; Villarreal et al, 1990; Himura et al, 1994). Plasma renin activity and aldosterone concentrations are also increased in dogs with spontaneous heart disease and failure (Knowlen et al, 1983; Buoro et al, 1992; Pederson et al, 1995). As disease in human patients progresses from early asymptomatic (heart disease but no heart failure) or mildly symptomatic left ventricular dysfunction to symptomatic heart failure, neuroendocrine mechanisms are progressively activated (Francis et al, 1990). The point at which significant neuroendocrine activation occurs in dogs and cats with spontaneous heart disease and failure has not been well documented.

CARDIORENAL INTERACTIONS

The volume expansion induced by activation of the RAA system is helpful to a point, after which deleterious clinical signs of pulmonary and peripheral edema begin to develop. ANP, primarily of atrial origin, counteracts these effects. An increase in transmural pressure (atrial distention or stretch) causes release of ANP, which triggers natriuresis and vasodilatation. ANP acts directly on the kidneys to: 1) cause diuresis through increased sodium and chloride excretion, 2) promote vasodilatation and 3) suppress aldosterone secretion and plasma renin activity. The last effect is presumably a result of the increase in sodium and chloride delivery to the distal tubules and macula densa. Studies have demonstrated a significant natriuretic and diuretic response using physiologic levels of ANP in normal dogs and dogs with experimental heart failure (Riegger and Liebau, 1982; Scriven and Burnett, 1985; Zimmerman et al, 1987). The renin-inhibiting effects of ANP may be dependent on the degree of activation of the RAA sys-

Table 36-3. Cardiovascular and neurohumoral adaptations that occur during the transition from lean to obese body condition.

Increased perfusion requirements of expanding adipose tissue

Increased plasma aldosterone and norepinephrine concentrations
Increased left atrial pressure
Increased heart rate
Exercise intolerance

tem (Kivlighn et al, 1990).

Although ANP is unable to normalize hemodynamics and natriuresis, it appears to provide an important modulating effect on the pathogenesis of CHF. Elevated ANP concentrations occur in dogs with spontaneous heart failure; furthermore, ANP concentration increases with increasing severity of heart failure (Takemura et al, 1991; Vollmar et al, 1991; Haggstrom et al, 1994).

CHF-ASSOCIATED HYPONATREMIA

Although the precise pathogenesis of CHF-associated hyponatremia remains controversial, the important factors can be divided into two categories (Oster et al, 1994). First, the increase in plasma angiotensin II concentration promotes thirst resulting in greater water intake. Second, renal diluting ability is impaired because the delivery of glomerular filtrate to the distal renal tubules is decreased (resulting from a reduced glomerular filtration rate and enhanced reabsorption proximally) and the plasma levels of AVP are increased. Both of these abnormalities might be mediated in part by angiotensin II. The osmotically inappropriate increase in plasma AVP concentration may be caused by a downward resetting of the osmostat because of a reduction in the effective blood volume (Oster et al, 1994). Aggressive use of diuretics may also contribute to the pathogenesis of hyponatremia in some patients.

CHF-associated hyponatremia is an important marker of poor prognosis in people with heart failure; it is seen almost exclusively in decompensated patients (Lee and Packer, 1986). People with heart failure and hyponatremia seem to have decreased renal blood flow, higher serum urea nitrogen concentrations, lower blood pressure and higher plasma renin activity (Oster et al, 1994; Lee and Packer, 1986). Anecdotal reports also suggest that hyponatremic patients in CHF have a poorer prognosis.

Obesity

Obesity has potentially profound cardiovascular consequences. From a cardiovascular perspective, obesity is a disease of blood volume expansion with: 1) elevated cardiac output, 2) increased plasma and extracellular fluid volume, 3) increased neurohumoral activation, 4) reduced urinary sodium and water excretion, 5) increased heart rate, 6) abnormal systolic and diastolic ventricular function, 7) exercise intolerance and 8) variable blood pressure response (**Table 36-3**) (Alexander, 1986; Crandall and DiGirolamo, 1990).

Obese people have increased plasma volume, cardiac output and plasma insulin, aldosterone and norepinephrine concentrations when compared with age-matched nonobese individuals (Rocchini et al, 1989). These changes occur whether the individuals eat high- or low-salt foods. Increases in blood pressure, heart rate, cardiac output, left atrial pressure and extracellular fluid volume also occur in dogs with experimentally induced obesity (Hall et al, 1993; Mizelle et al, 1994). Blood pressure always increases with increasing weight in dogs, regardless of the initial blood pressure.

The tendency toward blood volume expansion and neurohumoral activation in obese animals parallels the compensatory changes that often occur in patients with cardiac disease. Obesity, therefore, may have profound adverse effects in patients with concomitant cardiovascular disease.

Body weight and blood pressure correlate strongly in people. Hypertension occurs more often in obese individuals than in nonobese individuals (Alexander, 1986). The increase in blood pressure may be due to the combined effects of hyperinsulinemia, hyperaldosteronemia and increased sympathetic nervous system activity that characteristically occur in obesity (Rocchini et al, 1989). Hyperinsulinemia and blood pressure elevation also occur in dogs that have become rapidly obese (Rocchini et al, 1987). Hyperinsulinemia markedly reduces urinary sodium excretion (antinatriuresis) with resultant sodium and water retention (Hall et al, 1990, 1990a; Brands et al, 1991), possibly contributing to blood pressure changes. However, hyperinsulinemia for up to 28 days at levels comparable to those found in obese hypertensive people does not elevate mean arterial pressure in dogs with reduced renal mass even when sodium intake is high (Hall et al, 1990). This finding suggests that chronic hyperinsulinemia per se cannot account for obesity-associated hypertension. Further studies are needed to elucidate the pathophysiology of blood pressure responses and hypertension in obese patients.

Cachexia

Cachexia is a syndrome of weight loss (defined generally as unintentional loss of more than 10% body weight), lean tissue wasting and anorexia seen clinically in a variety of diseases, including chronic heart failure. The loss of lean body mass seen in cachexia is caused by a mismatch between food intake and nutritional requirements, resulting in negative nitrogen and energy balances (Freeman and Roubenoff, 1994). These imbalances may be due to inadequate intake, excessive losses or altered metabolism (**Figure 36-4**).

In patients with heart failure, anorexia may be due to the clinical signs of heart failure itself (dyspnea, fatigue), the presence of concomitant disease (nausea associated with renal failure), use of drugs that cause nausea (e.g., toxic doses of cardiac glycosides), the presence of elevated levels of inflammatory cytokines or sudden nutritional changes. The rate of loss of lean body mass with cardiac cachexia exceeds that attributable to anorexia alone, and reflects in part the excessive caloric expenditures of the increased work of respiration and elevated heart

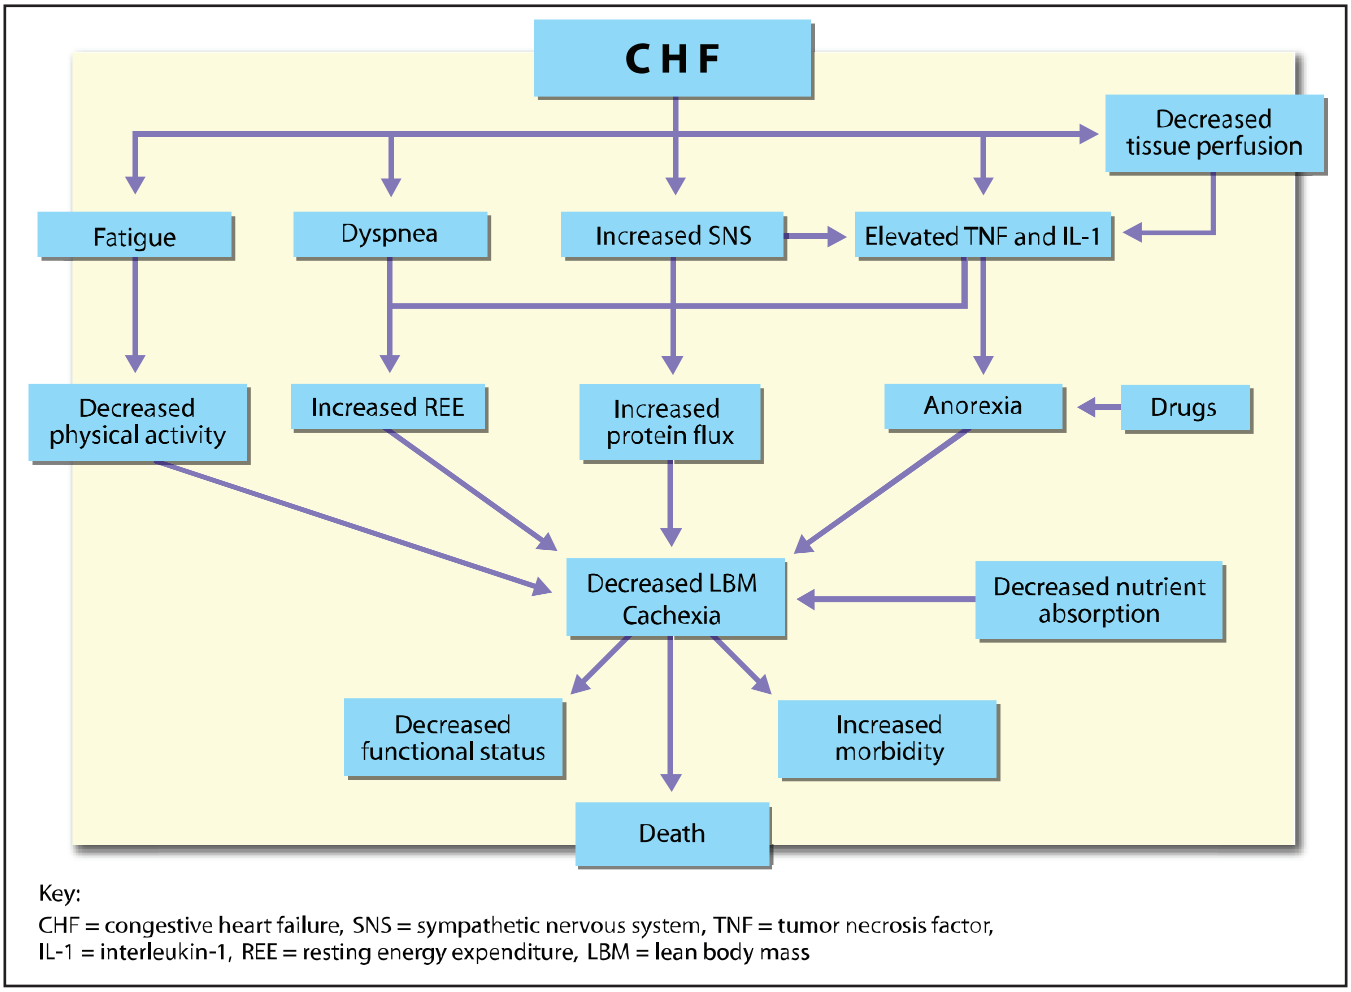

Figure 36-4. The cascade of factors in CHF that contributes to loss of lean body mass and cardiac cachexia. (Adapted from Freeman LM, Roubenoff R. Nutrition Reviews 1994; 52: 340-347.)

rate and in part, more complex metabolic issues. With simple starvation, most weight loss is loss of fat mass, whereas lean tissue is relatively spared, at least early on. Cachexia involves depletion of lean body mass. Physical inactivity may also contribute to loss of lean body mass because exercise is routinely restricted in patients with moderate to severe heart failure.

Altered metabolism appears to play a role in the pathogenesis of cachexia (**Figure 36-4**). Resting energy expenditure is elevated in some people with heart failure (Riley et al, 1991), and may be caused by increased ventilatory effort, sympathetic nervous system activity and concentrations of certain cytokines, specifically tumor necrosis factor (TNF, cachectin) and interleukin-1 (IL-1). Elevated serum TNF concentrations occur in people, dogs and cats with CHF (Levine et al, 1990; Freeman et al, 1994; Meurs et al, 1995). Both TNF and IL-1 cause cachexia by suppressing food intake and altering metabolism (Le and Vilcek, 1987; Oliff, 1988; Tracey et al, 1988, 1988a; Schollmeier, 1990). TNF suppresses the expression of several genes that encode for essential lipogenic enzymes, including lipoprotein lipase, and promotes the breakdown of adipose tissue and skeletal muscle (Le and Vilcek, 1987; Oliff, 1988; Tracey et al, 1988, 1988a; Schollmeier, 1990). TNF may also change the normal metabolic adaptation that accompanies caloric restriction and thus contribute to the nutritional imbalances observed in cachectic patients (Oliff, 1988).

As heart failure worsens, tissue perfusion and renal blood flow decline progressively. The kidneys release renin and prostaglandins, particularly prostaglandin E2, into the circulation in response to decreased renal blood flow. Prostaglandin E2 stimulates production of TNF from monocytes in vitro (Levine et al, 1990). Further studies are needed to confirm whether this pathogenic mechanism occurs in animals with cardiac cachexia and to explore the interaction of TNF with IL-1 and other cytokines.

Relationship of Taurine Deficiency to Myocardial Disease

Taurine is an essential amino acid in cats. Cats have a limited ability to synthesize taurine from cysteine and methionine because their tissues contain low concentrations of cysteine dioxygenase and cysteine sulfinate acid decarboxylase, key enzymes in the synthesis of taurine. Cats must also use taurine exclusively for conjugation of bile acids, which contributes to an obligatory loss of taurine. The decreased ability to synthesize

taurine and the continuous obligatory losses predispose cats to taurine deficiency when they eat foods with low taurine concentrations.

The association of feline dilated cardiomyopathy with low plasma concentrations of taurine was first reported in 1987 (Pion et al, 1987). This observation was subsequently confirmed by large studies in North America and Europe (Sisson et al, 1991). Treatment with oral taurine supplements significantly improved clinical signs, restored myocardial function and improved survival of cats with dilated cardiomyopathy. Since 1987, supplementation of most commercial cat foods with taurine has resulted in a marked decline in the number of feline dilated cardiomyopathy cases. Several controlled experiments support the clinical studies. Myocardial taurine concentrations are reduced and left ventricular dilatation and myocardial dysfunction occur in cats fed foods low in taurine (Pion et al, 1992, 1992a; Fox and Sturman, 1992). However, idiopathic dilated cardiomyopathy is occasionally diagnosed in cats that show no evidence of taurine deficiency, and the condition does not improve with taurine supplementation (Sisson et al, 1991).

Dilated cardiomyopathy has also been associated with plasma taurine deficiency and low myocardial taurine concentrations in captive foxes (Moise et al, 1991) and a small number of dogs (Kramer et al, 1995; Kittleson et al, 1997; Pion et al, 1998). A retrospective study was conducted to determine dietary taurine concentrations in dogs with dilated cardiomyopathy and compare clinical outcomes (Freeman et al, 2001). Taurine concentrations were low in blood samples from 20 of 37 dogs with dilated cardiomyopathy but there was no correlation between dietary and circulating taurine concentrations. Other studies have confirmed that there is no clear and constant association between diet and taurine status in dogs with dilated cardiomyopathy (Vollmar and Biourge, 2004).

The mechanism of heart failure in taurine-deficient cats and dogs is poorly understood. Taurine may function in osmoregulation, calcium modulation and inactivation of free radicals (Pion et al, 1998). Other unidentified factors may be involved in the development of myocardial failure in patients with taurine deficiency. Many cats fed taurine-deficient foods for prolonged periods fail to develop clinical myocardial dysfunction. Dilated cardiomyopathy and heart failure may result from an inciting or contributing factor or factors in combination with taurine deficiency (Fox and Sturman, 1992).

Several studies have demonstrated an association between taurine and potassium balance in cats (Dow et al, 1992). Inadequate potassium intake may be sufficient to induce significant taurine depletion and cardiovascular disease in healthy cats (Dow et al, 1992). Female cats with dilated cardiomyopathy have significantly lower plasma taurine concentrations than do similarly affected male cats (Fox et al, 1994). This finding suggests that male cats are more prone to developing taurine-dependent dilated cardiomyopathy than are female cats, or they are more prone to developing clinical signs associated with cardiac decompensation at higher plasma taurine concentrations (Fox et al, 1994).

Relationship of L-Carnitine Deficiency to Myocardial Disease

L-carnitine is a small, water-soluble, vitamin-like quaternary amine found in high concentrations in mammalian heart and skeletal muscle. In dogs, L-carnitine is synthesized from the amino acids lysine and methionine, primarily in the liver. A poorly understood transport mechanism concentrates L-carnitine in cardiac and skeletal myocytes.

Although the heart uses various metabolic substrates to maintain the constant energy supply needed to sustain effective contraction and relaxation, it is well established that long-chain fatty acids are quantitatively the most important. Carnitine is a critical component of the mitochondrial membrane enzymes that transport activated fatty acids in the form of acyl-carnitine esters across the mitochondrial membranes to the matrix, where β-oxidation and subsequent high-energy phosphate generation occur (**Figure 36-5**). In addition to its role in fatty acid transport, free L-carnitine serves as a mitochondrial detoxifying agent by accepting (or "scavenging") acyl groups and other potentially toxic metabolites and transporting them out of the mitochondria as carnitine esters (Pion et al, 1998).

A subset of dogs with dilated cardiomyopathy apparently suffers from myopathic L-carnitine deficiency and may respond to L-carnitine supplementation (Keene, 1992; Pion et al, 1998). Plasma L-carnitine deficiency appears to be a specific but insensitive marker for myocardial L-carnitine deficiency in dogs with dilated cardiomyopathy (Keene, 1992; Pion et al, 1998); unfortunately, dogs with myocardial L-carnitine deficiency do not always have low plasma L-carnitine concentrations. Most dogs in which myocardial L-carnitine deficiency has been associated with dilated cardiomyopathy fall into the classification of myopathic L-carnitine deficiency (i.e., decreased myocardial L-carnitine concentrations in the presence of normal or elevated plasma L-carnitine concentrations). Many of these dogs may suffer from a membrane transport defect that prevents adequate amounts of L-carnitine from moving into the myocardium from the plasma at plasma L-carnitine concentrations found in dogs fed most commercial foods. Systemic L-carnitine deficiency (decreased plasma and myocardial L-carnitine concentrations) accounts for approximately 20% of the cases.

Hypertension

Regulation of systemic blood pressure involves complex relationships between central and peripheral nervous, renal, endocrine and vascular systems (Littman and Drobatz, 1995). Most people with hypertension have essential hypertension, which means their hypertension occurs without a discernible organic cause (primary or idiopathic hypertension). Hypertension secondary to an identifiable underlying cause is more common in dogs and cats.

The kidneys ultimately provide long-term control of blood pressure because they are able to excrete sodium and water (Guyton, 1981). This control is accomplished by manipulating the determinants of systemic blood pressure: cardiac output and total peripheral resistance (BP = CO x TPR). Cardiac output is

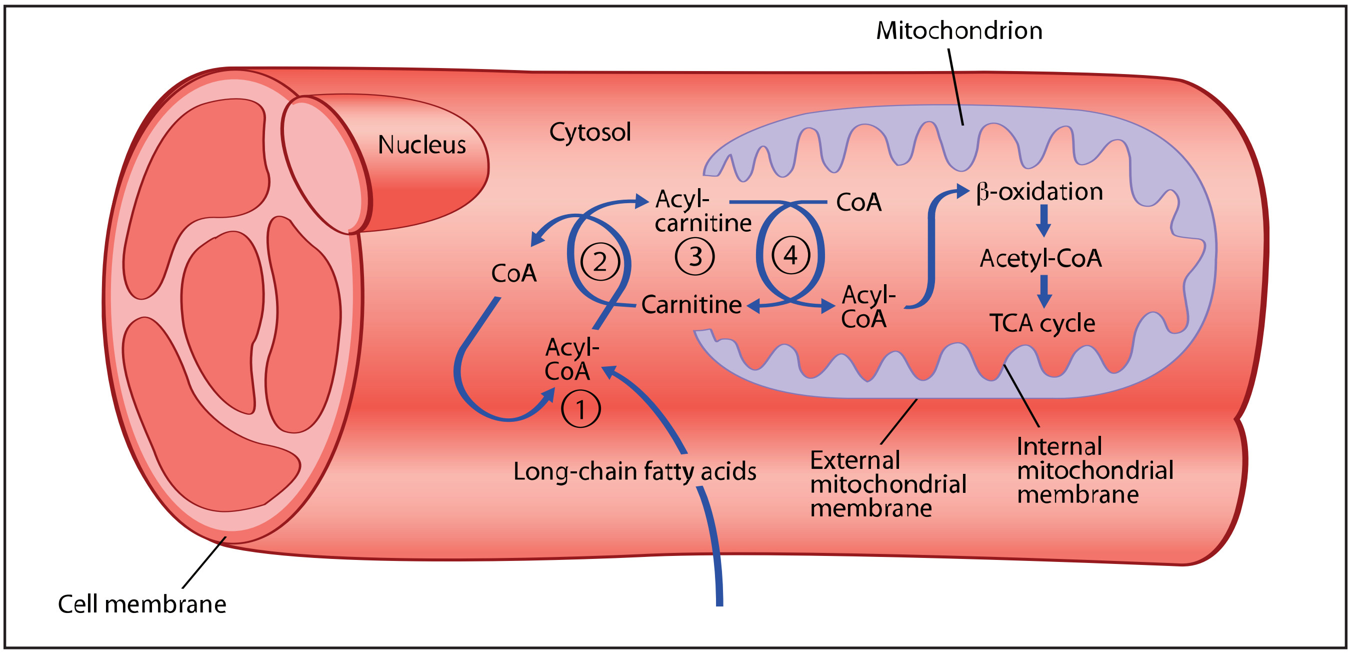

Figure 36-5. L-carnitine is essential for aerobic mitochondrial energy production and assists in the transit of energy (ATP) into the cytoplasm, where it provides the fuel for cellular functions. After entry into the cell, fatty acids are activated to form acyl-CoA (1). The acyl-CoA can then be transported into the mitochondrion as acyl-carnitine (2) via a carnitine-dependent shuttle (3). Acyl-carnitine then undergoes beta-oxidation to acetyl-CoA on the inner mitochondrial membrane (4) for entry into the TCA cycle and production of ATP. Secondarily, L-carnitine is involved in processes that prevent accumulation of toxic metabolites inside the mitochondrion. (Adapted from Neu H. Kleintierpraxis; 40: 197-220.)

related to heart rate and stroke volume (CO = HR x SV). Diseases associated with hypertension that increase heart rate include: 1) hyperthyroidism, 2) anemia, 3) hyperviscosity, 4) polycythemia and 5) pheochromocytoma. Increased stroke volume may occur during hypervolemic states, but is usually due to increased retention of sodium, chloride and water. Renal failure, hyperadrenocorticism and hyperaldosteronism may cause increased total body sodium, chloride and water.

Activation of the RAA pathway may elevate blood pressure by increasing stroke volume and total peripheral resistance. Angiotensin II is a potent vasoconstrictor, and angiotensin II and aldosterone stimulate renal sodium and chloride retention. Increased arteriolar tone, sensitivity to circulating vasopressors and levels of circulating catecholamines and decreased arteriolar elasticity may also increase total peripheral resistance.

Common causes of secondary hypertension include: 1) chronic progressive renal disease in dogs and cats (glomerulonephritis, amyloidosis, chronic interstitial nephritis, pyelonephritis and polycystic renal disease), 2) hyperadrenocorticism in dogs and 3) hyperthyroidism in cats. The "target organs" or end organs or systems that appear most sensitive to increased blood pressure include the eyes, kidneys, cardiovascular system and cerebrovascular system (Littman and Drobatz, 1995). Clinical signs related to end-organ damage are usually the reason an animal with hypertension is brought to a veterinarian for examination.

Pleural Effusion

Hydrostatic and oncotic forces (Starling's forces) are balanced within the pleurae and pleural space. Hydrostatic and oncotic pressures within the systemic circulation, pulmonary circulation and intrapleural space favor transudation of pleural fluid from the parietal pleura (pleura covering the inner chest wall) into the pleural space with subsequent absorption of the fluid into the visceral pleura's vasculature (Bauer and Woodfield, 1995). The result is a continuous flow of fluid through the pleural space. This delicate balance can be disrupted by any disorder that alters oncotic pressure, systemic or pulmonary capillary pressure, lymphatic compliance, capillary permeability or effective pleural surface area.

Biventricular CHF with systemic and pulmonary venous hypertension is a primary cause of pleural effusion. However, other causes of pleural effusion can masquerade as heart failure and may occur in patients with known heart disease, especially older dogs and cats. Other common causes of pleural effusion include diseases that increase capillary permeability and alter the normal flow and absorption of pleural fluid (e.g., primary intrathoracic or metastatic malignancy, pleural space infection, traumatic diaphragmatic hernia with incarceration of abdominal viscera).

Chylothorax is the accumulation of intestinal lymph (chyle) in the pleural space. This milky fluid has a high concentration of chylomicrons and triglycerides (the triglyceride concentration usually exceeds 100 mg/dl) and is low in cholesterol (the triglyceride-cholesterol ratio is greater than 1) (Fossum et al, 1986). The etiology of chylothorax is poorly understood, but has been associated with: 1) traumatic leakage, 2) diaphragmatic hernia, 3) lymphosarcoma, 4) cranial mediastinal masses, 5) pulmonary neoplasia, 6) dirofilariasis, 7) congenital abnormalities of the thoracic duct and 8) CHF. Experimental and clini-

Table 36-4. Key nutritional factors for foods for dogs and cats with cardiovascular disease.*

Factors	Recommended levels
Sodium	Dogs: Class Ia = 0.15 to 0.25%** Class Ib, II and III = 0.08 to 0.15% Cats: 0.07 to 0.30%
Chloride	Dogs: Class Ia = 1.5 x sodium levels** Class Ib, II and III = 1.5 x sodium levels Cats: 1.5 x sodium levels
Taurine	Dogs: ≥0.1% Cats: ≥0.3%
L-Carnitine	Dogs: ≥0.02%
Phosphorus	Dogs: 0.2 to 0.7% Cats: 0.3 to 0.7%
Potassium	Dogs: ≥0.4% Cats: ≥0.52%
Magnesium	Dogs: ≥0.06% Cats: ≥0.04%

*All values are expressed on a dry matter basis.
**Also appropriate in Class Ib, II and III patients when ACE inhibitors are used, especially when used in combination with diuretics.

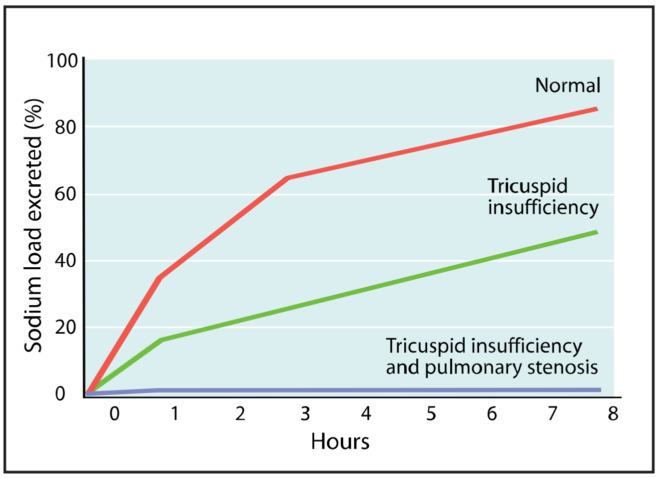

Figure 36-6. The cumulative excretion of sodium after a sodium load in a normal dog (top curve), the same dog with tricuspid insufficiency (middle curve) and the same dog with combined tricuspid insufficiency and pulmonary stenosis with the development of CHF (bottom curve). The inability of the dog to excrete excess sodium is the result of compensatory mechanisms that occur with advanced heart disease. (Adapted from Barger AC, et al. American Journal of Physiology 1955; 180: 249-260.)

cal evidence suggests that cranial mediastinal lymphangiectasia in cats is produced by either a functional or mechanical obstruction to thoracic duct flow. Obstruction of blood flow to the heart via the cranial vena cava, increased lymph flow from biventricular heart failure, elevated central venous pressure and direct duct obstruction may also contribute to lymphangiectasia and chyle accumulation in the pleural space (Smeak and Kerpsack, 1995).

Removal of large volumes of chyle via thoracentesis or chest drains may cause dehydration, electrolyte imbalances and protein-calorie malnutrition. A balance must be established between adequately evacuating the pleural space to prevent respiratory distress and meeting the animal's nutritional, fluid and electrolyte needs.

Key Nutritional Factors

The key nutritional factors for dogs and cats with cardiovascular disease are listed in **Table 36-4** and described in more detail below.

Sodium and Chloride

Because CHF is associated with retention of sodium, chloride and water, these nutrients are of primary importance in patients with cardiovascular disease. Within a few hours of ingesting high levels of sodium, normal dogs and cats easily excrete the excess in their urine. Early in the course of cardiac disease, patients may lose this ability to excrete excess sodium because of compensatory mechanisms described previously. In one experimental model, creation of valvular insufficiency in a dog reduced the excretion of excess sodium by almost 50% (**Figure 36-6**) (Barger et al, 1955). As heart disease worsens and CHF ensues, the ability to excrete excess sodium is severely depressed (**Figure 36-6**).

In the past, retention of sodium was primarily implicated in the pathogenesis of CHF and some forms of hypertension. A number of studies have examined the interaction of sodium with other ions, including chloride. The full expression of sodium chloride-sensitive hypertension in people depends on the concomitant administration of both sodium and chloride (Kurtz et al, 1987; Boegehold and Kotchen, 1989; Luft et al, 1990). In experimental models of sodium chloride-sensitive hypertension in rodents and in clinical studies with small numbers of hypertensive people, blood pressure or volume was not increased by a high sodium intake provided with anions other than chloride, and high chloride intake without sodium affected blood pressure less than the intake of sodium chloride (**Figure 36-7**) (Kurtz et al, 1987; Boegehold and Kotchen, 1989; Kotchen et al, 1981). The failure of nonchloride sodium salts to produce hypertension or hypervolemia may be related to their failure to expand plasma volume; renin release occurs in response to renal tubular chloride concentration (Boegehold and Kotchen, 1989; Luft et al, 1990; Kotchen et al, 1981, 1987). Chloride may also act as a direct renal vasoconstrictor (Boegehold and Kotchen, 1989). These findings suggest that both sodium and chloride are nutrients of concern in patients with hypertension and heart disease.

The minimum recommended allowance for sodium and chloride in foods for adult dogs is 0.08 and 0.12% dry matter (DM), respectively (NRC, 2006); for foods for cats it is 0.068 for sodium and 0.096% for chloride DM (NRC, 2006). In general, sodium levels for foods for cardiovascular disease should be restricted to 0.08 to 0.25% DM for dogs and 0.07 to 0.3% DM for cats. Recommended chloride levels are typically 1.5 times sodium levels. Avoiding excess sodium chloride in cat foods is more difficult than in dog foods because ingredients used to meet the higher protein requirement of cats also contain sodium and chloride and thus increase the sodium chloride content of cat food.

Specific evidence is not available to support the idea that foods low in sodium chloride fed to dogs in the early stages of heart disease will delay disease progression. However, a prudent recommendation for these patients is to begin avoiding excess sodium chloride early in the disease process. Thus, at the first sign of heart disease without cardiac dilatation (Class Ia), foods with levels of sodium and chloride in the upper part of the recommended range (0.15 to 0.25% DM sodium) should be introduced. Cardiac dilatation implies abnormal sodium chloride handling and intravascular volume expansion and, thus, dilatation is a prelude to venous congestion. When cardiac dilatation becomes evident on radiographs or echocardiograms (Class Ib), then foods that are even more sodium chloride restricted (sodium = 0.08 to 0.15% DM) are advised (Roudebush et al, 1994; Rush et al, 2000). As might be expected, moderate to severe cardiac dilatation, congestion or both conditions (Class II or III) also require foods with sodium chloride levels in the lower end of the range.

Water can be a potential source of sodium and chloride. Distilled water or water with less than 150 ppm sodium should be considered for patients with advanced CHF in whom more strictly limited sodium intake is desirable.

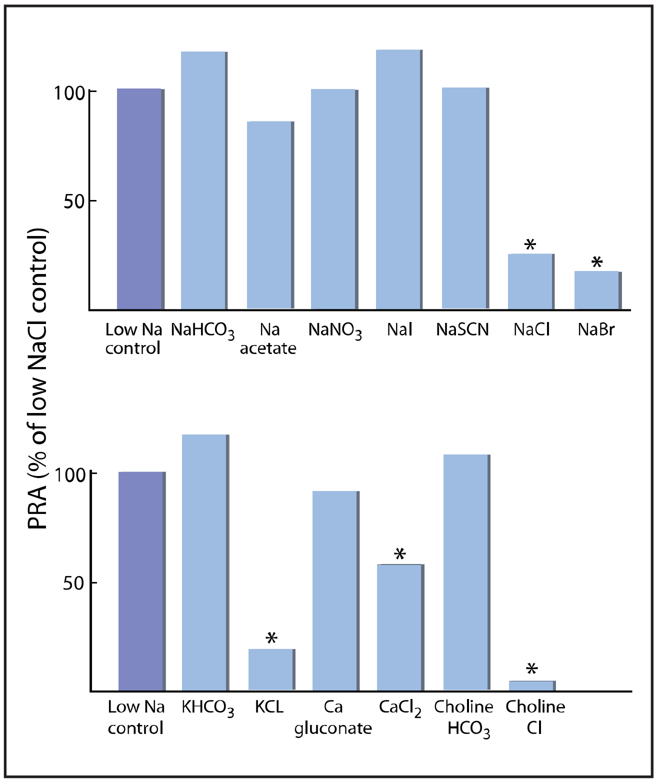

Figure 36-7. Effect of nutritional loading with different sodium and chloride salts on plasma renin activity (PRA) in sodium chloride-deprived rats. Bars marked with * are significantly different ($p < 0.05$) compared with the low-sodium control. These data suggest that chloride is an important determinant of renin secretion by the kidneys. (Adapted from Kotchen TA, et al. Journal of Laboratory Clinical Medicine 1987; 110: 533-539.)

Taurine

Taurine can be important in dogs and cats with myocardial failure. The mechanism of heart failure in taurine-deficient cats and dogs is not well understood. Taurine may function in inactivation of free radicals, osmoregulation and calcium modulation (Pion et al, 1998). Taurine also has direct effects on contractile proteins and is a natural antagonist to angiotensin II (Lake, 1993; Gentile et al, 1994). Other unidentified factors may be involved in the development of myocardial failure in patients with taurine deficiency. Dilated cardiomyopathy and heart failure may result from an inciting or contributing factor, or factors, in combination with taurine deficiency (Fox and Sturman, 1992). For example, studies have demonstrated an association between taurine and potassium balance in cats (Dow et al, 1992). Inadequate potassium intake may be sufficient to induce significant taurine depletion and cardiovascular disease in healthy cats (Dow et al, 1992).

Because taurine is an essential amino acid in cats, there is a minimum recommended allowance for taurine in highly digestible purified foods for healthy adult cats, which is 0.04% DM; the minimum recommended allowances for dry expanded and moist foods for adult cats are 0.10 and 0.17% DM, respectively (NRC, 2006). Taurine content of foods for cats with cardiovascular disease should probably contain at least 0.3% DM. Levels of taurine typically recommended for supplementation of feline cardiovascular patients (250 to 500 mg taurine/day) (Pion et al, 1989) provide approximately twice that much. There are no reports of acute or chronic toxicity related to feeding large quantities of free taurine to cats. In one study, foods containing up to 1.0% DM taurine were fed for up to three years and no adverse effects were noted (Sturman and Messing, 1992). The safe upper limit of taurine in foods for kittens is more than 0.89% DM (NRC, 2006).

Taurine is not an essential amino acid for dogs. However, dilated cardiomyopathy has been associated with plasma taurine deficiency and low myocardial taurine concentrations in captive foxes and a small number of dogs (Moise et al, 1991; Kramer et al, 1995; Kittleson et al, 1997; Pion et al, 1998; Freeman et al, 2001). In dogs, the association between taurine deficiency and dilated cardiomyopathy is strongest in American cocker spaniels and golden retrievers (Kramer et al, 1995; Kittleson et al, 1997, 1991; Pion et al, 1998). An association between taurine deficiency and dilated cardiomyopathy has also been shown in Newfoundlands, Labrador retrievers, Dalmatians, English bulldogs, Portuguese water dogs and Irish wolfhounds (Sanderson, 2006; Vollmar and Biourge, 2004). Even if plasma and whole blood taurine levels are normal in canine dilated cardiomyopathy patients, additional taurine may still be beneficial. Thus, it is reasonable that foods for dogs with cardiovascular disease contain added taurine. Because dogs can synthesize taurine, the level for foods for canine patients can be lower than for cats. The recommendation for taurine in foods for canine cardiovascular disease patients is at least 0.1% DM. This is somewhat lower than would be supplied by the typical recommendation for taurine supplementation of foods for dogs with dilated cardiomyopathy (500 to 1,000 mg taurine/day) (Pion et al, 1998). In dogs, as in cats, taurine is safe. No reports

could be found on acute or chronic toxicity related to feeding large quantities of taurine to dogs and no safe upper limit has been established (NRC, 2006).

L-Carnitine
L-carnitine deficiency has been associated with dilated cardiomyopathy in dogs. Carnitine is important to cardiac muscle function because it is a critical component of the mitochondrial membrane enzymes that transport activated fatty acids in the form of acyl-carnitine esters across the mitochondrial membranes to the matrix, where β-oxidation and subsequent high-energy phosphate generation occur. Also, free L-carnitine serves as a mitochondrial detoxifying agent by scavenging acyl groups and other potentially toxic metabolites and transporting them out of the mitochondria as carnitine esters (Pion et al, 1998).

A subset of dogs with dilated cardiomyopathy apparently suffers from myopathic L-carnitine deficiency and may respond to L-carnitine supplementation (Keene, 1992; Pion et al, 1998). Plasma L-carnitine deficiency appears to be a specific but insensitive marker for myocardial L-carnitine deficiency in dogs with dilated cardiomyopathy (Keene, 1992; Pion et al, 1998). Thus, dogs with myocardial L-carnitine deficiency do not always have low plasma L-carnitine concentrations. Most dogs in which myocardial L-carnitine deficiency has been associated with dilated cardiomyopathy fall into the classification of myopathic L-carnitine deficiency (i.e., decreased myocardial L-carnitine concentrations in the presence of normal or elevated plasma L-carnitine concentrations). Many of these patients suffer from a membrane transport defect that prevents adequate amounts of L-carnitine from moving into the myocardium from the plasma at plasma L-carnitine concentrations found in dogs fed most commercial foods. Systemic L-carnitine deficiency (decreased plasma and myocardial L-carnitine concentrations) accounts for approximately 20% of the cases.

Most authors recommend supplementing canine dilated cardiomyopathy patients with 50- to 100-mg L-carnitine/kg body weight three times daily. One report suggests that in dogs with systemic carnitine deficiency, a much lower dose generated a better response than the effective dose for myopathic cardiomyopathy (Sanderson, 2006). Even if carnitine deficiency was not the cause of cardiomyopathy in a heart disease patient, supplementing dogs with carnitine does no harm and may be beneficial. Because carnitine is expensive, foods for canine patients with cardiovascular disease do not contain the higher levels recommended for supplementation. Foods for heart disease patients should provide at least 0.02% DM. For a point of reference, this inclusion level provides approximately 1/20th of the amount that would be achieved by supplementing at 50- to 100-mg carnitine/kg body weight.

Phosphorus
Phosphorus is a nutrient of concern in patients with concurrent chronic kidney disease (Chapter 37). To avoid excess phosphorus in patients with concurrent chronic kidney disease, restrict phosphorus to 0.2 to 0.7% DM in dogs and 0.3 to 0.7% DM in cats.

Potassium and Magnesium
Potassium and magnesium metabolism is a concern in patients with cardiovascular disease. Hypokalemia, hyperkalemia and hypomagnesemia, are potential complications of drug therapy in patients with cardiovascular disease. Abnormalities in potassium or magnesium homeostasis can: 1) cause cardiac dysrhythmias, 2) decrease myocardial contractility, 3) produce profound muscle weakness and 4) potentiate adverse effects from cardiac glycosides and other cardiac drugs.

Foods for dogs and cats with CHF should contain at least the amounts of potassium and magnesium recommended for adult maintenance (0.4 and 0.52% DM potassium, respectively, and 0.06 and 0.04% DM magnesium) (NRC, 2006). If abnormalities in these electrolytes occur, supplementation or switching to a different food may be necessary.

Other Nutritional Factors
Protein
The protein requirements of patients with cardiac cachexia have not been investigated and it is unknown how the metabolic changes associated with cachexia affect overall nutrient requirements. Many patients with cachexia have concomitant disease, such as chronic kidney disease, which affects nutrient requirements. Profound anorexia enhances protein-energy malnutrition in patients with cachexia. Patients with cachexia should be encouraged to eat a complete and balanced food that contains adequate calories and adequate high-quality protein.

Omega-3 Fatty Acids
The cytokines TNF and IL-1 have been implicated as pathogenic mediators in cardiac cachexia. Fish oil, which is high in omega-3 (n-3) fatty acids, alters cytokine production. Preliminary results suggest that fish-oil-mediated alterations in cytokine production may benefit dogs with CHF (Freeman et al, 1995). Circulating TNF and IL-1 concentrations decreased significantly in a group of dogs with CHF secondary to idiopathic dilated cardiomyopathy when they were treated with fish oil supplements. Dogs receiving fish oil tended to be judged as less cachectic when compared with those in the placebo group. Ventricular function also improved significantly in the group treated with fish oil when compared with dogs receiving a placebo. These findings suggest that heart failure patients with cachexia may benefit from the alterations of cytokine production brought about by omega-3 fatty acid supplementation or other methods.

Parenteral administration of omega-3 fatty acids (α-linolenic acid, eicosapentaenoic acid [EPA], docosahexaenoic acid [DHA]) was shown to prevent sudden cardiac death in an experimental model of myocardial infarction in dogs (Billman et al, 1999; Leaf et al, 2005). Omega-3 fatty acids appear to electrically stabilize heart cells through modulation of the fast voltage-dependent $Na(^{+})$ currents and the L-type $Ca(2^{+})$ channels in a manner that makes the heart cells resistant to dysrhythmias (Leaf et al, 2005a). Clinical studies have also confirmed that fish oil as a source of long-chain omega-3 fatty acids will reduce the frequency of ventricular arrhythmia in

boxer dogs with arrhythmogenic right ventricular cardiomyopathy (Smith et al, 2007). These data suggest that fish oil supplementation may be useful to help reduce cardiac arrhythmias in dogs. Further studies are needed to determine optimal dose and duration of treatment.

FEEDING PLAN

Assess and Select the Food

The food for patients with cardiovascular disease should be evaluated for all the key nutritional factors mentioned in **Table 36-4**. **Tables 36-5** and **36-6** list key nutritional factor content of selected veterinary therapeutic and other commercial foods marketed for dogs and cats with cardiovascular disease, respectively, and compares them to the recommended levels. Key nutritional factor amounts for foods not listed in these tables must be obtained by contacting the manufacturer or consulting published product information. The levels of the key nutritional factors for regular commercial dog and cat foods typically are considerably outside the recommendations for patients with cardiovascular disease. Some commercial foods greatly exceed the minimum recommended allowance for sodium chloride (Roudebush et al, 2000). Nutrient sources other than commercial pet foods should be investigated. Water quality varies considerably, even within the same community. Water can be a significant source of sodium, chloride and other minerals. Veterinarians should be familiar with the mineral levels in their local water supply. Water samples can be submitted to state or other government laboratories for analysis; municipal water companies can be contacted or private companies that market water conditioning systems can be asked about mineral levels in local water supplies. Distilled water or water with less than 150 ppm sodium is recommended for patients with advanced heart disease and failure (Morris et al, 1976).

Other sources of nutrients include commercial treats and snacks for pets, and human foods offered as snacks or part of the pet's food. Processed human foods are often high in sodium (**Table 36-7**). Some commercial rawhide chews do not contain excessive levels of sodium (Morris and Ettinger, 1995). **Table 36-8** lists selected commercial low sodium canine treats.

Although there is currently little or no evidence that proves foods low in sodium chloride delay disease progression in the initial stages of heart disease in dogs, a prudent recommendation is to begin avoiding excess sodium chloride early in the disease process. Thus, at the first sign of heart disease without cardiac dilatation (Class Ia), foods with levels of sodium in the upper part of the recommended range (0.15 to 0.25% DM) should be introduced. Early intervention may help the patient accept foods if more restricted sodium chloride levels are necessary later, and reminds the owners to remain vigilant for signs of disease progression. Furthermore, avoiding excessive amounts of sodium chloride early in heart disease has not been shown to be harmful.

When cardiac dilatation becomes evident on radiographs or echocardiograms (Class Ib), then sodium chloride-restricted foods are appropriate (Roudebush et al, 1994; Rush et al, 2000). Cardiac dilatation implies abnormal sodium chloride handling and intravascular volume expansion, and it is a prelude to venous congestion. The presence of moderate to severe cardiac dilatation, congestion or both conditions (Class II or III) indicates that foods lower in sodium chloride are appropriate. Many veterinary cardiologists prescribe foods with levels of sodium in the upper part of the recommended range (0.15 to 0.25% DM) when ACE inhibitors are used, especially when used in combination with diuretics. **Table 36-9** outlines the daily sodium intake of a 15-kg dog and a 4-kg cat fed different foods, including grocery, specialty and veterinary therapeutic foods. Normal dogs and cats are able to eliminate the excess levels of sodium found in many commercial foods, but patients with heart disease and failure have an impaired ability to handle these sodium levels. There is often concern about the palatability of low-salt foods compared to that of a patient's current food. Low-salt foods can be even more palatable than maintenance foods with higher salt content (**Box 36-1**). However, a few patients might not eat low-salt foods. A common mistake is to insist that an owner feed only a salt-restricted food even if caloric intake is inadequate. Although avoiding excess sodium chloride is important in CHF patients, offering only a salt-restricted food should not be imposed to the detriment of overall nutrient intake. Changing to a different commercial food or homemade food may be a more beneficial solution in some patients. Appetite may be cyclical in patients with advanced heart failure, both in respect to overall appetite and food preferences. A dedicated owner is often required and a trial-and-error approach should be used with different foods and feeding methods.

Low-salt foods may also be of value in the management of respiratory diseases (**Box 36-2**). Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Adjunctive Management: Drugs and Supplements

Most patients with cardiovascular disease in which nutritional management is used also receive drug therapy. In the past, drug-drug interactions received considerable attention but few investigators evaluated or discussed how nutrient levels might affect drug availability and pharmacokinetics and vice versa (Chapter 69). Because many cardiovascular patients are treated with a combination of veterinary therapeutic foods and drugs, potential food-drug or nutrient-drug interactions are important.

Key: Na = sodium, P = phosphorus, K = potassium, Mg = magnesium, na = information not available from the manufacturer, g = grams.

*Values are on a dry matter basis unless otherwise stated.

**Also recommended for Class Ib, II and III patients when ACE inhibitors are used, especially when used in combination with diuretics.

***As fed energy values (kcal/cup or can) are useful for determining the amount to feed; these values can be converted to an amount of food to feed by dividing the energy density of the food (as fed basis) by the patient's daily energy requirement (DER); cup = 8-oz. measuring cup; to convert kcal to kJ, multiply kcal by 4.184. Providing the right amount of food is vital for managing patients with cardiovascular disease. Overweight patients should be fed foods with reduced energy as part of a weight-reduction program (Chapter 27). Patients suffering from cardiac cachexia may need more energy than otherwise normal pets. Body condition scoring should be used frequently to determine the patient's response to the amount of food fed.

†See discussion under "Adjunctive Management: Drugs and Supplements" in the "Feeding Plan" section if additional supplementation is required beyond that present in foods in this table.

Diuretics

Diuretics continue to be a pharmacologic mainstay of acute therapy for heart failure. Sodium restriction, ACE inhibition, venodilating drugs and diuretics represent the major available methods for preload reduction.

Sodium chloride restriction is a key component of CHF treatment even with the use of diuretics. Well-controlled studies have demonstrated that loop diuretics such as furosemide given once daily fail to achieve a negative sodium balance in people with high sodium intake (Wilcox et al, 1983). Although there is an impressive natriuresis for several hours after furosemide administration, a compensatory increase in sodium reabsorption in the next 24 hours exactly matches the earlier losses (Wilcox et al, 1983). Thus, it is essential to limit sodium intake to ensure negative sodium balance. Balance studies with normal people have demonstrated that significant negative sodium balance can be predictably obtained with loop diuretics if sodium intake is limited to 20 mEq/day (roughly equivalent to 460 mg sodium or 1.2 g sodium chloride per day) (Kokko, 1994). This level of sodium restriction in people is equivalent to that achieved with use of foods formulated for patients with cardiovascular disease (**Tables 36-5** and **36-6**).

Blood volume contraction and circulatory impairment are potential complications of aggressive diuretic therapy. These complications can exacerbate pre-existing renal disease, alter excretion of drugs dependent on renal elimination and reduce cardiac output by reducing cardiac filling pressures (Fox, 1992). Reduced levels of sodium in the food have been implicated, but have not been proven to contribute to volume depletion from excessive diuresis (Fox, 1992). Fractional excretion of sodium in urine actually decreases in normal dogs fed a sodium-restricted food (Navar et al, 1982). The influence of diuretics on sodium and chloride balance in dogs with heart disease and failure fed sodium- and chloride-restricted foods has not been evaluated.

Furosemide contributes to hypokalemia and hypomagnesemia because of increased urinary loss of potassium and mag-

Table 36-7. Sodium content of selected human foods.*

Food	Amount	Sodium (mg)

nesium (Fox, 1992). The role of magnesium and potassium in the development of cardiac dysrhythmias has not received attention beyond the recognition that digitalis toxicosis appears to be much more dysrhythmogenic in hypomagnesemic and hypokalemic patients (Edwards, 1991). Hypomagnesemia may potentiate cardiac dysrhythmias caused by catecholamine release and is also associated with increased vascular reactivity (Bean and Varghese, 1994).

Conflicting reports have been published about the serum electrolyte and magnesium concentrations of dogs with CHF. A study of 113 dogs with CHF identified only four dogs with hypomagnesemia (Edwards, 1991). Three of the four hypomagnesemic dogs received combined therapy with a commercial sodium-restricted veterinary therapeutic food, furosemide and either hydralazine or enalapril. In another study, furosemide-treated dogs with heart failure had significantly lower serum magnesium and potassium values than did age-matched healthy controls (Cobb and Mitchell, 1991). A third study showed no significant differences in serum magnesium concentrations between clinically normal dogs, dogs with heart failure before any treatment, heart-failure dogs treated only with furosemide and heart-failure dogs treated with furosemide and digoxin (O'Keefe and Sisson, 1993). The feeding history was not included in the last two studies; therefore, specific food-diuretic interactions could not be interpreted. Normal dogs treated with a commercial sodium-restricted veterinary therapeutic food and furosemide for four weeks had no significant change in serum potassium concentrations (Roudebush et al, 1994).

Several studies have shown that the RAA system is not activated in human patients with moderate heart failure in the absence of diuretic therapy (Kubo, 1990; Bayliss et al, 1987). The major increase in plasma renin activity and plasma aldosterone concentration occurs with the introduction of diuretic drugs into the treatment regimen rather than as a result of the disease process itself. Furosemide apparently stimulates renin release by inhibiting chloride transport in the ascending limb of the loop of Henle, even if blood volume contraction is prevented (Kotchen et al, 1981). Treatment of normal geriatric dogs with moderate doses of furosemide profoundly stimulates the RAA system, irrespective of the sodium level in the food (Roudebush and Allen, 1996; Lovern et al, 2001). Use of furosemide with either hydralazine or enalapril also stimulates the RAA system in dogs with heart failure due to acquired mitral valve regurgitation (Haggstrom et al, 1996).

Although diuretics will remain important first-line drugs for management of acute cardiogenic pulmonary edema, findings in people suggest that diuretics continue to stimulate the RAA system and may play a pivotal role in the progressive self-perpetuating cycle of heart failure (Kubo, 1990). Veterinary cardiologists now recommend against the use of diuretic monotherapy early in the management of symptomatic heart failure (Keene and Rush, 1995; Keene and Bonagura, 2009). Diuretics should be reserved for managing more advanced heart failure in patients already receiving moderately sodium chloride-restricted foods, ACE inhibitors, pimobendan or combination thera-

py. Feeding patients foods without excess sodium chloride may allow lower dosages of diuretics to be used for control of the clinical signs of CHF.

Sodium, chloride, potassium and magnesium levels vary in commercial veterinary therapeutic foods for dogs and cats with cardiovascular disease (**Tables 36-5** and **36-6**). These nutrients in regular commercial foods vary markedly. Mineral levels should be considered when using concurrent diuretic therapy.

Long-term furosemide therapy may be associated with clinically significant thiamin deficiency, due to excessive urinary loss of thiamin, and may contribute to impaired cardiac performance in patients with CHF (Seligman et al, 1991). Patients receiving long-term diuretic therapy should be given supplements containing thiamin and other water-soluble vitamins or be fed a commercial food with increased concentrations of these vitamins. Veterinary therapeutic foods for patients with cardiac and renal disease are often formulated with higher levels of water-soluble vitamins to offset excessive urinary losses.

ACE Inhibitors

Enalapril, benazepril, ramipril and lisinopril, all ACE inhibitors, are commonly used to treat dogs and cats with CHF. Inhibition of the conversion of angiotensin I to angiotensin II results in vascular dilatation and decreased circulating plasma aldosterone concentrations. Angiotensin II and aldosterone play important roles in the maintenance of vascular volume and potassium balance. Both increase the reabsorption of sodium and chloride, and aldosterone promotes the excretion of potassium.

The use of ACE inhibitors in human patients with severe renal insufficiency or in patients given potassium supplements may increase the risk for hyperkalemia (Warren and O'Connor, 1980; Dzau et al, 1980; Rotmensch et al, 1988). In a study, more than half the dogs with CHF developed mild serum potassium elevations when treated with a commercial sodium-restricted veterinary therapeutic food, furosemide and captopril (Roudebush et al, 1994). Another study confirmed that heart-failure dogs treated with furosemide, digoxin and an ACE inhibitor had significantly higher mean serum potassium concentrations when compared with clinically normal dogs, dogs with heart failure before any treatment, heart-failure dogs treated only with furosemide and heart-failure dogs treated with furosemide and digoxin (O'Keefe and Sisson, 1993). Mild elevations in serum potassium concentrations have also been observed in dogs treated with enalapril (COVE, 1995). In another study, serum potassium concentration decreased in a subset of heart-failure dogs treated with ACE inhibitors and furosemide, although the specific feeding history was not reported (Cobb and Mitchell, 1991).

When mild hyperkalemia occurs in people with heart failure, reducing oral potassium intake and discontinuing potassium-sparing diuretics is recommended (Rotmensch et al, 1988). Although clinically significant hyperkalemia (serum potassium 6.5 mEq/l) is uncommon, the use of ACE inhibitors in dogs with CHF or renal insufficiency fed commercial or veterinary therapeutic foods with high potassium content may increase the risk for hyperkalemia (Roudebush et al, 1994).

Functional renal insufficiency occurs in up to one-third of human patients with severe CHF treated with sodium chloride restriction, ACE inhibitors and diuretics (Parker et al, 1987). This decline in renal function has been attributed to loss of angiotensin II-mediated systemic and intrarenal vasoconstrictor effects, which maintain renal perfusion pressure and glomerular filtration rate in low-output heart failure. Functional renal insufficiency appears to be alleviated in human patients when efforts are made to replenish total body stores of

Box 36-1. Palatability of Low-Salt Foods.

The question often arises whether sodium chloride enhances palatability of foods for dogs and cats. Sodium chloride and other inorganic salts stimulate specific taste chemosensory neural groups in these species. This finding suggests that dogs and cats can indeed taste sodium chloride and other inorganic salts. These "taste" groups are also stimulated by simple sugars in dogs and specific amino acids in dogs and cats. Standard palatability testing indicates that dogs prefer the taste of a moist food as the level of sodium chloride is increased, whereas increasing levels of salt in a dry food have no effect on palatability of the food. Palatability enhancers added topically to dry pet foods probably mask any taste effects of sodium chloride or other salts. Many foods with reduced sodium chloride levels for use in patients with cardiovascular disease have comparable or better palatability than grocery or specialty brand pet foods.

The Bibliography for **Box 36-1** can be found at www.markmorris.org.

Box 36-2. Use of Low-Salt Foods in Chronic Respiratory Diseases.

Avoiding excess sodium chloride may also be important in patients with some forms of chronic respiratory disease such as chronic bronchitis or asthma. Both epidemiologic and experimental evidence in people suggest that high sodium chloride intake may increase airway responsiveness and exacerbate clinical signs associated with asthma. When some people with asthma are subjected to salt loading, clinical signs worsen, lung function deteriorates and the need for antiasthmatic drugs increases. However, not all studies in people with asthma show benefits of avoiding excess dietary sodium. A serum-borne factor in human patients with airway hyperresponsiveness stimulates increased sodium influx into cells. Reduced sodium levels in food also result in increased levels of vasoactive intestinal peptide (VIP) in the plasma and lung; VIP acts as a bronchodilator. Although similar canine and feline studies have not been completed, foods that avoid excess salt may be helpful in conjunction with other forms of therapy in animals with chronic bronchitis or asthma-like clinical signs.

The Bibliography for **Box 36-2** can be found at www.markmorris.org.

sodium by reducing the diuretic dosage and liberalizing sodium intake (Parker et al, 1987). Renal insufficiency is a potential complication of ACE inhibitor therapy in dogs with CHF, but the role of sodium restriction is unknown (Roudebush et al, 1994; Longhofer et al, 1993; DeLillis and Kittleson, 1992). Four of 10 heart-failure dogs treated with captopril, furosemide and a sodium-restricted veterinary therapeutic food developed azotemia during the first five weeks of treatment; one of these dogs developed clinical signs of uremia (Roudebush et al, 1994). Two of the dogs that developed severe azotemia had isosthenuria on the initial urinalysis, which suggested some degree of pre-existing renal insufficiency. Azotemia is a more frequent complication when canine heart failure is treated with furosemide and enalapril rather than with furosemide alone (DeLillis and Kittleson, 1992).

Drug-induced azotemia in heart failure patients is treated by reducing the diuretic dose (usually at least by half–skip a dose if there is not active pulmonary edema); if that fails to resolve the problem, the ACE inhibitor dose can be reduced by half, the sodium intake can be increased to the next level (**Tables 36-5** and **36-6**) or a combination of these tactics may be used.

Management of Hyponatremia

The correction of hyponatremia associated with CHF has been evaluated in people but not in domestic animals. The combined administration of an ACE inhibitor and furosemide (but usually not of either agent alone) usually reverses CHF-associated hyponatremia in people, at least in part (Oster et al, 1994). The reversal of hyponatremia probably results from the combined effects of the ACE inhibitor (i.e., decreased thirst, decreased proximal tubular reabsorption of sodium chloride, interference with the hydro-osmotic effect of AVP) and the loop diuretic (i.e., increased distal delivery of glomerular filtrate, reduction in urine osmolality) acting to offset the pathophysiologic factors that impair excretion of water (Oster et al, 1994; Packer et al, 1984). Studies are needed to determine whether similar measures are effective in reversing CHF-associated hyponatremia in animals. Hyponatremia secondary to severely decreased cardiac output and inappropriate secretion of ADH would not be expected to resolve with either further diuretic therapy, or with ACE inhibition. In this case, increasing cardiac output (generally accomplished by inotropic stimulation, afterload reduction or a combination of the two) would be needed, and pimobendan would be the most easily available potentially effective therapy.

Pimobendan

Pimobendan is an inodilator drug (combination positive inotrope and vasodilator) approved by the FDA for the treatment of heart failure in dogs in 2007 in the United States.[d] This drug, used at an oral dose of 0.3 mg/kg twice daily in combination with an ACE inhibitor and furosemide, is now part of the standard medical therapy for dogs in heart failure from either chronic valvular heart disease or dilated cardiomyopathy. There are no known dietary considerations that influence the pharmacodynamic effects of pimobendan. The drug appears to be associated with a dramatic and helpful appetite stimulating effect in many patients. It is not approved by the FDA for use in cats.

Cardiac Glycosides

Pimobendan has largely supplanted the routine use of digoxin in dogs and cats in sinus rhythm, at least until their heart failure becomes refractory to standard treatment with pimobendan, furosemide, an ACE inhibitor and moderate dietary salt

restriction. Cardiac glycosides have been used for more than two centuries and are still widely prescribed to manage cardiac disorders in dogs and cats when atrial fibrillation is present. Appropriate use of cardiac glycosides is based on an appreciation of the nutritional factors that influence the pharmacokinetic properties of these drugs.

Absorption of cardiac glycosides is influenced by the formulation of the drug and its administration in relation to meals (Chapter 69). Because administering digoxin or digitoxin with food may result in up to a 50% reduction in serum concentrations, these drugs are best given between meals (Snyder and Atkins, 1992). The body condition of the patient can also influence the pharmacokinetics of these drugs. Digoxin is minimally distributed in adipose tissue; the dosage of the drug should be based on lean body weight even for obese patients. Digitoxin is more lipid soluble than digoxin; so its dosage need not be adjusted for overweight animals.

The dosage of digoxin for cats is influenced by concurrent drug and nutritional therapy. The digoxin dose should be reduced by one-third if the cat is receiving concomitant furosemide, aspirin and a sodium-restricted veterinary therapeutic food (Atkins et al, 1988).

Metabolic derangements associated with increased risk of digoxin toxicosis include hypokalemia, hypomagnesemia, hypercalcemia, renal insufficiency, hypothyroidism and obesity (Snyder and Atkins, 1992). Serum electrolyte and magnesium concentrations should be measured and corrections made before starting cardiac glycoside therapy.

Potassium and/or Magnesium Supplementation

Electrolyte abnormalities, including hypokalemia, hyperkalemia and hypomagnesemia, are potential complications of drug therapy in patients with cardiovascular disease. Patients receiving diuretic therapy should receive adequate amounts of potassium and magnesium. Patients treated with ACE inhibitors may be predisposed to mild hyperkalemia; so their food should not contain excess levels of potassium. If hyperkalemia develops, switch to a food with a lower potassium level and discontinue any potassium supplementation. Loop or thiazide diuretics should be considered instead of potassium-sparing ones. Chronic kidney disease is often a concomitant disease of patients with cardiovascular disorders. If hypokalemia develops, feed a food with a higher potassium level or supplement the existing food with 3 to 5 mEq or mmol of potassium/kg body weight per day. If hypomagnesemia develops, feed a food with a higher magnesium content or provide oral magnesium supplementation (magnesium oxide, 20 to 40 mg/kg body weight per day).

Taurine Supplementation

Cats and dogs with myocardial failure may benefit from taurine supplementation to their regular food or use of foods that already contain increased levels of taurine. Patients with documented taurine deficiency are more likely to respond favorably to taurine supplementation. In dogs, the association between taurine deficiency and dilated cardiomyopathy is strongest in American cocker spaniels and golden retrievers (Kramer et al, 1995; Kittleson et al, 1997, 1991; Pion et al, 1998). Cats should receive 250- to 500-mg taurine per os daily (Pion et al, 1989), whereas dogs should receive 500- to 1,000-mg taurine per os three times daily (Pion et al, 1998). Some foods formulated for nutritional management of cardiovascular disease usually already contain increased levels of taurine (**Tables 36-5** and **36-6**). Patients eating these foods usually do not need additional taurine supplementation. **Table 36-10** lists levels of taurine found in various types of natural foods.

Table 36-10. Taurine concentrations (mg/kg dry matter) in selected natural food sources.

Source	Concentration
Beef muscle, uncooked	1,200
Chicken muscle, uncooked	1,100
Cod fish, uncooked	1,000
Lamb muscle, uncooked	1,600
Mouse carcass	7,000
Pork muscle, uncooked	1,600
Tuna, canned	2,500

Taurine supplementation of feline foods can be discontinued within 12 to 16 weeks if: 1) clinical signs of heart failure have resolved, 2) echocardiographic values are near normal and 3) the cat will eat a food known to support normal whole blood taurine concentrations. The length of time needed for taurine supplementation of canine foods is currently unknown.

L-Carnitine Supplementation

The recommended oral dosage for dogs with myocardial L-carnitine deficiency is 50- to 100-mg L-carnitine/kg body weight three times daily (Keene, 1992). Dogs weighing 25 to 40 kg are most often affected and should receive 2 g of L-carnitine mixed with food three times daily. This high oral dosage will elevate plasma L-carnitine concentration 10 to 20 times above usual pretreatment values (Keene et al, 1991). These high plasma L-carnitine levels will usually, but not always, raise myocardial L-carnitine concentrations into the normal range. The cost of this level of L-carnitine supplementation is approximately $80 (U.S.) per month for a large-breed dog. L-carnitine is usually available in human health food stores.

Dogs that respond dramatically to L-carnitine therapy do so in a reasonably predictable manner. Owners often report generalized improvement in clinical signs within one to four weeks and echocardiographic improvement is noted after eight to 12 weeks of supplementation. Improvement may continue for about six to eight months, at which time patients often reach a plateau and though they appear clinically normal they have depressed ventricular function as determined by echocardiography (Keene, 1992).

Assess and Determine the Feeding Method

The method of feeding is often not altered in the nutritional management of cardiovascular disease. If a new food is fed, the amount to feed can be determined from the product label or other supporting materials. The food dosage may need to be

changed if the caloric density of the new food differs from that of the previous food. The food dosage is usually divided into two or more meals per day. The food dosage and feeding method should be altered if the patient's body weight and condition are not optimal. If the patient has a normal body condition score (2.5/5 to 3.5/5), the amount of food it was fed previously (energy basis) was probably appropriate. To determine the starting point for the amount of new food to feed, if the patient's body condition score is within the normal range (2.5/5 to 3.5/5), the amount of calories were appropriate. If the energy density of the previous food is available, the number of calories consumed per day (daily energy requirement [DER]) can be determined by multiplying the energy density of the food (kcal/cup and/or can) by the number of cups and/or cans fed. Then the amount of new food to feed can be obtained by dividing the DER value by the energy density of the new food. The energy densities of foods for heart disease are included in **Tables 36-5** and **36-6**. Manufacturers' feeding information can also be used to determine an initial amount of new food to feed. Body weight should be monitored for a few weeks after the food change is accomplished.

Food dosage should be modified for patients with obesity or cachexia. A diary maintained by the client is helpful for documenting what types and quantities of foods and supplements are being offered and eaten by the patient. This caloric intake can be compared with the number of calories that are usually needed to maintain ideal body weight and condition in that patient.

Obesity causes profound changes that can complicate cardiovascular disorders. Obese patients should undergo management with a calorie-restricted food and client education should focus on the importance of the pet achieving an ideal body weight and condition (Chapter 27). The veterinary health care team should emphasize the potentially damaging effects of obesity in patients with heart disease to clients to enlist their active participation in a successful weight-management program.

For clinical nutrition to be effective, there needs to be good compliance. Enabling compliance includes limiting access to other foods and knowing who feeds the patient. If the patient comes from a household with multiple pets, it should be determined whether the pet with cardiovascular disease has access to other pets' food. Access to other food (table food, other pets' food, etc.) may contribute to cardiovascular disease and thus should be denied (Chapter 1).

Occasionally, it is difficult to get a patient to accept a change to a lower salt commercial food. This can occur because of: 1) advanced illness associated with heart failure, 2) established feeding habits of older patients and their owners, 3) anorexia associated with concurrent renal failure and some cardiac drugs and 4) the "all or nothing" approach to feeding, rather than slowly changing to the new food. Changing the eating habits of most dogs is relatively easy, but changing the feeding habits and preconceptions (e.g., "low-salt food is always unpalatable") of some pet owners and veterinarians is often much more difficult. Results of feeding studies using hospitalized dogs have shown that most dogs will readily accept a food that is very low in sodium chloride by the third day (Ross, 1987). For individual dogs, these foods can be made more palatable by warming the food or adding flavor enhancers (low-sodium soup or tomato sauce; sweeteners such as honey or syrup). Use of foods that are very low in sodium chloride in advanced heart disease and failure will be much easier if the dog has already been fed a low-sodium food (Tables 13-4 and 14-3 for dogs and Tables 20-4 and 21-4 for cats).

REASSESSMENT

In general, the survival of patients with heart failure is related to the degree of myocardial failure, whereas their clinical signs are related more to CHF and its compensatory mechanisms. The overall objectives of treatment for chronic heart failure, as for almost any cardiovascular disease, are threefold: 1) prevention (prevent myocardial damage, prevent recurrence of heart failure), 2) relief of clinical signs (eliminate edema and fluid retention, increase exercise capacity, reduce fatigue and respiratory compromise) and 3) improvement of prognosis (reduce mortality).

Dogs and cats with suspected cardiovascular disease should undergo a routine serum biochemistry profile and urinalysis before any nutritional or drug therapy is initiated. Dogs and cats with heart failure and evidence of preexisting renal disease, including isosthenuria, may be at increased risk for developing azotemia during combined food-drug therapy. There are no universal recommendations for controlling: levels of sodium, chloride and potassium; fluid intake; ACE inhibition and diuretic administration for patients with cardiovascular disease. Rather, each patient should be monitored frequently (weekly for the first four to six weeks). Reassessment should include: 1) measurement of body weight, 2) assessment of body condition, 3) determination of serum electrolyte and magnesium concentrations and 4) evaluation of renal function.

FEEDING PLANS FOR PATIENTS WITH CHYLOTHORAX

Depending on the chronicity of the disease, amount of pleural effusion and prior treatment attempts, dogs and cats with chylothorax may be emaciated and dehydrated. The goal of medical management is to support the metabolic and nutritional needs of the patient until the effusion spontaneously resolves, specific therapy for an underlying disease is instituted (e.g., chemotherapy, radiation therapy or both for a mediastinal mass; surgical correction of diaphragmatic hernia) or the patient's thoracic duct is ligated.

Dehydration and electrolyte abnormalities should be corrected before initiating nutritional support. Serious hyponatremia and hyperkalemia occur in dogs with chylothorax and should be corrected, especially if anesthesia is planned for placement of a thoracic tube or exploratory thoracotomy (Willard et al, 1991). Parenteral nutrition is a proven way to reduce the quantity of

INTRODUCTION

Chronic kidney disease (CKD) is the most common disease affecting the kidneys of dogs and cats. It may be recognized by reduced kidney function or the presence of kidney damage. CKD is defined as kidney damage present for at least three months, with or without decreased glomerular filtration rate (GFR) or greater than 50% reduction in GFR persisting for at least three months (Polzin et al, 2005). Kidney damage is further defined as either 1) microscopic or macroscopic pathologic changes detected by histologic or direct visualization of the kidneys or 2) markers of damage detected by blood or urine tests or imaging studies. In the past, multiple terms were used to define the severity of renal functional abnormalities including renal insufficiency, renal failure and uremia. However, there has not been uniform agreement on the specific definition of renal insufficiency vs. renal failure. Therefore, it has been recently proposed by the International Renal Interest Society (IRIS) to replace these terms with a scheme to classify severity of CKD into four stages based on stable serum creatinine concentrations (**Table 37-1**). Two of the foundational assumptions inherent in this classification scheme are that the presence of CKD has been confirmed and that azotemia, if present, has been localized as renal in origin. This classification scheme emphasizes the continuum of severity of renal injury of dogs and cats with documented presence of kidney damage without evidence of azotemia in stage 1 CKD, to progressively more severe CKD with resultant increasing serum creatinine concentration for stages 2 to 4. Furthermore, by using the term "kidney disease" and staging the severity of disease, it is possible to facilitate understanding, communication and application of management guidelines for patients in each stage.

The goals of this chapter are to provide pathophysiologic concepts and practical nutritional management recommendations for dogs and cats with CKD. Nutritional management of patients with CKD includes measures to reduce signs of uremia and slow progression to later stages of disease. There is general agreement regarding nutritional management of CKD when overt signs exist; however, the role of nutritional intervention during earlier stages of CKD is less well defined. Thus, in a sense, the question is not whether to use nutritional management but when should it be initiated. Because detection of CKD in its early stages is difficult and there appears to be no harm in avoiding nutrient excess (e.g., phosphorus) during earlier stages, nutritional management should be considered by stage 2 CKD and is clearly indicated when serum creatinine exceeds 2 mg/dl (179 µmol/l) (Jacob et al, 2002; Ross et al, 2006). Similarly, significant and persistent renal proteinuria,

Table 37-1. International Renal Interest Society (IRIS) Staging System for Chronic Kidney Disease in Dogs and Cats.

Stage	Serum creatinine (dogs)	Serum creatinine (cats)	Substage based on proteinuria and hypertension	Comments
1	<1.4 mg/dl (<125 µmol/l)	<1.6 mg/dl (<140 µmol/l)	Proteinuria: NP/BP/P* Hypertension: N/L/M/H/nc/c/RND**	Non-azotemic CKD Clinical signs (other than PU/PD) usually absent
2	1.4-2.0 mg/dl (125-179 µmol/l)	1.6-2.8 mg/dl (140-249 µmol/l)	Proteinuria: NP/BP/P* Hypertension: N/L/M/H/nc/c/RND**	Mild renal azotemia (overlaps with reference range) Clinical signs (other than PU/PD) usually mild or absent
3	2.1-5.0 mg/dl (180-439 µmol/l)	2.9-5.0 mg/dl (250-439 µmol/l)	Proteinuria: NP/BP/P* Hypertension: N/L/M/H/nc/c/RND**	Moderate renal azotemia Extrarenal clinical signs usually begin in this stage
4	>5.0 mg/dl (>440 µmol/l)	>5.0 mg/dl (>440 µmol/l)	Proteinuria: NP/BP/P* Hypertension: N/L/M/H/nc/c/RND**	Severe renal azotemia Many extrarenal clinical signs usually present

Key: PU/PD = polyuria/polydipsia, UPC = urine protein-creatinine ratio, BP = blood pressure.
*NP = non-proteinuric (UPC <0.2), BP = borderline proteinuric (UPC = 0.2 to 0.4 in cats and 0.2 to 0.5 in dogs), P = proteinuric (UPC >0.4 in cats and >0.5 in dogs).
**N = minimal risk of complications (systolic BP <150 mm Hg), L = low risk of complications (systolic BP 150 to 159 mm Hg), M = moderate risk of complications (systolic BP 160 to 179 mm Hg), H = high risk of complications (systolic BP >180 mm Hg), nc = no evidence of hypertensive complications, c = hypertensive complications present, RND = risk not determined (blood pressure not measured).

even in the absence of azotemia, reflects marked renal damage and signals the need for nutritional management regardless of the CKD stage.

CLINICAL IMPORTANCE

Prevalence of Chronic Kidney Disease

CKD is a common cause of morbidity and mortality in dogs and cats. In a survey of 1,600 pet dogs over five years of age examined at a European veterinary college for a variety of reasons, approximately 20% had abnormally increased markers of renal function. It is not known how many of these dogs had kidney disease (Leibetseder and Neufeld, 1991). In a cross-sectional study of 31,484 dogs and 15,226 cats evaluated in private practices across the United States in 1995, the prevalence of kidney disease was 2.2% in cats and 0.8% in dogs (Kirk et al, 2001). During 1990, the diagnosis of CKD in cats of all ages reported to the Veterinary Medical Data Base was 16 cases/1,000 cats examined. By 2000, diagnosis of CKD in cats of all ages was 96 cases/1,000 cats examined (Ross et al, 2006). Increased diagnosis of CKD in cats may be due to their living longer, more of them being screened for CKD and/or increased awareness of CKD by veterinarians. CKD appears to be a common cause of death in dogs and cats. In a retrospective study of dogs, 2% died from chronic nephritis, 2% from pyelonephritis and 1% from glomerulonephritis (Bronson, 1982). Thus, the overall mortality from kidney diseases was 5%. With the exception of cancer, kidney disease was the most common cause of death in this study. In a 1991 survey by the Morris Animal Foundation of readers of *Companion Animal News,* respondents indicated that of 325 cats that had died, 94 succumbed to kidney disease (MAF, 1991). By comparison, 39 of the 325 died of feline leukemia and 45 died due to other causes.

Relationship Between Age and Kidney Disease

CKD occurs in dogs and cats of all ages, but it is frequently a disease of older pets. In a retrospective study of 70 cats with CKD, diagnosed from 1973 to 1984, ages ranged from nine months to 22 years (mean, 9.2 ± 5.5 years). Nine cats (12.8%) were less than three years old, 24 (34.3%) were four to seven years old and 37 (52.9%) were more than seven years old (DiBartola et al, 1987). In a study of 175 cats diagnosed with CKD in Australia from 2000 to 2003, ages ranged from two to 21 years (mean, 13.2 ± 3.7 years). However, the majority (69%) were 12 to 18 years old (White et al, 2006). The mean age for cats diagnosed with CKD at the Animal Medical Center in New York from 2000 to 2002 was 12.8 ± 4.4 years (Boyd et al, 2008). Analysis of data from university teaching hospitals contributed to the Veterinary Medical Data Base from 1980 to 1990 indicated that 37% of cats with CKD were less than 10 years old, 31% of cats were between 10 and 15 years old and 32% of cats were older than 15 years (Lulich et al, 1992). In a 1995 survey of private practices, the mean ages of dogs and cats with kidney disease were 10.2 and 13.2 years, respectively (Kirk et al, 2001). Another study in dogs showed a similar relationship between aging and occurrence of CKD. Prevalence of CKD was reported to be nine cases/1,000 dogs of all ages examined, 12.5 cases/1,000 in dogs between seven and 10 years old, 24 cases/1,000 in dogs between 10 and 15 years old and 57 cases/1,000 in dogs over 15 years old (Polzin et al, 1995).

Causes of Kidney Disease

Familial Kidney Diseases

Juvenile kidney disease increases suspicion of a familial

tain <20% DM fat, which would be appropriate for a dog with a history of pancreatitis (**Table 2**). The dog's current food contained approximately 9% DM fat; therefore, it was recommended to initially transition to a veterinary therapeutic renal food[f] formulated for early kidney disease that contained a similar amount of fat.

The amount of new food to feed was based on an estimate of the patient's resting energy requirement (RER) at its ideal weight (7.3 kg) and multiplying it by a factor of 1.2 (assumes a small amount of physical activity) to determine the daily energy requirement (DER). RER at 7.3 kg = 311 kcal (1,300 kJ); DER = RER x 1.2 = 373 kcal (1,561 kJ). The as fed energy density of the food was 358 kcal/8-oz. measuring cup. The daily amount to feed is estimated by dividing the DER (373 kcal) by the as fed energy density (358 kcal/cup), which equals slightly more than one cup of food daily. The patient was offered small quantities of the food every three to four hours.

The owners were instructed to return the dog to their primary care veterinarian seven to 10 days after discharge for physical examination, urine culture, blood pressure evaluation and measurement of serum biochemistries and UPC ratio. Long-term monitoring was recommended every one to four months indefinitely to assess effectiveness of treatment and make adjustments as needed. The dog's condition continued to decline over the next six months and the patient was euthanized after it began having seizures; a postmortem examination was not done.

Table 2. Fat content of canine therapeutic renal foods.

Table 37-2. Kidney diseases suspected or confirmed to be inherited in dogs and cats.

Kidney disease	Canine breeds	Feline breeds
Amyloidosis	Beagle, collie, foxhound, Chinese Shar-Pei, Walker hound	Abyssinian, Siamese, Oriental
Atrophic glomerulopathy	Rottweiler	–
Fanconi syndrome	Basenji, border terrier, miniature schnauzer, Norwegian elkhound, Shetland sheepdog	–
Glomerulonephropathy	Beagle, Bernese mountain dog, bull mastiff, Dalmatian, Doberman pinscher, soft-coated wheaten terrier	–
Glomerulosclerosis	Newfoundland	–
Hereditary nephritis	Bull terrier, English cocker spaniel, Samoyed	–
Medullary cystic disease	Miniature schnauzer	–
Polycystic kidney disease	Beagle, cairn terrier, collie, foxhound, miniature poodle	Domestic longhair cat, Himalayan, Persian
Primary renal glucosuria	Norwegian elkhound, Scottish terrier	–
Renal cystadenocarcinoma	German shepherd dog	–
Renal dysplasia	Alaskan malamute, beagle, boxer, bulldog, cavalier King Charles spaniel, chow chow, cocker spaniel, Dutch kookier, Great Dane, Great Pyrenees, golden retriever, Irish wolfhound, keeshond, Lhasa apso, Samoyed, Shih Tzu, soft-coated wheaten terrier, standard poodle, Yorkshire terrier	Persian
Renal telangiectasia	Pembroke Welsh corgi	–
Tubulointerstitial nephropathy	Norwegian elkhound	–
Unilateral renal agenesis	Beagle, Doberman pinscher	Domestic shorthair cat, Himalayan

nephropathy; however, juvenile kidney disease may be due to non-genetic causes. The specific term juvenile nephropathy has been used to describe disorganized nephrogenesis including kidney failure in young dogs. The term renal dysplasia describes abnormal differentiation of the kidneys. Specific histologic findings in renal dysplasia include fetal glomeruli, atypical tubular epithelia and persistent mesenchyme. Although renal dysplasia occurs most often as an inherited disorder, it can also be an isolated congenital abnormality that is not inherited. Juvenile nephropathy has been reported to occur in Alaskan malamutes, boxers and golden retrievers. Both males and females were affected. The lesions included moderate to severe interstitial fibrosis and mild to moderate lymphoplasmacytic interstitial inflammation. Mild to moderate tubular dilatation and atrophy were also present. Cystic glomerular atrophy and periglomerular fibrosis were prominent findings in most dogs (de Morais and DiBartola, 1995; de Morias et al, 1996; Chandler et al, 2007).

Familial disorders resulting in CKD have been documented or suspected to occur in a number of breeds (**Table 37-2**) (Lees, 1996). Familial nephropathies should be suspected when CKD is diagnosed in related pets with a higher frequency than would be expected by chance and there is no apparent underlying cause. Age of cats and dogs with familial nephropathies at presentation often is less than that of most pets presenting with CKD. In some familial nephropathies, the kidneys are seemingly normal at birth but because of an inborn metabolic defect, progressive structural and functional deterioration develops in the first few years of life. The term hereditary nephropathy is reserved for conditions in which an inherited basis has been documented by pedigree analysis or test breeding.

Hereditary nephropathy has been reported to occur in several breeds of dogs including Samoyeds, English cocker spaniels and bull terriers. Affected male Samoyed dogs with X-linked hereditary nephritis have splitting of glomerular basement membranes and develop overt CKD within the first year of life (Valli et al, 1991; Grodecki et al, 1997). The underlying inborn error is a defect in the formation of Type IV collagen. Carrier females with X-linked nephritis have isolated splitting of glomerular basement membranes although advanced CKD is not observed until later in life (Valli et al, 1991). In English cocker spaniels, a Type IV collagen defect is transmitted as an autosomal recessive trait (Davidson et al, 2007). Proteinuria is the initial finding and affected dogs typically die of terminal CKD between six and 24 months of age (Nash, 1989). Light microscopic renal lesions are mild and nonspecific but distinctive electron microscopic changes are observed in the glomerular basement membrane (Lees et al, 1998). The defect in bull terriers appears to be an autosomal dominant disorder (Hood and Savige, 1995). The rate of progression in bull terriers is quite variable with dogs dying of terminal CKD from a few months to 10 years of age. Hematuria is observed in many affected bull terriers.

Two distinct familial nephropathies have been reported to occur in soft-coated wheaten terriers (Littman et al, 2000; Ericksen and Grondalen, 1984). One nephropathy is a form of renal dysplasia. Kidneys from affected dogs are small, irregular and fibrous. Glomeruli are small and hypercellular and there are increased numbers of fetal glomeruli. The second form of nephropathy in soft-coated wheaten terriers is characterized by protein-losing enteropathy and concomitant nephropathy. Although a genetic basis for this syndrome has not been proven, dogs become symptomatic between two and five years of age. Membranoproliferative glomerulonephritis, glomerulosclerosis, or both, are present microscopically.

Renal amyloidosis has been recognized in related dogs of two

Table 37-3. Elements of the physical examination that should be emphasized in patients with suspected chronic kidney disease.

Body weight and body condition score
Cardiovascular system: Abnormal heart sounds? Increased tortuosity of superficial veins? Systemic blood pressure (direct or indirect measurement) abnormalities? Pulse rate and character?
Cervical region: Thyroid masses (cats)?
Fundus: Retinal detachment? Hemorrhage? Increased tortuosity of arteries? Retinal edema? Lipemia retinalis?
Genitourinary tract (urethra, prostate gland, penis, prepuce, vulva): Shape? Position? Pain? Discharge?
Hydration status
Kidneys: Both palpable? Size? Shape? Position? Surface contours? Pain? Bilaterally symmetrical?
Musculoskeletal: Muscle masses? Evidence of osteodystrophy?
Oral examination: Mucosal ulcers? Pallor? Necrosis or discoloration of tongue?
Temperature, pulse, heart and respiratory rates
Urinary bladder: Size? Position? Shape? Pain? Thickness of wall? Intraluminal masses? Grating sensation?

Table 37-4. Diagnostic tests for evaluating patients with suspected chronic kidney disease.

Bacterial urine culture
Complete blood cell count
Diagnostic imaging (abdominal radiography and/or ultrasonography)
Excretory urography, if indicated for obstructive uropathy
Renal biopsy, if indicated for evaluation of persistent proteinuria or suspected renal neoplasia
Serum biochemistry profile
Systemic blood pressure measurement
Urinalysis, including microscopic examination of urine sediment
Urine protein-creatinine ratio

breeds (beagles, Chinese Shar-Peis) and related Abyssinian cats (Chew et al, 1982; Boyce et al, 1984; Bowles and Mosier, 1992; DiBartola et al, 1986, 1990). Histologic findings in renal tissue from beagles include moderate to severe glomerular amyloidosis with inconsistent mild medullary interstitial amyloidosis (Bowles and Mosier, 1992). Medullary amyloid was identified in all Chinese Shar-Pei dogs and nine dogs (64%) had glomerular involvement (DiBartola et al, 1990). In 15 Abyssinian cats involved in one study, amyloid was deposited in the medullary interstitium of all cats and 11 cats had glomerular involvement (DiBartola et al, 1986).

Acquired Kidney Diseases

CKD may result from a variety of systemic conditions that cause kidney damage or there may be no apparent underlying cause. Infectious, inflammatory and immune-mediated diseases (e.g., leptospirosis, rickettsial diseases, pyelonephritis, amyloidosis) may cause inflammation of the renal interstitium or glomeruli. Glomerulonephritis secondary to systemic infectious, inflammatory or neoplastic diseases may be a common cause of CKD, especially in dogs. Renal neoplasia, particularly lymphoma in cats, may be a cause of CKD. Drugs that may cause nephrotoxicosis include antimicrobials (aminoglycosides), antifungals (amphotericin B), analgesics (aspirin, ibuprofen and phenylbutazone), immunosuppressive agents (penicillamine) and chemotherapeutic drugs (cisplatin, methotrexate and daunorubicin) (Grauer, 1996). Geriatric patients may be at greater risk for drug-induced nephrotoxicity because of a decline in kidney function associated with aging, use of multiple drugs with nephrotoxic potential and altered metabolism and excretion that occurs in older patients.

PATIENT ASSESSMENT

History

Historical findings in patients with CKD may include polyuria/polydipsia (less frequent in cats than dogs), lethargy, inappetence, vomiting, weight loss, nocturia, constipation, diarrhea, acute blindness (associated with hypertension) and seizures or coma (terminal uremia). Cats also may have ptyalism and muscle weakness with cervical ventriflexion due to hypokalemic myopathy. In a retrospective study of cats with CKD, polyuria and polydipsia were observed in 40%, vomiting in 52%, inappropriate urination in less than 10% and diarrhea in 3% (Lulich et al, 1992). Nonspecific signs such as inappetence and weight loss also are common in dogs and cats with CKD. Rarely, signs of thromboembolic disease (e.g., severe respiratory distress, posterior paresis) may be present in patients with nephrotic syndrome (i.e., proteinuria, hypoalbuminemia, hypercholesterolemia and ascites/peripheral edema). Occurrence of clinical signs may depend on the stage of CKD at diagnosis. Dogs and cats with stage 1 CKD generally have no or minimal clinical signs. However, polyuria/polydipsia may occur in some patients during this stage. Systemic clinical signs become more obvious in stages 3 and 4.

Physical Examination

A thorough physical examination is indicated for patients with suspected CKD, with emphasis on those items listed in **Table 37-3**. Dehydration (70%) and decreased body condition (58%) were the most common abnormal physical examination findings in a clinical series of cats with CKD (Lulich et al, 1992). An abnormally large kidney was detected by palpation in 25% of cases and an abnormally small kidney in 16% of cases in this series. Gingivitis, halitosis and oral ulcers were occasionally reported. Firm swellings in the nasomaxillary region, including the maxillary and mandibular gingival surfaces and extending to frontal sites, may be present in young dogs with stage 4 CKD. These changes result from renal osteodystrophy. Ascites or peripheral edema may be identified in patients with nephrotic syndrome; this finding is more common in dogs than cats.

The primary abnormal findings in some patients with CKD are due to ocular changes (e.g., retinal hemorrhage and detachment) associated with hypertension. In one study, 15 of 23 cats (65%) with CKD had indirect blood pressure measurements

consistent with systemic hypertension (Stiles et al, 1994). Twelve of the 15 cats (80%) with hypertension had active hypertensive retinopathy including increased tortuosity of arteries, retinal edema and focal detachments. In a larger study of cats with CKD in a primary care practice setting, prevalence of hypertension in cats with CKD was about 20% (Syme et al, 2002). Hypertensive retinopathy has been reported to occur in dogs with CKD, but it appears to be less common than in cats (Jacob et al, 2003).

Routine Laboratory Evaluation

Most major renal functions can be evaluated diagnostically by routine laboratory tests including complete blood counts (CBC), serum biochemistry profiles and urinalyses (DiBartola, 2005). **Table 37-4** lists diagnostic tests that are recommended for patients with suspected CKD. CBC results are useful in dogs and cats with CKD to evaluate the presence of anemia and concurrent disorders such inflammation from systemic infection. Azotemia is increased serum urea nitrogen or creatinine concentrations. Increased serum concentrations of urea nitrogen or creatinine may result from prerenal, renal or postrenal disorders. (See Glomerular Filtration and Localization of Azotemia below.) Results of serum biochemistry profiles reveal renal azotemia from reduced GFR in patients in stages 2 to 4 CKD. Dogs and cats with stage 1 CKD do not have azotemia. Dogs and cats with CKD have impaired urine concentrating ability and usually have urine specific gravity values <1.030 (dogs) or <1.040 (cats), with concurrent clinical dehydration or azotemia. Some cats with stage 2 CKD may retain urine concentrating ability (urine specific gravity values >1.040). However, these patients have gradually decreasing urine specific gravity values as CKD progresses (e.g., over a period of 18 months) (Polzin et al, 2005). Additional notable urinalysis findings may include proteinuria (See Altered Membrane Permselectivity below.), glucosuria from tubular dysfunction or pyuria associated with urinary tract infection.

Diagnostic Imaging

Radiography and ultrasonography are complementary imaging modalities that help assess renal structure and localize disease within the urinary tract (Rivers and Johnston, 1996). Survey radiographs can assess renal size by comparing the length of the kidneys with the length of the second lumbar vertebral body on the ventrodorsal view. In a retrospective series of cats with CKD, 33% had small kidneys, 40% had kidneys of normal size and 27% had larger than normal kidneys as determined by imaging procedures (Dibartola et al, 1987). Polycystic kidney disease and lymphoma were the most common causes of renomegaly in cats. Feline polycystic kidney disease can be diagnosed ultrasonographically with a high level of confidence, although extensive polycystic disease must be differentiated from severe hydronephrosis and perirenal pseudocysts (Walter et al, 1988). Excretory urography can be used to qualitatively assess renal function and detect evidence of upper urinary tract obstruction.

Ultrasonography provides information about intrarenal architecture even when reduced renal function makes excretory urography impractical (Walter et al, 1987, 1988). It also can provide images of the kidneys when abdominal effusion or loss of abdominal fat reduces radiographic contrast. Ultrasonographic patterns are not specific for histologic lesions. However, it is possible to differentiate solid lesions from fluid-filled lesions and to assess distribution patterns. Ultrasonography also may be used to detect renal pelvic dilatation secondary to obstruction of the ureter by ureteroliths or nephroliths.

Radiography also is useful in the diagnosis of renal osteodystrophy. In young dogs with advanced CKD, radiographs of the skull reveal generalized osteopenia, irregular mineralization and dense soft-tissue swelling of the mandibles, maxillae and zygomatic arches. The most striking radiographic finding is demineralization of lamina dura dentes (i.e., bone surrounding the teeth). Radiographs of long bones reveal normal-appearing cortices with a coarse trabecular pattern of the metaphyseal and epiphyseal regions, suggesting demineralization. Spontaneous fractures may be evident. The radiographic diagnosis of fibrous osteodystrophy is applied to this constellation of findings.

Blood Pressure Measurement

Systemic blood pressure varies markedly in healthy pets and may be compounded further by effects of anxiety associated with blood pressure measurement in a hospital environment, and other factors (Bodey and Michell, 1996; Remillard et al, 1991; Brown et al, 2007). Several studies have evaluated different techniques for measuring blood pressure in dogs and cats. In the clinical setting, however, blood pressure is most often measured indirectly (e.g., Doppler ultrasonography, oscillometry). Follow a standard protocol to obtain reliable blood pressure values (**Table 37-5**) (Brown et al, 2007).

About 10% of apparently healthy dogs (Remillard et al, 1991) and 9 to 93% of dogs with CKD are hypertensive (Brown et al, 2007); whereas, 19 to 65% of cats with CKD are hypertensive (Syme et al, 2002; Brown et al, 2007). Depending on measurement techniques and methods used to determine reference ranges, indirect systolic arterial blood pressures greater than 141, 160, 170 or 185 mm Hg have been used to indicate systemic hypertension. Despite difficulties measuring blood pressure and confusion regarding diagnostic criteria, hypertension is a clinically important problem because of its apparent prevalence and potential for associated end-organ damage (e.g., retinal hemorrhage and left ventricular hypertrophy) (Morgan, 1986; Littman, 1994; Elliott et al, 2006a; Brown et al, 2007).

The IRIS has proposed that dogs and cats with CKD should be substaged on the basis of risk of hypertensive injury as determined by serial blood pressure measurements (**Table 37-1**). Dogs and cats with CKD with indirect systolic blood pressures less than 150 mm Hg are considered to have minimal risk of hypertensive injury. Patients with CKD and moderate or high risk of hypertensive injury or with overt evidence of hypertensive injury (e.g., hypertensive retinopathy) should be treated with appropriate antihypertensive medications.

Table 37-5. Standard protocol for measuring blood pressure in dogs and cats.*

Calibrate the blood pressure measurement device twice yearly.
Standardize the procedure used.
- Obtain measurements in an environment that is quiet, located away from distractions (e.g., other patients) and with the owner present.
- Restrain patients in a comfortable position, ideally in ventral or lateral recumbency to limit the distance from the base of the heart to the measurement cuff. Patients should be calm and motionless during the procedure.
- Use a cuff that is approximately 30 to 40% of the circumference of the measurement site in cats and 40% in dogs.
- Have the same trained individual, ideally a technician, perform blood pressure measurements each time.
- Determine and record five to seven consecutive and consistent (<20% variability) values.
- Discard the first measurement and determine the mean of all remaining values to obtain the patient's blood pressure measurement.
- Record the cuff size and site of placement (e.g., limb, tail), values for all measurements obtained, final (mean) value, details of any additional information (e.g., nervous patient) and interpretation of results by a veterinarian.

Evaluation of Renal Function

The primary functions of the kidneys are to excrete metabolic wastes (e.g., urea, creatinine), regulate fluid, electrolyte and acid-base balance and produce or activate several hormones including erythropoietin, calcitriol and renin. Anatomically, these functions occur in glomeruli (i.e., glomerular filtration and membrane permselectivity), renal tubules (i.e., urine concentration and tubular resorption) and other areas of the kidney (i.e., erythropoietin, calcitriol, renin). CKD may be associated with generalized renal dysfunction or it may involve only one function (e.g., tubular resorptive defect in Fanconi syndrome).

Glomerular Filtration

The most commonly evaluated renal function is glomerular filtration, which is determined by estimating or measuring GFR. Under steady state conditions, serum concentrations of urea nitrogen and creatinine are the time-honored methods for indirectly estimating GFR. These tests are useful for detecting large decreases in GFR (75% or greater), but lack sensitivity for detecting smaller decreases in glomerular filtration (**Figure 37-1**). In addition, serum urea nitrogen and creatinine values are affected by nonrenal factors, which contribute to the broad ranges for normal values.

Urea is produced in the liver from ammonia derived from the ornithine cycle, which catabolizes amino acids. The catabolized amino acids come from exogenous (dietary) and endogenous proteins. Urea is distributed throughout intracellular and extracellular water and is freely diffusible; therefore, it is common to use the terms blood urea nitrogen, serum urea nitrogen and plasma urea nitrogen interchangeably. The kidneys excrete urea by glomerular filtration, and serum urea nitrogen concentrations are inversely proportional to GFR. However, because urea is passively reabsorbed in the tubules, especially at reduced tubular flow rates, urea clearance is not an accurate measure of GFR. Clinical conditions that can increase serum urea nitrogen concentration include gastrointestinal hemorrhage, consumption of high-protein foods and catabolic drugs (e.g., glucocorticoids). Severe hepatic disease (e.g., portosystemic vascular shunts), feeding a low-protein food and conditions causing increased urine volume (e.g., intravenous fluid therapy) can decrease serum urea nitrogen concentrations independent of renal function.

Creatinine results from the nonenzymatic breakdown of muscle phosphocreatine. During steady states, creatinine production is constant and related to muscle mass. Serum creatinine concentration is less influenced by feeding than serum urea nitrogen concentration. However, it may be affected by breed and body size (Gleadhill, 1995). In a study of retired racing greyhounds, mean values for serum creatinine concentration (1.8 ± 0.1 mg/dl) and GFR (3.0 ± 0.1 ml/min./kg) were significantly greater than values from control dogs. However, blood urea nitrogen values were not different (Drost et al, 2006). Increased serum creatinine levels in greyhounds may be due to increased muscle mass in this breed. In contrast, it is possible for serum creatinine concentration to remain lower than expected or to not be increased in proportion to the decrease in GFR in older patients with decreased muscle mass and kidney disease.

When considering the magnitude of azotemia it's important to recognize that the relationship between serum urea nitrogen and creatinine concentrations and GFR is not linear (**Figure 37-1**). Thus, very large changes in GFR early in the natural course of CKD cause only small changes in serum urea nitrogen and creatinine concentrations. These small changes may not exceed the upper limit of the laboratory reference range and thus may go unrecognized throughout most of stage 1 CKD. Small decreases in GFR cause disproportionately large increases in serum urea nitrogen and creatinine concentrations in more advanced CKD (stages 3 and 4).

Evaluation of serum urea nitrogen and creatinine is used to indirectly assess GFR in most patients; however, measuring GFR is helpful for identifying kidney dysfunction that occurs before the onset of azotemia (e.g., breeds known to have familial kidney disease, patients with polyuria/polydipsia due to kidney disease, when potentially nephrotoxic treatment will be used). Urinary clearance of infused inulin is the gold standard for measuring GFR. However, this technique is limited to research settings because it requires collection of multiple, timed blood and urine samples and a constant rate infusion of inulin. Other methods have been used to estimate GFR but each has disadvantages. Endogenous creatinine clearance underestimates GFR because non-creatinine chromogens are present in plasma. Exogenous administration of creatinine reduces this potential problem by decreasing the proportion of non-creatinine chromogens in plasma. A newer creatinine-specific enzymatic analytical method eliminates the problem

(Finco et al, 1993). However, in cats, exogenous creatinine clearance does not accurately estimate GFR (Finco et al, 1996). In addition, factors other than GFR (e.g., hydration status) can affect creatinine clearance and serum creatinine concentration. Clearance of iohexol, a readily available radiographic contrast medium, has been used to reliably estimate GFR in dogs and cats and is a convenient method that can be used in clinical practice (Finco et al, 2001; Miyamoto 2001, 2001a; Goy-Thollot et al, 2006; Sanderson, 2009).

Altered Membrane Permselectivity

Proteinuria is the hallmark of altered glomerular membrane permselectivity. In patients with glomerular disease, permselective properties of the glomerular capillary wall are altered and increased amounts of protein are present in urine. Glomerulopathies are the most common cause of severe (heavy) proteinuria in dogs and cats although they appear to be more common in dogs than cats. Glomerulopathies can be primary (e.g., renal amyloidosis in dogs or idiopathic membranous nephropathy) or secondary to systemic infectious, inflammatory or neoplastic diseases (e.g., lupus erythematosus, heartworm disease, ehrlichiosis, lymphoma).

Proteinuria is defined as excretion of greater than normal amounts of protein in urine. Potential causes include urinary tract hemorrhage or inflammation, tubular resorptive defects, "overflow" proteinuria and altered glomerular permselectivity. Clinical significance of proteinuria depends on its severity and persistence. In the absence of hyperproteinemia, hematuria and urinary tract inflammation, persistent proteinuria usually indicates kidney disease and severe proteinuria (urine protein-creatinine ratio [UPC] ≥2) is generally associated with glomerular disease. The magnitude of proteinuria does not predict reversibility of the underlying disease, however. Serial quantitative evaluation of proteinuria is necessary for prognosis and assessment of response to treatment. Clinicians should confirm the persistence of proteinuria and attempt to localize its source before performing invasive and expensive diagnostic tests such as renal biopsy. Significance of proteinuria should always be interpreted in context of other laboratory and clinical findings (e.g., microscopic urine sediment examination).

Qualitative techniques for measurement of proteinuria include dipstick methods and precipitation techniques such as the sulfosalicylic acid (SSA) test. Urine concentration (refractive index, specific gravity) should be considered when interpreting results of these qualitative techniques (Finco, 1995). The most commonly used qualitative test is the colorimetric dipstick test. The test depends on ability of proteins, especially albumin, to alter the color reaction in paper impregnated with a pH-sensitive dye, tetrabromophenol blue. The test pad is buffered so that color changes reflect changes in protein concentration. In one study, sensitivity of the urine protein test strip for albuminuria in canine and feline urine was 54 and 60%, respectively. This means that 46 and 40% of dogs and cats, respectively, had proteinuria that was not detected by the dipstick (Grauer et al, 2004). Urine protein test strip specificity for

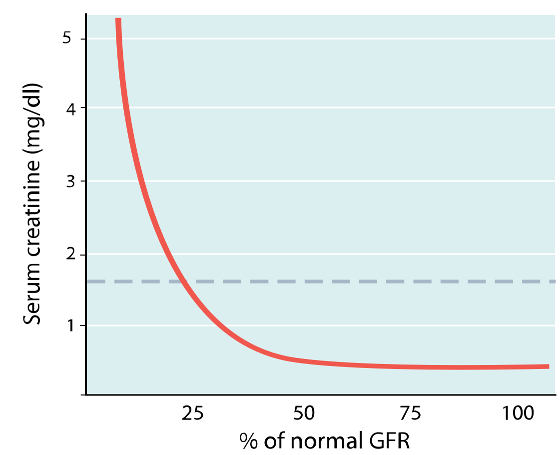

Figure 37-1. The relationship between serum creatinine concentration and % of normal glomerular filtration rate (GFR) or % of remaining functional nephrons is not linear. Therefore, small changes in GFR during early chronic kidney disease do not result in increased serum creatinine concentrations. Notice that values for serum creatinine do not exceed the upper reference range (broken line) until kidney dysfunction is marked (i.e., when 75% of nephrons are nonfunctional).

canine and feline albuminuria was 69 and 31%, respectively. Therefore, 31 and 69% of dogs and cats, respectively, with a positive dipstick reaction for protein did not have proteinuria. Based on this, false positive reactions are common, especially in cats, and may occur with concentrated or alkaline urine, hematuria, pyuria, urine contaminated with quaternary ammonium compounds or with excessive urine contact time with the dipstick pad (Grauer et al, 2004). Observer variation is a documented and unavoidable source of error with dipstick tests. All positive dipstick reactions for proteinuria should be followed up with additional testing such as the SSA test or testing for microalbuminuria (Lees et al, 2005). The SSA test is used by most commercial laboratories and can be performed in-house by mixing equal volumes of centrifuged urine and 5% SSA,[a] available from chemical supply companies. Resulting turbidity of urine is graded on a scale of 0 (no turbidity) to 4+ (completely opaque). Microalbuminuria can be detected in-house using a species-specific point-of-care test.[b]

In patients with stable renal function, the UPC ratio is a semiquantitative method for assessing proteinuria. The UPC ratio is calculated by dividing urinary protein concentration by urinary creatinine concentration. Urinary protein is measured by a quantitative analytical technique rather than by dipstick. It may be determined in commercial laboratories or by using an in-house kit.[c] Because urinary excretion of creatinine and protein is presumed constant in the presence of stable GFR, the UPC ratio in a single urine sample can be used to estimate 24-hour urinary protein loss. The time of day and method of urine sample collection are not critical. The UPC ratio eliminates the potentially confounding effect of urine concentration on interpretation of urinary protein concentration. A UPC ratio less

than 0.5 was found in the majority of non-proteinuric dogs studied (Grauer et al, 1985; White et al, 1984; Center et al, 1985). The upper limit of the reference range for UPC ratios in cats is 0.2 (Monroe et al, 1989; Adams et al, 1994). However, in one study of healthy male cats, the 24-hour urinary protein loss was greater in males than females and UPC values up to 0.6 were observed. This difference may be attributable to secretions of secondary sex glands in male cats (Monroe et al, 1989). Dietary protein intake significantly affected UPC values in normal cats and cats with surgically induced CKD (Adams et al, 1994). Consequently, dietary protein levels should be considered when interpreting UPC values because high protein intake may increase proteinuria.

UPC ratios should be performed on all dogs and cats with CKD to allow for substaging based on severity of proteinuria (**Table 37-1**). Studies in dogs and cats with CKD indicate that proteinuria is an important predictor of survival (Syme et al, 2006; Jepson et al, 2007; Jacob et al, 2005). Cats with UPC values consistently less than 0.2 have significantly longer survival than cats with UPC values greater than 0.4 (Syme et al, 2006; Jepson et al, 2007). Similarly, dogs with CKD and UPC values above 1.0 had significantly shorter survival than dogs with UPC values less than 1.0 (Jacob et al, 2005). Despite correlation of survival with proteinuria in cats with CKD, there is considerable overlap of survival times across the severity range of proteinuria. Accurate prediction of survival time for individual patients is not possible based on severity of proteinuria (Syme et al, 2006).

Urine Concentration

Disorders of urine concentrating ability generally involve abnormalities in the secretion of, or response to, antidiuretic hormone. Loss of concentrating ability can be one of the earliest indicators of kidney dysfunction, which is generally recognized when two-thirds of nephrons are nonfunctional. In CKD, the renal interstitial osmolality gradient is decreased because of increased urine flow per nephron or because of inability to establish and maintain the medullary concentration gradient. The resultant decrease in responsiveness to antidiuretic hormone leads to excretion of urine with osmolality or specific gravity values similar to those of plasma (i.e., isosthenuria).

Estimation of urine concentrating ability from urine specific gravity or refractive index is most often used for clinical purposes. The physiologic range for urine specific gravity is 1.001 to 1.070 in dogs and 1.001 to 1.080 in cats. Any urine specific gravity value may be normal; therefore, it's important to interpret specific gravity in the context of clinical findings including hydration status, concurrent disease and medications. (See Diagnosis of Chronic Kidney Disease.) In a retrospective series of cats with CKD, 37% had urine specific gravity values between 1.008 to 1.012 and 60% were between 1.013 and 1.034 (Lulich et al, 1992). However, some cats with CKD may have urine specific gravity values greater than 1.040 and remain persistently azotemic (up to 18 months) before losing concentrating ability (Polzin et al, 2005). In a study of cats with induced kidney disease (5/6 reduction of renal mass), mean urine specific gravity was 1.050 ± 0.015 in cats fed a 27.6% protein food and 1.038 ± 0.013 in a group fed a 51.7% protein food (Adams et al, 1994). However, the majority of cats with spontaneously occurring CKD have urine specific gravity values less than 1.035 (Polzin et al, 2005). Although it has not been reported, it is generally accepted that urine specific gravity in dogs with naturally occurring CKD is less than 1.030.

Tubular Resorption

Water and many solutes are reabsorbed from the tubular lumen into the peritubular interstitial fluid and ultimately the blood. In general, tubular resorption conserves substances that are essential for normal function (e.g., electrolytes, water, glucose and amino acids). Alterations in the renal handling of solutes may indicate kidney dysfunction. Abnormalities in tubular resorption may be generalized or limited to one or more tubular transport processes. Clinical syndromes are defined by the particular transport process involved. These syndromes include diverse disorders such as nephrogenic diabetes insipidus, renal tubular acidosis, renal glucosuria and aminoaciduria (e.g., cystinuria). Diagnosis is based on urinalysis findings (e.g., cystine crystalluria) or other tests such as quantitation of urinary amino acid concentrations.

Endocrine Function

Renal endocrine function can be evaluated by directly measuring the plasma concentration of the hormone or by indirectly assessing the action of that hormone. Erythropoietin concentration can be measured, but it is more practically assessed by serial monitoring of CBCs to detect progressive non-regenerative anemia that may occur in patients with stages 2 to 4 CKD. In CKD, reduced renal excretion of phosphorus causes phosphorus retention, which in turn stimulates increased parathyroid hormone (PTH) production and secretion. Phosphorus retention and hyperphosphatemia also inhibit renal tubular activity of 1-α hydroxylase, the enzyme responsible for renal conversion of inactive vitamin D to its active form, calcitriol. Decreased calcitriol concentrations, along with hypocalcemia (decreased ionized calcium) and hyperphosphatemia, contributes to development of hyperparathyroidism. Diagnosis of hyperparathyroidism is based on increased plasma concentrations of intact PTH. Although measurement of PTH is not routinely performed for patients with CKD, it should be measured (with serum calcium, phosphorus and ionized calcium) when calcitriol is administered for management of CKD. In the future, it may be recommended to monitor serum PTH concentrations in all patients with CKD, before the onset of hyperphosphatemia, so that treatment (e.g., dietary phosphorus restriction) can be adjusted to control secondary renal hyperparathyroidism earlier.

Diagnosis of Chronic Kidney Disease

Most routine tests used to diagnose CKD do not identify abnormal findings until there is advanced disease (stage 2 or higher). At present, the most common way to diagnose CKD

is by first detecting evidence of changes in renal function (e.g., azotemia, proteinuria) that arise as a result of renal lesions (Lees, 2004). Looking for subtle changes (e.g., gradually increasing serum creatinine over time, progressive decline in urine concentrating ability or presence of mild proteinuria) is helpful for identifying CKD at earlier stages (Lees, 2004). Earlier diagnosis of CKD allows earlier therapeutic intervention, which could slow or halt disease progression.

Localizing Azotemia

Azotemia is present by the time CKD is diagnosed in most dogs or cats. Increased serum concentrations of urea nitrogen or creatinine may result from prerenal, renal or postrenal disorders. Prerenal azotemia may be caused by catabolic states (e.g., treatment with corticosteroids), consumption of a high-protein food, gastrointestinal hemorrhage, dehydration, hypovolemia or decreased cardiac output. Renal structure remains normal and the kidneys are capable of normal function if the prerenal insult is corrected before permanent damage occurs. Renal azotemia is caused by kidney disease and generally occurs when 75% of nephrons are nonfunctional. Renal azotemia should be further classified as either acute or chronic because of differences in treatment and prognosis. Postrenal azotemia is caused by disorders that impair elimination of urine from the body (e.g., urinary tract obstruction or rupture). Sites most often affected are the urethra and urinary bladder, and less often, ureters and kidneys. For upper urinary tract disease to cause postrenal azotemia, bilateral renal or ureteral disease must be present (unless the patient has concomitant kidney disease). As with prerenal disorders, renal function in patients with postrenal azotemia is normal initially; development of irreversible renal injury depends on severity, duration and nature of the disorder impairing urine outflow.

One of the most useful tests for distinguishing between prerenal and renal azotemia is analysis of urine obtained before any treatment, especially fluid therapy. Patients with azotemia and evidence of adequate urine concentration (i.e., specific gravity >1.030 in dogs and >1.040 in cats) usually have prerenal disorders. There are two exceptions to this rule: 1) some cats with CKD may have renal azotemia and still retain urine concentrating ability (specific gravity >1.040); it may be many months before they finally develop concurrent azotemia and inadequate concentrating ability, 2) some dogs with glomerular disease may develop azotemia initially and then lose concentrating ability; this "glomerulotubular imbalance" should be suspected in dogs that have significant proteinuria, azotemia and urine specific gravity values greater than 1.030. When azotemia is initially identified, it's important to determine if the patient has received any treatment that may interfere with urine concentrating ability such as intravenous fluids, diuretics or corticosteroids. Also, disorders that may cause prerenal azotemia but concomitantly decrease urine specific gravity must be excluded; examples include hypoadrenocorticism, diabetic ketoacidosis, hypercalcemia, hepatic disease and pyometra. Hypoadrenocorticism may be easily misdiagnosed as acute kidney failure because of similar clinical and laboratory findings. Dogs and cats with renal azotemia usually have either isosthenuria (urine specific gravity of 1.008 to 1.013) or minimally concentrated urine (specific gravity <1.025). However, as previously noted, some patients with CKD may retain the ability to produce concentrated urine.

Postrenal azotemia should be suspected in patients with stranguria, dysuria, pollakiuria, abdominal pain, ascites, firm/painful urinary bladder, subcutaneous swelling or discoloration of the perineum or a history of recent abdominal trauma. Palpable urethroliths or masses in the urethra, urinary bladder or prostate gland also suggest a postrenal cause of azotemia. Complete absence of urine production (i.e., anuria) most often is caused by lower urinary tract obstruction, although it may occur in some cases of acute kidney disease (e.g., ethylene glycol toxicosis). An attempt should be made to pass a urinary catheter if there is any question regarding patency of the lower urinary tract. However, the ability to pass a urinary catheter does not definitively exclude urethral obstruction. Urine specific gravity often is not helpful for distinguishing between renal and postrenal azotemia because urinary tract obstruction may cause renal tubular dysfunction and interfere with urine concentrating ability. Abdominal ultrasonography is helpful for detecting masses and accumulation of fluid when urinary tract obstruction or rupture is suspected. Abdominal fluid analysis in patients with uroabdomen reveals a modified transudate or exudate characterized cytologically by neutrophils, macrophages and mesothelial cells; bacteria may be seen if there is urinary tract infection. If uroabdomen is suspected, a sample of abdominal fluid should be submitted for measurement of creatinine and potassium concentrations so these values can be compared to concomitant serum concentrations. Measurement of urea nitrogen concentration in abdominal fluid often equals that of serum or blood and is therefore not helpful in patients with uroabdomen. Contrast urethrocystography is indicated when rupture or obstruction of the urethra or urinary bladder is likely; whereas, excretory urography is indicated when rupture of the upper urinary tract is suspected. If available, urethrocystoscopy may also be used to confirm rupture of the bladder or urethra.

Response to treatment may help localize azotemia. In general, pre- and postrenal azotemia resolve rapidly within one to three days after the underlying cause is corrected. In contrast, renal azotemia usually decreases more slowly, persists after appropriate treatment or recurs soon after discontinuation of treatment. Note that severe or prolonged pre- or postrenal azotemia may cause renal injury, which eventually leads to permanent kidney disease. It is also possible for renal azotemia to exist concomitantly with either pre- or postrenal disorders; this possibility should be suspected in patients that do not respond to treatment as expected.

Differentiating Between Acute and Chronic Kidney Disease

After renal azotemia is confirmed, additional evaluation is indicated to distinguish between acute and CKD (Vaden, 2000). Careful review of history, physical examination findings and laboratory evaluation results usually distinguishes between acute and CKD (**Table 37-6**). Acute kidney disease is a rapid

Table 37-6. Distinguishing between acute and chronic kidney disease in dogs and cats on the basis of clinical and laboratory findings.*

Findings	Acute kidney disease	Chronic kidney disease
Clinical findings	Acute onset of clinical signs (usually <seven days)	Vague onset of clinical signs (often over weeks to months)
	Usually moderately to severely depressed	Alert, responsive or only slightly depressed
	Urine volume often decreased	Polyuria/polydipsia more likely
	Often good body condition	May be thin
	Kidneys enlarged, painful or may be normal	Kidneys small, irregular or may be normal
Laboratory and diagnostic imaging findings	Normal or increased hematocrit; anemia may result from blood loss (e.g., gastrointestinal hemorrhage)	Nonregenerative anemia typical; hematocrit decreases progressively over time
	Serum urea nitrogen and creatinine previously normal but increase progressively	Serum urea nitrogen and creatinine previously increased and typically remain stable
	Normal to increased serum potassium	Normal to decreased serum potassium, especially in cats
	Moderate to severe metabolic acidosis	Mild to moderate metabolic acidosis
	Urinary casts in some patients	Usually no urinary casts
	Proteinuria or glucosuria may result from acute tubular necrosis	Proteinuria often present, more likely due to glomerular disease
	Bone density normal	Bone density may be decreased

Inadequate urinary concentration
Increased renal ammoniagenesis
Metabolic acidosis
Renal oxidative stress
Systemic hypertension
Tubulointerstitial changes

deterioration of renal function that occurs over a period of hours to days, whereas CKD occurs over a period of months to years. A careful medical history may reveal causes of acute kidney disease (e.g., ingestion of a nephrotoxin such as ethylene glycol). Patients with acute kidney disease generally are healthy before sudden onset of lethargy, depression and vomiting, whereas clinical signs in CKD such as inappetence, weight loss and polyuria/polydipsia occur more gradually. Patients with acute exacerbation of CKD are common and may present a diagnostic challenge. However, careful questioning of owners in these cases usually establishes a more chronic history. If it is still not possible to distinguish between acute and chronic disease, renal biopsy may be helpful, particularly if results will alter treatment or provide prognostic information that would help owners decide on a course of action.

Etiopathogenesis of Chronic Kidney Disease

A variety of compensatory and adaptive responses are likely involved in the pathogenesis and progression of naturally occurring CKD (**Table 37-7**). In addition, sequelae of CKD (e.g., hypertension, proteinuria, metabolic acidosis and tubulointerstitial injury), changes in lipid metabolism and coagulation and normal renal aging may contribute to progression. Although some of these mechanisms initially are adaptive when renal function declines, they may ultimately lead to progressive renal injury (**Figure 37-2**). In addition, these etiopathogenic mechanisms are not mutually exclusive and in some instances may act synergistically. Understanding these mechanisms helps guide selection of treatment for patients with CKD.

Much of what we currently know about etiopathogenic mechanisms in CKD comes from studies in which kidney disease was induced by reduction or ablation of renal mass. This "remnant kidney model" causes progressive azotemia, mild proteinuria and arterial hypertension. In rats, this model is characterized by relentless progression to endstage kidney disease following the loss of a critical number of functioning nephrons (i.e., approximately three-fourths of the functional renal mass). Similarly, in human patients, progression from early to late stages of CKD has been reported regardless of the inciting renal injury and whether the initiating cause is present or not (Ihle et al, 1989).

Some controversy has existed about whether similar progressive renal injury occurs in other species, because the remnant kidney model has not been uniformly progressive in dogs and cats. Reduction of renal mass by 7/8 or less did not result in a consistently progressive decline in GFR in studies in dogs and cats (Polzin et al, 1991; Adams et al, 1994; Finco et al, 1998). It is possible that progression was not observed in these studies because the extent of the induced renal injury was insufficient to alter glomerular hypertension or renal autoregulation or perhaps because only mild proteinuria occurred. In experimental studies in dogs, reduction of renal mass resulted in glomerular changes and proteinuria; the severity of these changes appeared

to correlate with the amount of renal tissue ablated (Bourgoignie et al, 1987). In a remnant kidney model in which renal mass was reduced by 15/16 in dogs, GFR progressively declined, providing evidence that progressive kidney disease occurs in dogs if adequate renal tissue is ablated (Brown et al, 1991; Finco et al, 1992). It is generally accepted that naturally occurring CKD (stages 2 through 4) in dogs and cats tends to be progressive (Allen et al, 1987; Jacob et al, 2002; Ross et al, 2006; Polzin et al, 2005). Therefore, it appears that after a critical mass of nephrons becomes nonfunctional in dogs and cats, either due to renal ablation or natural causes, disease characterized by several pathophysiologic adaptations progresses. See sections below for more detailed information about specific mechanisms and how they may contribute to progression of CKD in dogs and cats.

Glomerular Hypertension and Hyperfiltration

In normal kidneys, single-nephron GFR and single-nephron plasma flow are submaximal under basal conditions. Reduction of nephron mass leads to hypertrophy of the residual nephrons with increases in filtration and perfusion of surviving nephrons to maintain total GFR (Polzin et al, 2005). Although these compensatory increases in single-nephron GFR and renal plasma flow initially help maintain homeostasis, eventually they contribute to progressive kidney damage. Single-nephron GFR increases are accompanied by glomerular hyperfiltration and intraglomerular hemodynamic changes, which increase flux of plasma proteins through the glomerular mesangium. These proteins stimulate mesangial cell proliferation and matrix production and eventually lead to glomerulosclerosis (**Figure 37-3**). Glomerular capillary hypertension is the critical intraglomerular hemodynamic factor responsible for promoting glomerular injury, perhaps through increasing proteinuria. Decreased dietary protein intake prevents these hemodynamic changes and preserves normal glomerular structure in rats (Brenner et al, 1982). The impact of dietary protein intake on glomerular hemodynamics and structure in dogs and cats is less certain.

As kidney disease develops, the afferent renal arterioles dilate, directly exposing glomeruli to systemic blood pressure; this causes glomerular hypertension, which distends the capillaries. The resultant mesangial stretch stimulates accumulation of collagen and progressive loss of glomerular function (**Figure 37-4**) (Riser et al, 1992). Continued strain on mesangial cells is a stimulus for cytokine release and extracellular matrix production (Polzin et al, 2005). Mesangial cells are stretched because of their relationship to capillaries and their attachment to the glomerular basement membrane. When mesangial cells in culture are stretched and relaxed repeatedly, stretch-induced release of transforming growth factor-β mediates production of collagen (Cortes et al, 1994). Intraglomerular hypertension also may lead to decreased glomerular permselectivity with resultant proteinuria (Polzin et al, 2005). Proteinuria, in turn, may mediate progressive injury of glomeruli and the renal tubulointerstitium (Lees et al, 2005; Polzin et al, 2005). Proteinuria has been associated with more rapid progression of CKD in dogs (Jacob et al, 2005) and cats (Syme et al, 2006).

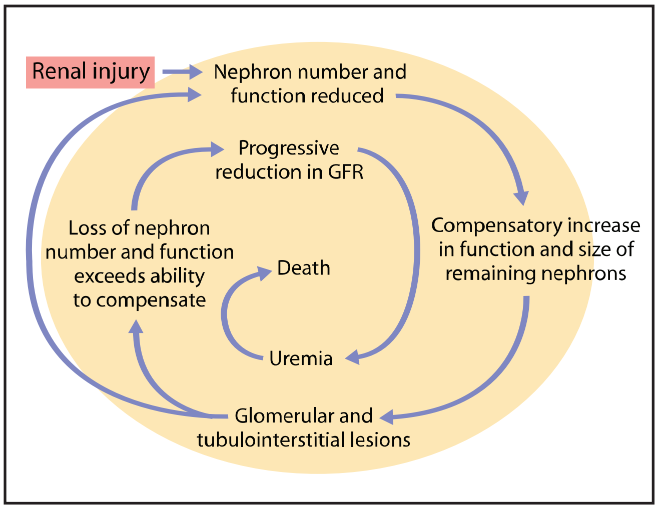

Figure 37-2. Vicious cycle of relentless progression of chronic kidney disease. After a critical amount of damage has occurred, compensatory mechanisms, which are initially beneficial, are activated and ultimately contribute to progressive injury. The amount of damage required to trigger progression probably varies from species to species and from individual to individual. (Adapted from Churchill J, Polzin DJ, Osborne CA, et al. The influence of dietary protein intake on progression of chronic renal failure in dogs. Seminars in Veterinary Medicine and Surgery: Small Animal 1992; 7: 246.)

Proteinuria

Proteinuria may mediate progressive renal injury through several mechanisms (Polzin et al, 2005; Elliott and Syme, 2006). Impaired glomerular permselectivity allows passage of proteins that are not normally filtered including albumin, transferrin and complement (Polzin et al, 2005). Proteinuria may result in direct mesangial cell toxicity, fibrosis of glomeruli and subsequent glomerulosclerosis. Progression of CKD in experimental models more closely relates to the degree of tubulointerstitial disease than to the severity of glomerular lesions. Proteinuria may injure tubular cells through overloading tubular reabsorptive mechanisms or by receptor-mediated mechanisms (Polzin et al, 2005). Proximal tubular cells reabsorb abnormally filtered proteins such as albumin through endocytosis and lysosomal degradation. Excessive albuminuria can overload this resorptive capacity, causing lysosomal swelling and rupture, leading to lysosomal enzyme-mediated injury of tubular cells. Excessive albuminuria also increases oxidative stress, which appears to be an important mechanism of progressive renal injury. (See Renal Oxidative Stress.)

Abnormally filtered transferrin, a plasma protein that transports iron, increases absorption of iron by proximal tubular cells. Increased intracellular iron concentration of tubular cells produces reactive oxygen species (ROS) leading to oxidative injury. Complement binds to the luminal membrane of tubular cells and activates the membrane attack complex, culminating in cellular injury and lysis. These mechanisms contribute to loss of tubular cells and ultimately loss of nephrons. Cellular activation of inflammatory genes also stimulates secretion of inflammatory mediators into the interstitium, which promotes inter-

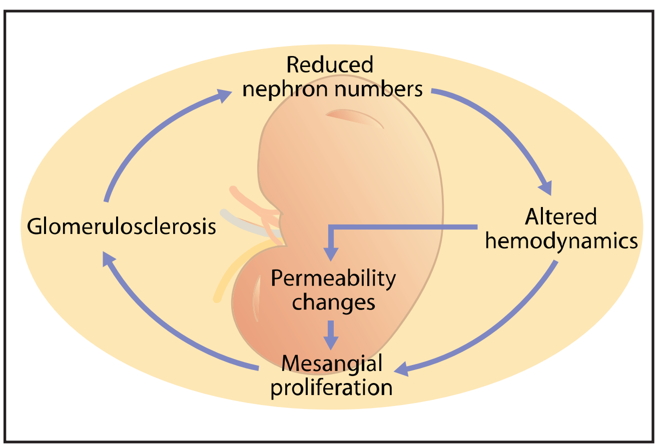

Figure 37-4. Schematic showing the progressive effect of glomerular capillary hypertension.

stitial fibrosis. These mechanisms of glomerular and tubular injury explain why even modest levels of proteinuria are associated with more rapid progression of CKD in dogs (Jacob et al, 2005) and cats (Syme et al, 2006).

Systemic Hypertension

In dogs and cats, hypertension usually occurs secondary to other diseases including kidney disease, obesity, hyperadrenocorticism, hyperthyroidism, pheochromocytoma and diabetes mellitus (Kobayashi et al, 1990; Rocchini et al, 1987; Brown et al, 2007). However, CKD appears to be the disease most commonly associated with systemic hypertension (Brown et al, 2007). When considering hypertension in CKD, it is important to note that CKD may cause hypertension and hypertension can promote progression of CKD. Systemic hypertension can also damage a number of other end organs, including the eyes, central nervous system and cardiovascular system (Morgan, 1986). The IRIS scheme for staging CKD in dogs and cats identifies substages based on magnitude of systemic blood pressure and risk of end-organ damage (**Table 37-1**).

Impaired autoregulation occurs in dogs with ischemic acute kidney failure and reduced renal mass. In normal dogs, the renal autoregulatory mechanism limits the effect of systemic blood pressure changes on renal blood flow and GFR. This protection is achieved by adjusting preglomerular resistance so that renal hemodynamics remain stable between mean systemic arterial blood pressures of 70 to 150 mm Hg. Dogs with severe reductions in functional mass have impaired renal autoregulation with elevations in renal arterial pressure. Impaired autoregulation may lead to renal injury during systemic hypertensive episodes and contribute to a progressive decline in kidney function (Brown et al, 1995; Polzin et al, 2005). Hypertension has been associated with increased risk of uremic crisis and death in dogs with CKD (Jacob et al, 2003).

Hyperphosphatemia and Secondary Renal Hyperparathyroidism

Hyperphosphatemia and secondary renal hyperparathyroidism have been incriminated as causes of progressive renal injury (Felsenfeld and Llach, 1993; Lumlertgul et al, 1986). Secondary renal hyperparathyroidism, characterized by increased PTH concentration, is an inevitable consequence of CKD (Nagode and Chew, 1992; Nagode et al, 1996; Barber and Elliott, 1998; Barber et al, 1999) (**Figure 37-5**). A study of cats with spontaneous CKD found an overall prevalence of secondary renal hyperparathyroidism of 84% (Barber and Elliott, 1998). Hyperparathyroidism was present in 100% of cats with endstage CKD and 47% of cats with biochemical evidence of CKD, but no clinical signs. Secondary renal hyperparathyroidism may be present based on increased PTH concentrations, even if serum phosphorus concentrations are within the reference range.

The inciting event in the pathogenesis of secondary renal hyperparathyroidism is phosphate retention (**Figure 37-6**). Destruction of nephrons decreases phosphorus filtration with a subsequent increase in serum phosphate, which stimulates PTH release from the parathyroid gland (Burkholder, 2000; Polzin et al, 2005). Hyperphosphatemia also decreases ionized calcium concentration, which stimulates PTH secretion. In a normal kidney and in early CKD, one effect of PTH is to decrease phosphate resorption in the proximal tubules so that

more phosphate is excreted and serum phosphorus concentration is maintained within the normal range. However, as CKD progresses and more nephrons become nonfunctional, a greater concentration of PTH is required to maintain serum phosphorus concentration and eventually hyperphosphatemia develops. The primary consequence of hyperphosphatemia is development and progression of hyperparathyroidism. Although hyperparathyroidism helps maintain serum phosphorus concentrations initially, it has other effects that may be harmful. PTH stimulates resorption and release of minerals (e.g., phosphate) from bone, which increases the amount of phosphate that remaining nephrons must excrete. Increased PTH concentration correlates with histologic evidence of renal tissue inflammation and mineralization; therefore, hyperparathyroidism may damage the kidneys (Finco et al, 1992, 1992a; Ross et al, 1982; Brown et al, 1991).

Chronic Renal Hypoxia

The kidney has a very high rate of oxygen consumption, the majority of which is expended reabsorbing sodium. With kidney damage, surviving nephrons increase sodium resorption and correspondingly increase oxygen consumption. The renal medulla concentrates urine by means of the countercurrent system of blood vessels and tubules that actively absorb sodium. The major determinant of medullary oxygen demand is the rate of active absorption in the medullary thick ascending loop, which is a relatively hypoxic environment. Hypoxia of the renal medulla can predispose to acute and chronic renal injury because the kidneys are extremely susceptible to hypoxic injury (O'Connor, 2006; Eckardt et al, 2005; Brezia and Rosen, 1995).

In CKD, increased fibrosis in the kidneys may result from intrarenal hypoxia due to increased oxygen consumption by surviving nephrons. Acute kidney injury often is associated with altered intrarenal microcirculation and oxygenation (Rosenberger et al, 2006). Hypoxia deprives tissues of energy and induces various regulatory mechanisms. The transcription factor, hypoxia-inducible factor, is involved in cellular regulation of development of new blood vessels, blood vessel tone, glucose metabolism and cell death. Kidney disease activates hypoxia-inducible factor, which presumably is renoprotective during oxygen deprivation (Eckardt et al, 2005). Hypoxia induces profibrogenic changes in proximal tubular epithelial cells and interstitial fibrosis (Norman and Fine, 2006). Hypoxia causes release of cytokines such as TGF-β and platelet derived growth factor, which stimulate intrarenal production of collagen. Furthermore, anemia may contribute to progression of CKD because anemia reduces oxygen delivery within the kidney, further promoting hypoxia and progressive renal damage (Rossert and Froissart, 2006).

A variety of mechanisms regulate medullary oxygen homeostasis; these include medullary vasodilators (e.g., nitric oxide, prostaglandin E_2, adenosine, dopamine and urodilatin) and vasoconstrictors (e.g., endothelin, angiotensin II and vasopressin). Tubuloglomerular feedback controls glomerular filtration and, indirectly, medullary oxygen demand. Reduced resorption of sodium activates signals that constrict the glomerulus, reducing glomerular filtration and subsequent delivery and resorption of sodium from the tubule. A related

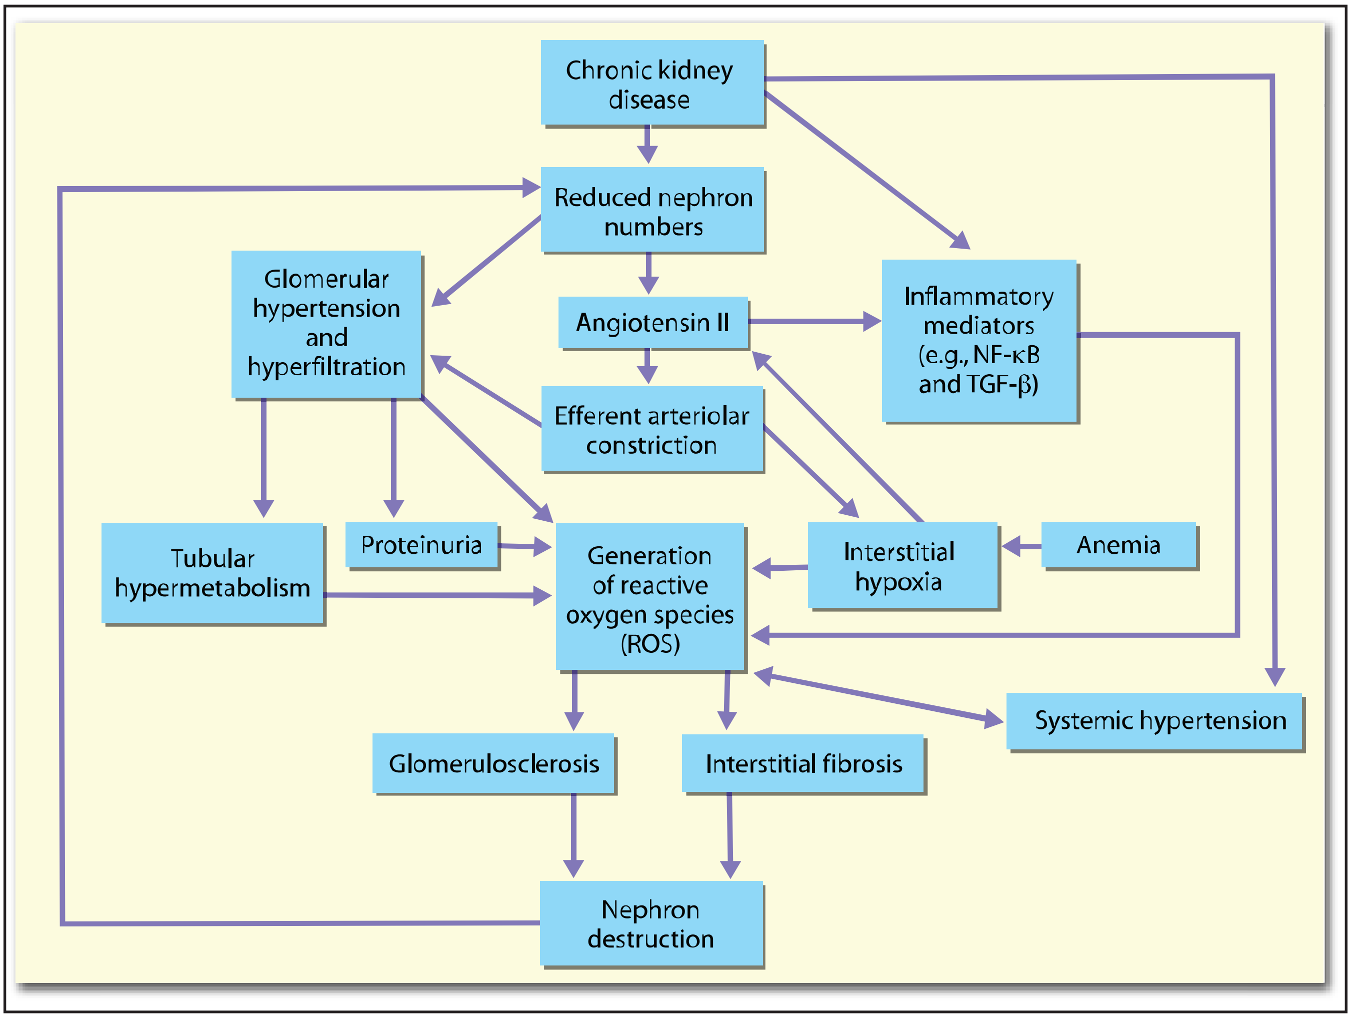

Figure 37-7. Increased generation of reactive oxygen species (ROS) occurs in chronic kidney disease and may play a role in disease progression. (Adapted from Brown SA. Oxidative stress and chronic kidney disease. Veterinary Clinics of North America: Small Animal Practice 2008; 38: 157-166).

reaction is shifting of the corticomedullary blood flow to the medulla when renal blood flow is reduced. Because the work of concentrating urine predisposes a patient to medullary hypoxic injury, reducing the need for concentration of urine may prevent medullary injury. Reducing transport activity protects medullary tubules from hypoxic injury. Dehydration, volume depletion and renal hypoperfusion stimulate urine concentration; avoiding these conditions reduces the work of urine concentration and stimulates intrarenal protective mechanisms, such as prostaglandin and dopamine production.

Renal Oxidative Stress

ROS are examples of free radicals that are produced at low levels by normal aerobic metabolism in the kidney (Brown, 2008). Examples of ROS produced in the kidney include hydrogen peroxide (H_2O_2), hydroxyl radical (OH), superoxide anion (O_2^-), lipid peroxy radicals, lipid and DNA hydroperoxides, hypochlorous acid and peroxynitrite. These ROS may damage proteins, lipids, DNA and carbohydrates, resulting in structural and functional abnormalities and progressive renal injury. Antioxidant defense mechanisms are designed to minimize damage by ROS including superoxide dismutase, catalase, nitric oxide synthase, glutathione peroxidase, vitamins E and C and carotenoids (Brown, 2008). Erythrocytes and albumin may also play important roles in minimizing oxidative injury to tissues (Agarwal, 2003; Brown, 2008; Rossert and Froissart, 2006). Erythrocytes represent a major antioxidant component of blood through enzymes such as superoxide dismutase, catalase and glutathione peroxidase. Also, erythrocyte glutathione reductase can regenerate reduced glutathione from its oxidized form (Rossert and Froissart, 2006).

Renal tissue damage occurs when production of ROS exceeds capacity of antioxidant defense mechanisms and is called renal oxidative stress (Brown, 2008). Oxidative damage has been incriminated as a cause of progressive renal injury in several types of kidney disease (Diamond et al, 1986; Agarwal, 2003; Vasavada and Agarwal, 2005; Brown, 2008) (**Figure 37-7**). In rats with remnant kidneys, increased oxygen consumption associated with increased dietary protein is accompanied by increased urinary clearance of oxidative products (Nath et al,

1994). The role of ROS in progressive renal injury has also been evaluated in studies using vitamin E and selenium-deficient diets (Nath et al, 1994). Vitamin E is a major scavenger of ROS in lipid bilayers and selenium is required for glutathione peroxidase activity. Glutathione peroxidase is the enzyme that degrades hydrogen peroxide. Deficiency of vitamin E or selenium favors hydrogen peroxide accumulation and its associated oxidative effects. Increased renal oxidative stress has been linked to proteinuria as a potential mediator of tubulointerstitial damage and to progression of CKD (Brown, 2008; Agarwal, 2003; Agarwal et al, 2004; Vasavada and Agarwal, 2005). Overloading tubular mechanisms for resorption of filtered albumin by proximal tubular cells can stimulate production of proinflammatory and profibrotic cytokines by activation of the redox-sensitive gene nuclear factor-κB thereby contributing to tubulointerstitial damage (Agarwal, 2003; Rossert and Froissart, 2006).

Hypokalemia

Several investigators have recognized an association between CKD and hypokalemia in cats (Lulich et al, 1992; Dow and Fettman, 1992; DiBartola, 1994). Hypokalemia occurred in 19% of cats with spontaneous CKD in one study and was moderate to severe in more than half (DiBartola et al, 1987). In cats with CKD and hypokalemia, renal function may improve after potassium supplementation and restoration of normokalemia, suggesting that hypokalemia may be associated with a reversible, functional decline in GFR. Renal function adversely affected normal cats when an acidified, low-potassium food was fed (Dow et al, 1990). In this study, potassium depletion and acidosis appeared to have additive effects on impairing renal function.

Limited evidence suggests; however, that hypokalemia is a cause of, and contributing factor to, CKD in cats rather than simply a consequence of the disease. In an uncontrolled study, renal lesions and dysfunction developed in three of nine cats fed a potassium-restricted, acidifying food for several months (DiBartola et al, 1993). However, it was not clear whether potassium depletion or hypokalemia preceded the onset of kidney disease. In another study, four of seven cats with induced CKD fed a food containing 0.3% dry matter (DM) potassium developed hypokalemia, but four cats with normal renal function fed the same food did not develop hypokalemia (Adams et al, 1993). Muscle potassium content is decreased in normokalemic cats with spontaneous CKD, indicating that a total body deficit of potassium may develop well before the onset of hypokalemia (Theisen et al, 1997). The latter findings support the concept that reduced renal function precedes the development of hypokalemia.

Metabolic Acidosis and Renal Ammoniagenesis

Metabolic acidosis appears to be a common complication of CKD in dogs and cats (DiBartola et al, 1987; Lulich et al, 1992; Jacob et al, 2002). In one report, six of 38 dogs with CKD had metabolic acidosis of sufficient severity to warrant treatment (Jacob et al, 2002). A cross-sectional study involving 59 cats with CKD showed that more than half of patients with severe CKD had acidemia and low plasma bicarbonate concentrations (Elliott et al, 2003, 2003a). These data also suggested that biochemical evidence of severe metabolic acidosis does not generally occur in cats until late in the course of CKD (Elliott et al, 2003). Patients with CKD tend to develop metabolic acidosis because of impaired ability of the failing kidneys to excrete the daily net acid load. The kidney eliminates hydrogen ions by three major mechanisms: reclaiming filtered bicarbonate, buffering secreted hydrogen ions with filtered phosphate and sulfate (titratable acidity) and renal ammoniagenesis. Of these three mechanisms, renal ammoniagenesis can be markedly upregulated to increase net acid secretion by the kidneys. As functional renal mass decreases in CKD, ammonia production per surviving nephron is increased several-fold, although total ammonia production is still reduced. Because ammonia is nonpolar, it diffuses into the tubular lumen and the surrounding interstitium.

Ammonia activates the alternate complement cascade, which may lead to renal injury by several mechanisms including: release of cytokines, prostanoids and ROS, cell lysis and stimulation of collagen synthesis. In studies involving rats, supplementation with bicarbonate reduced concentrations of complement components (i.e., C_3 and C_{5b-9}) (Nath et al, 1985). Bicarbonate administration also reduced cortical levels of ammonia, decreased proteinuria, reduced structural damage and improved tubular function. The interaction of ammonia and complement in the etiopathogenesis of tubulointerstitial disease has also been demonstrated in studies of hypokalemic nephropathy in rats (Nath et al, 1985). Studies in rats, however, failed to demonstrate a role for acidemia and increased renal ammoniagenesis as a cause of renal injury and progression of kidney disease (Throssell et al, 1995). In an investigation of cats with induced CKD, those fed an acidifying food for six months did not develop progressive glomerular dysfunction or renal tubulointerstitial injury vs. cats fed a non-acidifying food (James, 2001). Therefore the relative importance of renal ammoniagenesis in progressive renal injury in dogs and cats with CKD is unknown.

Lipid Disorders

Cholesterol, triglycerides and possibly some classes of lipoproteins are cytotoxic to endothelial cells and stimulate glomerular mesangial cell proliferation and production of excess mesangial matrix. Abnormalities of lipid metabolism in dogs with kidney disease generally include increased serum concentrations of total cholesterol, low-density lipoproteins and triglycerides (Brown et al, 1991). Cats with experimentally induced renal dysfunction demonstrate hypercholesterolemia compared with normal cats. Despite occurrence of lipid abnormalities in dogs and cats with CKD, there is little evidence to show they play a role in causing progression of disease.

Tubulointerstitial Changes

Endstage kidney disease is characterized by glomerulosclerosis, tubulointerstitial fibrosis and tubular atrophy (Wolf, 2006; Polzin et al, 2005). Tubulointerstitial changes are a consistent feature in CKD, irrespective of the cause or initial structure

Table 37-8. Potential etiopathogenic mechanisms in chronic kidney disease and therapeutic approaches for each.

Factors	Therapeutic approaches
Chronic renal hypoxia	Maintain hydration (increased water intake) Avoid excessive sodium intake ACE inhibitors Control anemia (erythropoietin)
Glomerular hypertension and hyperfiltration	Avoid excessive dietary protein and sodium Increased dietary omega-3 fatty acids ACE inhibitors
Hyperphosphatemia and secondary renal hyperparathyroidism	Limit dietary phosphorus Intestinal phosphate binders Calcitriol (after normophosphatemia is achieved)
Hypokalemia	Potassium supplementation
Metabolic acidosis	Avoid excessive dietary protein Alkalinizing foods (therapeutic renal foods) Alkalinizing agents (bicarbonate, potassium citrate)
Proteinuria	Avoid excessive dietary protein Increased dietary omega-3 fatty acids ACE inhibitors
Renal oxidative stress	Avoid excessive dietary protein, phosphorus and sodium Increased dietary antioxidants Omega-3 fatty acid supplementation
Systemic hypertension	Avoid excessive dietary sodium ACE inhibitors Calcium-channel antagonists (amlodipine)
Tubulointerstitial inflammation/fibrosis	Increased dietary omega-3 fatty acids Avoid excessive dietary phosphorus and protein

Key: ACE = angiotensin-converting enzyme.

involved (Eddy, 1994). The extent of tubulointerstitial injury correlates with the decline in renal function, whereas the severity of glomerular injury does not correlate well with progression of CKD models. It appears that GFR is influenced to a greater degree by interstitial fibrosis than by glomerulosclerosis (Nath, 1992).

Although chronic, progressive tubulointerstitial disease plays a critical role in progression of renal lesions, the basic mechanisms that generate the tubulointerstitial damage remain unclear. There appears to be a clinically silent acute phase that is characterized by inflammation and tubular cell injury. Possible mediators of tubular injury include antibodies, ROS, obstruction, complement and lysosomal enzymes (Eddy, 1994). Damaged tubular cells can regenerate or die. Factors responsible for recruitment of mononuclear cells to the interstitium are important because of evidence that monocytes and macrophages play a key role in interstitial fibrosis (Eddy et al, 1991). Recruitment is probably mediated by the release of fibrosis-promoting cytokines, such as TGF-β (Wolf, 2006). TGF-β directly stimulates transcription of many extracellular matrix genes in renal cells including mesangial, endothelial and tubular cells. TGF-β also appears to trigger increased matrix production by perivascular and interstitial fibroblasts. Dietary protein restriction inhibits secretion of TGF-β and glomerular scarring in rats with glomerulonephritis (Fukui et al, 1993). Furthermore, the renin-angiotensin-aldosterone system is linked to activation of the TGF-β pathway, which in turn promotes interstitial fibrosis (**Figure 37-7**) (Wolf, 2006).

Tubulointerstitial injury can impair renal function by a number of mechanisms: 1) vascular effects, 2) glomerular injury, 3) interstitial and tubuloepithelial processes, 4) nephron obstruction and 5) deposition of crystals (Nath, 1992). Postglomerular blood flow is decreased when the cortical interstitium expands due to fibrosis and mononuclear infiltration. Decreased blood supply also results from release of vasoactive cytokines, growth factors and ROS produced by the interstitial infiltrate and damaged tubules. Decreased postglomerular blood flow decreases tubular blood flow and changes glomerular size and pressure. Decreased tubular blood flow may impair tubular function and glomerular size and pressure changes may lead to glomerular injury (Nath, 1992).

As discussed above, abnormal glomerular function can incite tubulointerstitial injury (Diamond and Anderson, 1990). Loss of glomerular permselectivity and resultant proteinuria are accompanied by tubulointerstitial damage. Increased trafficking of protein in the proximal tubules may cause cellular damage. Filtered protein is endocytosed in the proximal tubules and subsequently degraded by lysosomal action. Excessive release of lysosomal enzymes may be one of the pathways for tubular damage. Tubular damage may also be induced by plasma proteins that have escaped into the urine. Incriminated plasma proteins include albumin, lipoproteins, complement components and transferrin. Studies in cats with spontaneously occurring CKD demonstrated that progression of CKD is most closely linked to severity of proteinuria, which may be explained by tubular damage during tubular resorption of leaked proteins (Syme et al, 2006; Jepson et al, 2007). Progression of spontaneously occurring CKD in dogs is also related to severity of proteinuria (Jacob et al, 2005).

Effects of Renal Aging

The kidney is one of the most vulnerable organs to age-associated changes. Renal changes associated with aging are manifested by significant structural and functional alterations. Functional changes include decreased GFR, decreased renal blood flow, decreased urine concentrating ability and decreased ability to maintain sodium, water, endocrine and acid-base homeostasis. Structural changes include alterations in renal weight, volume and histologic appearance. Fibroconnective tissue replaces functionally active parenchyma in aging kidneys. In a study of dogs with spontaneous glomerulonephritis, the incidence of interstitial nephritis increased with increasing age. Interstitial nephritis was present in 10% of dogs less than one year of age, in 60% of dogs between one and five years of age and in 85% of dogs more than five years of age (Muller-Peddinghaus and Trautwein, 1977). In another study, 59% of the dogs older than four years had evidence of interstitial nephritis (Shirota et al, 1979). Glomerular lesions were noted in 43 to 78% of these dogs. Based on these reports, interstitial

nephritis and glomerulosclerosis apparently are common and occur with increased frequency in aging dogs.

It is possible that CKD occurs as a consequence of life-preserving adaptive mechanisms that accompany the aging process (Lawler et al, 2006). A study of postmortem data collected from 1979 to 2001 revealed that of 676 cats living in a research colony, cats that died from kidney disease most often had renal histologic changes (i.e., progressive tubular deletion and peritubular interstitial fibrosis); however, their mean lifespan was longer than cats that died from other causes (Lawler et al, 2006). In addition, among cats that died from causes other than kidney disease, those with renal histologic changes had a longer mean lifespan compared with cats that had no changes in their kidneys. It was hypothesized that these renal changes may represent an intrinsic mechanism that is protective until the point of failure. Regardless of the initiating cause, CKD often is characterized by irreversible loss of renal functional mass. After a critical amount of kidney damage occurs, CKD tends to be a progressive condition that often terminates with uremia-associated death.

Key Nutritional Factors

The goals of managing patients with CKD are to: 1) control clinical signs of uremia, 2) minimize disturbances associated with fluid, electrolyte and acid-base balance, 3) support adequate nutrition and 4) modify progression of CKD (Polzin et al, 2005). Nutritional management plays a role in all of these goals and is indicated to address the etiopathogenic mechanisms that occur in CKD (**Table 37-8**). In addition, the use of an appropriately formulated commercial veterinary therapeutic renal food is the only treatment that has been shown in randomized, controlled clinical studies to prolong survival time and improve quality of life in dogs and cats with CKD (Polzin et al, 2009; Roudebush et al, 2009; Jacob et al, 2002, 2004; Ross et al, 2006). Therefore, nutritional intervention should be considered a critical component of managing patients with CKD.

When designing a therapeutic regimen for dogs and cats with CKD, it is helpful to consider a food's key nutritional factors. Recommended ranges of these key nutritional factors were determined by considering nutrient levels in foods evaluated in dogs and cats with naturally occurring CKD and experimentally induced kidney disease (**Table 37-9**). Although numerous studies have been published about dogs and cats regarding the benefits of various combinations of these factors, little work has been done to isolate effects of individual nutrients (Adams et al, 1993; Barber et al, 1999; Bovee, 1991; Brown et al, 1991, 1998, 2000; Burkholder, 2000; Burkholder et al, 2004; Elliott et al, 2000; Finco et al, 1985, 1992, 1992a, 1998; Jacob et al, 2002; McCarthy et al, 2001; Polzin et al, 1982, 1983, 1983a, 1984, 1991, 1991a, 2000; Robertson et al, 1986; Ross et al, 1982, 2006; Valli et al, 1991). Commercially available veterinary therapeutic foods for dogs and cats with CKD are usually designed with these key nutritional factors in mind. Compared with typical maintenance pet foods, appropriately formulated veterinary therapeutic foods for dogs and cats with CKD generally contain less protein, phosphorus and sodium and have increased fat, omega-3 fatty acids and buffering capacity. Feline renal foods contain increased potassium to help prevent hypokalemia. In addition to key nutritional factors, it is important to consider available evidence supporting effectiveness of specific veterinary therapeutic renal foods and other treatments for CKD (**Table 37-10**). Finally, individual patient needs and responses and owner preferences must be considered to design an optimal therapeutic regimen.

Table 37-9. Key nutritional factors for dogs and cats with chronic kidney disease.*

Factors	Dietary recommendations
Water	Parenteral fluid therapy if dehydration, blood volume contraction or renal hypoperfusion is clinically significant Offer water free choice at all times Recommend moist foods
Protein	14 to 20% in foods for dogs 28 to 35% in foods for cats
Phosphorus	0.2 to 0.5% in foods for dogs 0.3 to 0.6% in foods for cats
Sodium	≤0.3% in foods for dogs ≤0.4% in foods for cats
Chloride	1.5 x sodium levels in foods for dogs 1.5 x sodium levels in foods for cats
Potassium	0.4 to 0.8% in foods for dogs 0.7 to 1.2% in foods for cats If patient becomes hyperkalemic, switch to a lower potassium food
Omega-3 fatty acids	0.4 to 2.5% in foods for dogs and cats Omega-6:omega-3 fatty acid ratio of 1:1 to 7:1
Antioxidants	
Vitamin E	≥400 IU vitamin E/kg of food for dogs ≥500 IU vitamin E/kg of food for cats
Vitamin C	≥100 mg vitamin C/kg of food for dogs 100 to 200 mg vitamin C/kg of food for cats

*All values expressed on a dry matter basis, unless otherwise indicated.

Water

Kidney disease causes a progressive decline in urine concentrating ability, and maximal urine osmolality approaches that of plasma (300 mOsm/kg) (i.e., isosthenuria). As CKD progresses; these changes may be observed in patients with stage 1 CKD. If total solute excretion remains normal, but the maximal achievable urine osmolality decreases, obligatory water loss occurs to eliminate the osmolar load. This obligatory water loss may lead to development of polyuria. Compensatory polydipsia occurs to maintain fluid balance. Dehydration, volume depletion, renal hypoperfusion and dietary salt (sodium) intake stimulate urine concentration. Concentrating urine solutes represents "osmotic work" for the kidneys and represents a burden for diseased kidneys. Reducing the amount of solutes to be concentrated by decreasing dietary protein and sodium intake or by providing more water for the excretion of the same amount of solutes independently reduces the amount of osmotic work. Patients with CKD should have unlimited access to fresh water for free-choice consumption. If readily consumed by the patient, moist foods are preferred because their consumption gen-

erally results in increased total water intake compared with dry food consumption.

Protein

There is general consensus that avoiding excessive dietary protein intake is indicated to control clinical signs of uremia in dogs and cats with CKD; uremic signs most often occur in stage 4 disease but may be observed earlier (Polzin et al, 2005; Elliott et al, 2006). Many of the extrarenal clinical and metabolic disturbances associated with uremia are direct results of the accumulated waste products derived from protein catabolism. Early studies in laboratory animals showed rapid improvement when dietary protein was reduced (Klahr et al, 1983; Brenner, 1983). However, urea by itself does not account for all, if any, of the clinical signs of uremia. Serum urea nitrogen generally is considered to simply be a marker for other more important uremic toxins. Excessive dietary protein is catabolized to urea and other nitrogenous compounds that normally are excreted by the kidneys. And, as mentioned above, endogenous proteins will be degraded if amino acid intake is insufficient to maintain nitrogen balance. The goal of managing patients with CKD is to achieve nitrogen balance and limit accumulation of nitrogenous waste products by proportionally decreasing protein intake as renal function declines.

The role of decreased dietary protein intake is less clear in patients with CKD that do not have clinical signs of uremia (Polzin et al, 2005). Limiting protein intake has been advocated to slow progression of CKD on the basis of studies in rats, which revealed that excessive dietary protein consumption was associated with glomerular capillary hypertension and hyperfiltration (Brenner et al, 1982). Decreased dietary protein intake prevents these hemodynamic changes and preserves normal glomerular structure in rats (Brenner et al, 1982). The role of decreased dietary protein in delaying progression of CKD in dogs and cats is less clear and has been the subject of numerous studies and a topic of considerable debate (Polzin et al, 2000; Finco et al, 1998a) (**Box 37-1**).

Despite the lack of clarity about the effects of dietary protein on progression of CKD in dogs and cats, potential benefits should be considered. Decreased dietary protein intake inhibits secretion of TGF-β, a cytokine that may be involved in progression of kidney disease (Fukui et al, 1993). (See Etiopathogenesis of Chronic Kidney Disease, Tubulointerstitial Changes.) Decreased protein intake potentially reduces tubular hyperfunction by decreasing the renal acid load and decreasing renal ammoniagenesis. In general, protein metabolism is the major source of hydrogen ions. Consequently, avoiding excess dietary protein and decreasing endogenous protein catabolism for energy contribute markedly to the maintenance of acid-base balance (Relman et al, 1961). Primary dietary protein contributions to the renal acid load are from the sulfur-containing amino acids (methionine and cysteine). Animal proteins tend to be higher in sulfur-containing amino acids than plant protein sources. This is true whether the source of the animal pro-

Box 37-1. Role of Dietary Protein in Progression of Chronic Kidney Disease.

There has been considerable debate about the effects of dietary protein on the progression of chronic kidney disease (CKD) in dogs and cats. Studies that have attempted to evaluate the role of protein intake alone (vs. other nutrients such as phosphorus) have been conducted in dogs and cats with experimentally induced CKD (i.e., remnant kidney model or renal ablation); however, none have been performed in patients with naturally occurring disease. Feeding a veterinary therapeutic renal food, with decreased protein, significantly prolongs survival time, decreases uremic episodes and delays disease progression in dogs and cats with naturally occurring CKD. However, compared with typical maintenance pet foods, veterinary therapeutic renal foods have other features in addition to less protein (i.e., decreased phosphorus, increased fat, increased omega-3 fatty acids), which likely contribute to their effectiveness. When evaluating the evidence for or against limiting dietary protein intake, factors to consider include mechanism(s) by which protein may exert its effect(s), experimental design of previously conducted studies and appropriateness of the remnant kidney model as a predictor of what occurs in dogs and cats with naturally occurring CKD. Practically speaking, it's also important to consider what foods are readily available for patients with CKD.

When evaluating conclusions from reported studies, it is necessary to critically evaluate the research methods and results, which could affect interpretation of data. For example, in a study widely cited to support the position that feeding less protein is ineffective in slowing progression of kidney disease, some dogs in the high-protein groups, but not the low-protein groups, were supplemented with potassium citrate to correct metabolic acidosis observed with high dietary protein intake. Metabolic acidosis may contribute to renal injury by increasing renal ammoniagenesis and may increase renal oxygen consumption. Thus, conclusions regarding the effect of dietary protein on progression based on this study may be invalid because the study neutralized one mechanism by which protein may exert its beneficial effect. In the same study, some dogs developed "diet-related uremia" when they were abruptly switched to the high-protein food following renal ablation. Those dogs were removed from the study, which could have resulted in selecting for study dogs that were "resistant" to the effects of protein.

Another question that is not typically addressed in the debate on the effect of dietary protein intake on progressive renal injury is whether studies had sufficient statistical power. Before declaring that there is no treatment effect, it is useful to consider whether the group size studied was sufficient to detect an effect if one truly existed. At the conclusion of one frequently cited study, there were four dogs evaluated in the high-protein group, three dogs in the moderate-protein group and four dogs in the low-protein group. However, this study did not address the question of whether group sizes were adequate to support the conclusions made. Another study that did not show an effect of dietary protein levels on glomerular lesions in uninephrectomized dogs did mention low power in their study (i.e., power calculations of 15 and 20%). The authors indicated that factors responsible for the low power included small sample size and large inter-dog differences.

Finally, in evaluating the role of protein in CKD most veterinary investigators have used the remnant kidney model. Although this model eliminates some of the variability associated with clinical trials, it does not exactly mimic naturally occurring kidney disease and all conclusions drawn from this model may not be applicable to clinical patients. For example, in a study evaluating effects of different dietary protein levels in dogs with 75% nephrectomy, mean plasma creatinine concentrations during the four-year study ranged from 0.8 to 0.9 mg/dl in all diet groups; these values are much lower than expected in clinical patients with progressive CKD. Although it may be appropriate to conclude that feeding high levels of protein to dogs with 75% reduction in renal mass was not associated with a progressive decline in renal function, it would not be valid to state that similar dietary protein levels have the same effect in dogs with naturally occurring CKD. Several studies evaluating the role of dietary protein in limiting progression of CKD have been performed in dogs and cats that maintained stable renal function throughout the entire study period; the stable nature of renal dysfunction in such studies does not permit assessment of the role of dietary protein in limiting progression of CKD.

The Bibliography for **Box 37-1** can be found at www.markmorris.org.

tein is from food or catabolism of a patient's body tissue. Catabolism of a patient's protein stores can occur if insufficient energy (carbohydrates and fats) and/or protein are consumed. In the case of inadequate energy intake, the body's amino acids stores (tissue protein) are used for gluconeogenesis to meet glucose needs. Avoiding dietary protein excess, without imposing dietary protein deficiency can help limit the acid load imposed on patients with CKD (Burkholder, 2000).

Another potential benefit of limiting dietary protein is its effects on proteinuria. Results of studies in rats with experimentally induced nephrotic syndrome suggest that the permselective properties of the filtration barrier are altered as a consequence of increasing dietary protein intake, permitting albumin to cross the capillary wall more readily (Kaysen et al, 1984; Hutchison et al, 1987, 1990). In healthy dogs and in dogs with kidney disease, increasing dietary protein intake increases renal blood flow and GFR, which may increase filtration of plasma proteins through the glomerular membrane, resulting in proteinuria (Polzin et al, 1983a, 1984; Devaux et al, 1996; Bovee, 1991; Brown et al, 1992; Bovee et al, 1981). Proteinuria may result in direct mesangial cell toxicity, glomerular fibrosis and eventual glomerulosclerosis (**Figure 37-3**). Excessive albuminuria and abnormally filtered transferrin may lead to increased oxidative stress, which appears to be an important mechanism of progressive renal injury (**Figure 37-7**). (See Renal Oxidative Stress.) The end result of proteinuric-induced glomerulosclerosis and tubular damage is further loss of nephrons. This reduction of functional renal mass and subsequent increase in single-nephron GFR further increase proteinuria and progression of renal damage. The impact of varying dietary protein intake on glomerular hemodynamics and structure in dogs and cats with CKD is less certain; however, studies in dogs have shown that feeding a vet-

Box 37-2. Nutritional Management of Patients with Proteinuria.

Previously, it was recommended to estimate urinary protein loss and replace a similar amount by increasing dietary protein intake (e.g., supplementing with hard-boiled eggs) in patients with glomerular disease. This recommendation seemed prudent based on pathophysiologic rationale, but was not validated. Investigations in people and laboratory animals with protein-losing glomerulonephropathy indicate that reductions in dietary protein limit proteinuria and preserve serum albumin concentrations without impairing protein nutriture. The advisability of replacing persistent, severe renal protein loss has therefore been questioned.

Two studies have evaluated the effects of limiting dietary protein intake in dogs with X-linked hereditary nephritis, a glomerular disease that causes proteinuria. Male dogs have rapid progression of disease during the first year of life whereas females typically have stable disease characterized by proteinuria that may progress to advanced stages of CKD after five years of age.

In one study, effects of feeding a veterinary therapeutic renal food[a] were evaluated in male and female dogs with X-linked hereditary nephritis. One group of dogs was fed the therapeutic food with reduced protein (13.5% dry matter [DM]), phosphorus and sodium and the other group was fed a maintenance food (23% DM protein). Onset and progression of kidney disease were delayed and severity of glomerular basement membrane splitting was reduced in affected male dogs eating the commercial veterinary therapeutic renal food. In addition, these dogs lived 53% longer (362 ± 17 days vs. 239 ± 14 days) than dogs fed the regular maintenance food.

Effects of decreased dietary protein intake on proteinuria have also been studied in female dogs with heterozygous X-linked hereditary nephropathy. Dogs were blocked by urine protein-creatinine (UPC) ratios and randomly assigned to receive either a high-protein food (HP) (34.6% DM) or a veterinary therapeutic renal food[b] with less protein (LP) (14.1% DM). Phosphorus, sodium, chloride and potassium levels were essentially the same in both foods; the first three of these nutrients were decreased, relative to typical amounts in regular maintenance foods. The study was conducted using a three-period double-crossover design in which each dog served as its own control. Treatment periods 1 and 2 lasted 28 days each and treatment period 3 lasted 42 days. The groups were fed in HP-LP-HP or LP-HP-LP sequence. Proteinuria, as indicated by UPC ratios, was significantly decreased whenever the LP food was fed vs. when the HP food was fed (UPC 1.8 ± 1.1 vs. 4.7 ± 2.2; [$p < 0.0001$]). However, an unexpected result was that the dogs lost body weight when fed the LP food. Unfortunately, the energy content of the LP food was approximately 13 to 14% lower than that of the HP food due to energy digestibility differences between the two foods that were not determined until study completion. Whether or not the body weight loss was due to excessively low amounts of dietary protein or inadequate energy intake could not be determined.

On the basis of current evidence, dogs with protein-losing glomerulonephropathy should be fed reduced-protein foods designed for patients with kidney disease. Patients should be monitored periodically (e.g., every two to four weeks initially) to determine the optimal quantity of dietary protein. The food with reduced levels of dietary protein should continue to be fed if the magnitude of proteinuria declines (as measured by UPC ratios) without substantial evidence of protein malnutrition (i.e., stable or increasing serum albumin and total protein concentrations, stable body weight and body condition score). If evidence of protein malnutrition develops, dietary protein intake should be gradually increased in stepwise fashion while closely monitoring the patient.

Although proteinuria occurs in cats with CKD, glomerular disease is infrequently diagnosed. Feeding a veterinary therapeutic renal food may benefit cats with glomerular disease or proteinuria; however, this has not been studied.

erinary therapeutic renal food with decreased protein, before the onset of azotemia, has beneficial effects in dogs with proteinuria (Valli et al, 1991; Burkholder et al, 2004) (**Box 37-2**).

Effects of decreased dietary protein intake have been studied in dogs with induced CKD (Polzin et al, 1983; Finco et al, 1992a). In a 40-week study, dogs were fed a commercial veterinary therapeutic food[d] containing 8.2% DM protein, a commercial food[e] with 17.2% DM protein or a control food with 44.4% DM protein (Polzin et al, 1983). Feeding the lower protein foods was associated with reduced mortality, serum urea nitrogen concentrations and clinical signs of uremia. Throughout the study, all dogs fed the highest protein food had reduced physical activity and poorer hair quality compared with those parameters in dogs fed the lower protein foods. There were other nutrient differences between foods, which may have contributed to the beneficial effects observed. In another study conducted for two years, reduced dietary protein (16% DM) was not associated with a significant effect on mortality compared with feeding a food containing 32% DM protein (Finco et al, 1992a). Some differences in treatment in addition to nutritional management could have affected study outcome, however (**Box 37-1**).

Two studies evaluated effects of dietary protein on progression of induced CKD for one year in cats (Adams et al, 1993; Finco et al, 1998). In one study, renal function did not progressively decrease, regardless of dietary protein amount and caloric intake (Adams et al, 1993). However, remnant kidneys of cats with induced CKD that were fed a food containing 52% DM protein had significantly more severe glomerular and tubulointerstitial damage than cats with CKD that were fed a food containing 28% DM protein (Adams et al, 1993). Phosphorus amounts were similar between study groups (0.54% DM in the high-protein group and 0.61% DM in the low-protein group); however, cats in the high-protein group consumed significant-

ly more calories. Therefore, changes in renal morphology could have resulted from differences in protein and/or caloric intake. In the other study, no difference in renal function or glomerular lesions were found in cats consuming high-protein foods (52% DM) compared with lower protein foods (28% DM) (Finco et al, 1998). Phosphorus amounts were similar for all study groups (0.87 to 0.96% DM). There were mild and significant increases in cellular infiltrate and tubular lesions in cats that consumed more calories, but no differences were detected based on amount of dietary protein. The authors concluded that protein intake was not a risk factor for progression of renal lesions and that the practice of severe protein restriction was questionable. However, because renal function remained stable throughout both studies, it was not possible to assess the role of limiting dietary protein in decreasing progression of CKD.

Four clinical studies of cats or dogs with naturally occurring CKD compared effects of feeding a commercial veterinary therapeutic renal food with either a control or regular maintenance food that contained more protein (Harte et al, 1994; Elliott et al, 2000; Jacob et al, 2002; Ross et al, 2006). In a six-month study, mean serum creatinine and urea nitrogen concentrations progressively increased in 10 cats receiving more dietary protein (39.4% DM) and declined or remained stable in 25 cats that were fed a lower protein food[f] (25.2% DM) (Harte et al, 1994). In a non-randomized, prospective study, cats receiving a lower protein food[g] (22 to 24% protein) had significantly prolonged median survival time compared with cats that continued eating different maintenance cat foods with higher protein (48% DM) (Elliott et al, 2000). In a two-year study, cats eating a commercial veterinary therapeutic renal food[h] with 28 to 29% DM protein had no uremic episodes or renal-related deaths whereas 26% of cats in the control group consuming a food with higher protein (46 to 48% DM protein) had a uremic crisis and 22% died as a result of CKD (Ross et al, 2006). Finally, dogs receiving a commercial veterinary therapeutic renal food[e] with 14% DM protein had delayed time to onset of uremic crisis, slower decline in renal function and improved survival compared to parameters in dogs receiving a control food that contained 25% DM protein (Jacob et al, 2002). Based on these findings, it is clear that foods with less protein in these studies were associated with significantly improved quality and quantity of life in dogs and cats with naturally occurring CKD. However, because the protein amount was not the only nutrient difference between the veterinary therapeutic renal foods and comparison foods, it is not possible to conclude that limiting dietary protein alone was the sole reason for beneficial effects. **Box 37-3** provides detailed information about long-term studies that evaluated effects of veterinary therapeutic renal foods on survival time of dogs and cats with CKD.

In summary, limiting dietary protein intake is indicated to control clinical signs of uremia in dogs and cats with CKD. Although currently available evidence fails to support a recommendation for or against limiting dietary protein intake alone in non-uremic patients with CKD, there are potential benefits, assuming that patients maintain adequate caloric intake and body condition. Patients may be more likely to accept a change to a new food if it is offered before clinical signs of uremia occur and it may delay onset of uremic signs as CKD progresses (Polzin et al, 2005). On a practical note, it is difficult to achieve the degree of phosphorus restriction desired in veterinary therapeutic renal foods using typical ingredients without limiting the amount of dietary protein (Burkholder, 2000).

In regards to determining how much protein to recommend for dogs and cats with CKD, all patients should be monitored for signs of protein insufficiency and nutritional management adjusted to maintain ideal body condition (**Box 37-4**). For cats with CKD, the minimum dietary protein requirement identified in one study was 20% of calories (Kirk and Hickman, 2001); this translates to approximately 24% DM protein. Similar studies have not been reported for dogs. The minimum recommended allowances for DM dietary protein in foods for healthy adult dogs and cats are 10 and 20%, respectively (NRC, 2006). The minimum DM levels recommended by the Association of American Feed Control Officials are 18% for dog foods and 26% for cat foods (AAFCO, 2007). A report of the mean DM protein content of several popular U.S. grocery brand dog foods was 41.7% for moist foods and 25% for dry foods. For grocery brand cat foods it was 51.5% for moist foods and 35.1% for dry foods (Allen et al, 2000). The recommended range for DM protein levels in foods intended for most patients with CKD is 14 to 20% for dogs and 28 to 35% for cats. Foods with less protein may be needed to control signs of uremia in patients with more advanced CKD; in these patients, it's important to monitor for signs of protein deficiency. In addition to the amount of protein, patients with CKD should receive protein of high biologic value. The concept of ideal protein is useful when considering biologic value (Baker and Czarnecki-Maulden, 1991). Lysine is the limiting amino acid in practical foods for dogs and cats (Baker and Czarnecki-Maulden, 1991). However, experience with typical ingredients used in commercial veterinary therapeutic foods suggests that tryptophan is more frequently limiting. Therefore, based on the concept of ideal protein, foods that meet the requirement for lysine and tryptophan can be assumed to meet the requirement for all indispensable amino acids.

Phosphorus

Decreased dietary phosphorus intake is indicated in dogs and cats with CKD to limit phosphorus retention, hyperphosphatemia, secondary renal hyperparathyroidism (**Figures 37-8** and **37-9**) and progression of kidney disease (Polzin et al, 2005; Rutherford et al, 1977; Barber at al, 1999). The mechanism for the protective effect of limiting phosphorus intake is unknown. Possible factors include reduced nephrocalcinosis, suppression of hyperparathyroidism, reduced cellular energy metabolism and altered renal hemodynamics. It is possible that these mechanisms may synergistically contribute to the beneficial effects of lowering phosphorus intake.

Several studies evaluated effects of limiting dietary phosphorus intake in cats and dogs with induced kidney disease. In cats, high dietary phosphorus intake (1.56% DM phosphorus) for 65 to 343 days was associated with renal mineralization, fibrosis

Box 37-3. Summary of Studies Evaluating Effects of Veterinary Therapeutic Renal Foods on Survival in Dogs and Cats with Naturally Occurring Chronic Kidney Disease.

Numerous studies have evaluated effects of nutritional management of chronic kidney disease (CKD) in dogs and cats. Most were conducted using the remnant kidney model. Although we have learned valuable information from these studies, their findings may not be directly transferable to patients with naturally occurring disease. Three clinical studies evaluated the effects of commercial veterinary therapeutic renal foods on survival and quality of life in cats and dogs with CKD. Those studies are summarized below.

STUDY 1

Fifty cats with naturally occurring stable CKD were evaluated in a prospective study of the effects of feeding a dry or moist veterinary therapeutic renal food[a] compared with a maintenance food. The renal food contained 22 to 24% dry matter (DM) protein and 0.27 to 0.42% DM phosphorus whereas the maintenance food contained 48% DM protein and 1.9% DM phosphorus. Twenty-nine cats accepted the renal food and were assigned to the renal food group, whereas compliance (due to limited intake by the cats or owner resistance to diet change) was not achieved in the remaining 21 cats, which were assigned to the maintenance food group. Cats in the maintenance food group were fed commercial maintenance cat foods with varying amounts of fresh meat or fish. In all cases, the dietary regimens were considered appropriate for maintenance. At diagnosis, both groups of cats were matched in terms of age, body weight, plasma creatinine, phosphate, potassium and parathyroid hormone (PTH) concentrations, packed cell volume and urine specific gravity. Cats in the renal food group received their assigned food for an average of 86.6% of their survival time. Feeding the renal food was associated with a reduction in plasma phosphorus and urea nitrogen concentrations and prevented the increase in plasma PTH concentrations that occurred in the maintenance food group. Median survival time was significantly longer in the renal food group (633 days) compared with the maintenance food group (264 days). *Results of this study provide Grade III evidence for using this commercial veterinary therapeutic renal food to control secondary renal hyperparathyroidism and prolong survival time in cats with naturally occurring CKD.*

STUDY 2

Thirty-eight dogs with stable CKD (serum creatinine values between 2 and 8 mg/dl) were evaluated in a double-blinded, randomized, controlled prospective study to determine effects of feeding a commercial dry veterinary therapeutic renal food[b] compared with a control food formulated to represent the nutrient content of the 10 most popular selling grocery brand maintenance foods. The renal food contained 14% DM protein, 0.28% DM phosphorus and 1.6% DM omega-3 fatty acids, whereas the control food contained 25% DM protein, 1% DM phosphorus and 0.22% DM omega-3 fatty acids. At baseline, clinical and laboratory findings were similar between groups. At the end of the two-year study there were 17 dogs in the control group and 21 dogs in the renal food group. By the end of the study, 33% of dogs in the renal food group had developed uremic crises vs. 65% of dogs in the control group. Time to onset of uremic crises was significantly longer in the renal food group (615 days) compared with the control group (252 days). Feeding the renal food was associated with decreased progression of kidney disease and significantly prolonged median survival time (594 days) vs. the control group (188 days). As described elsewhere, feeding the renal food was associated with significantly improved health-related quality of life. *Results of this study provide Grade I evidence for using this commercial veterinary therapeutic renal food to decrease uremic episodes, delay onset of uremia and progression of kidney disease, increase survival time and improve quality of life in dogs with CKD.*

STUDY 3

Forty-five cats with stable CKD (serum creatinine values of 2.1 to 4.5 mg/dl) were evaluated in a double-blinded, randomized, controlled prospective study to determine effects of feeding a commercial dry and/or moist veterinary therapeutic renal food[c] compared with a control food that was similar to a typical adult maintenance cat food. The renal food contained 28 to 29% DM protein, 0.5% DM phosphorus, and 0.2 to 0.6% DM omega-3 fatty acids, whereas the control food contained 46 to 48% DM protein, 0.9 to 1% DM phosphorus and 0.2% DM omega-3 fatty acids. Cats were fed a combination diet (half renal food, half control food) for six weeks before random assignment to treatment groups; this was done to gradually transition cats to a new food. At the end of the two-year study there were 23 cats in the control group and 22 cats in the renal food group. Dietary compliance (defined as receiving >85% of daily caloric requirement from the assigned food) was excellent throughout the study; 91% of cats continued eating their assigned food. Four cats (two in each group) stopped eating due to nonrenal diseases. A significantly greater percentage of cats in the control group had uremic episodes (26%) compared with the renal food group (0%). There was significant reduction in deaths due to CKD in the renal food group; none of the cats receiving the renal food died during the study whereas 22% of cats in the control group died. *Results of this study provide Grade I evidence for using this commercial veterinary therapeutic renal food to decrease occurrence of uremic episodes and mortality in cats with CKD.*

Box 37-4. Dietary Protein Needs in Dogs and Cats with Chronic Kidney Disease and Maintenance of Lean Body Mass.

Minimum protein requirements for patients with chronic kidney disease (CKD) are assumed to be similar to those for healthy dogs and cats; however, this has not been well evaluated. Ten cats with CKD and nine healthy cats were fed foods (free choice) with different amounts of protein (16, 20 or 24% of calories as metabolizable energy [ME]) for four months. Body weight, lean body mass, nitrogen balance and laboratory parameters (hematocrit and serum concentrations of urea nitrogen, albumin and total protein) were measured to assess adequacy of dietary protein intake. Based on study findings, the authors concluded that the protein requirement for cats with CKD and healthy controls appeared to be approximately 20% ME, which is similar to results from previous studies that evaluated protein requirement in healthy cats.

The amount of protein contained in most commercially available veterinary therapeutic renal foods is more than adequate to meet minimum protein requirements of dogs and cats with CKD; however, there is a common perception that these foods are protein deficient. The terminology used to describe therapeutic foods formulated for management of kidney disease may encourage this perception. It may be more appropriate to refer to these foods as "formulated to avoid excessive protein" or "modified protein foods" instead of being "protein restricted", which may incorrectly be interpreted as protein-deficient by pet owners and health care team members.

Loss of lean body mass occurs in patients with kidney disease and may contribute to the perception that veterinary therapeutic renal foods do not contain adequate amounts of protein. Potential mechanisms for decreased lean body mass in dogs and cats with CKD include inadequate dietary protein or caloric intake, altered response to decreased protein intake, increased protein loss (e.g., proteinuria), metabolic acidosis and activation of cytokines by chronic inflammation. Failure to consume an adequate amount of calories may result in catabolism of muscle protein as a source of energy; this is one reason why veterinary therapeutic renal foods have relatively higher amounts of dietary fat. It is important to ensure adequate dietary protein intake; however, protein that is consumed in excess of the patient's needs is metabolized and used for energy, which could worsen clinical signs of uremia. Metabolic acidosis, a common complication of uremia, stimulates the degradation of branched-chain amino acids and proteins and blocks the ability of the patient to respond appropriately to lower protein intake. The specific mechanisms involve increased activity of branched-chain ketoacid dehydrogenase and the ubiquitin-proteasome proteolytic pathway. Besides acidosis, cytokines activate the ubiquitin-proteasome proteolytic pathway and cytokine release occurs with chronic inflammation. These potential mechanisms for loss of muscle mass emphasize the importance of controlling metabolic acidosis, infection and other stressors in patients with CKD.

Although some patients with CKD lose lean body mass, evidence supports that these patients can maintain body condition and weight while eating a veterinary therapeutic renal food. In a study of cats with induced CKD, those that consumed adequate calories of a low-protein food (28% dry matter protein; 20% protein as calories) maintained stable or increasing body weights, hematocrit values and serum albumin concentrations and had no clinical signs of protein-calorie malnutrition. In the absence of metabolic acidosis, dietary protein requirements did not appear to be different between cats with CKD and control cats with normal renal function. In another study of cats with naturally occurring CKD, mean body weight of the control group that received the higher protein food continued to decline, with most of the cats experiencing weight loss, compared with a mean weight gain in the group receiving a commercial veterinary therapeutic renal food with less protein. Although clinical condition (halitosis, gingivitis, appetite and body condition) deteriorated in both groups of cats, it was less apparent in the lower protein group based on observations by pet owners and veterinary clinical evaluations. The methods for assessing these observations were not indicated. In addition, packed cell volume, serum albumin and total protein increased in the lower protein group and decreased in the higher protein group. In another clinical study of cats with CKD that received either a veterinary therapeutic renal food or a typical maintenance food, no significant differences in body weights or hematocrit values were noted between groups at the midpoint of the study. In a randomized, double-blinded clinical study of cats with CKD managed by feeding either a veterinary therapeutic renal food or a control food (with higher protein), there were no significant differences in body weights or body condition scores at the midpoint and end of the two-year study.

In a double-blinded clinical study of dogs with naturally occurring CKD that received either a veterinary therapeutic renal food or a control food (with higher protein), health-related quality of life was determined using a content-validated questionnaire to obtain owner assessments. Nutritional status was assessed by periodic physical examinations and measurement of laboratory parameters. The renal food was superior to the control food for maintaining health-related quality of life and nutritional status; the renal food group remained stable based on body weights, body condition scores, hematocrit values and serum albumin concentrations.

It is highly likely that beneficial effects of feeding a veterinary therapeutic renal food are due to a combination of key nutritional factors (in addition to limited dietary protein). However, results of studies described above demonstrate that nutritional status can be maintained and quality of life improved in dogs and cats with CKD when fed a commercial veterinary therapeutic renal food containing less protein than typical adult maintenance pet foods. Regardless, all patients with CKD should be monitored for signs of protein-calorie malnutrition so that treatment can be adjusted to maintain body condition and improved quality of life.

and mononuclear cell infiltration whereas lower phosphorus intake (0.42% DM phosphorus) was not (Ross et al, 1982) (**Figure 37-10**). Progressive changes in GFR were not detected; however, in either the high- or low-phosphorus group. Effects of dietary phosphorus restriction were studied in dogs that were fed either a low-phosphorus (0.44% DM) food or a high-phosphorus (1.44% DM) food for 24 months (Brown et al, 1991). Both foods provided reduced amounts of protein (17% DM).

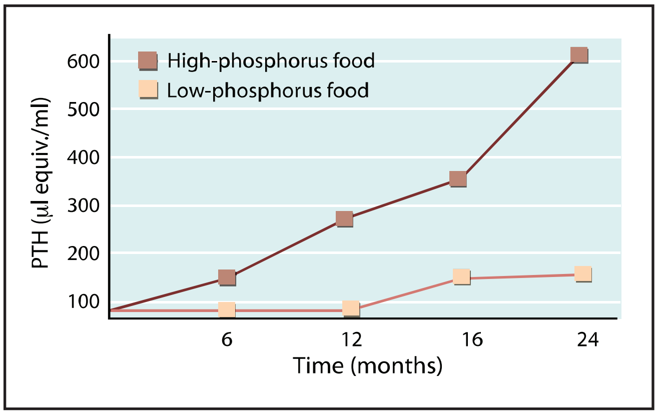

Figure 37-8. The effect of dietary phosphorus on serum parathyroid hormone (PTH) concentrations in dogs with experimentally induced kidney disease. Note that consumption of higher levels of phosphorus resulted in excessive PTH secretion. High phosphorus means dogs ingested 60 to 80 mg phosphorus/kg body weight/day, Low phosphorus means dogs ingested 15 to 40 mg phosphorus/kg body weight/day. (Adapted from Rutherford WE, Bordier P, Marie P, et al. Phosphate control and 25-hydroxycholecalciferol administration in preventing experimental renal osteodystrophy in the dog. Journal of Clinical Investigation 1977; 60: 332-341.)

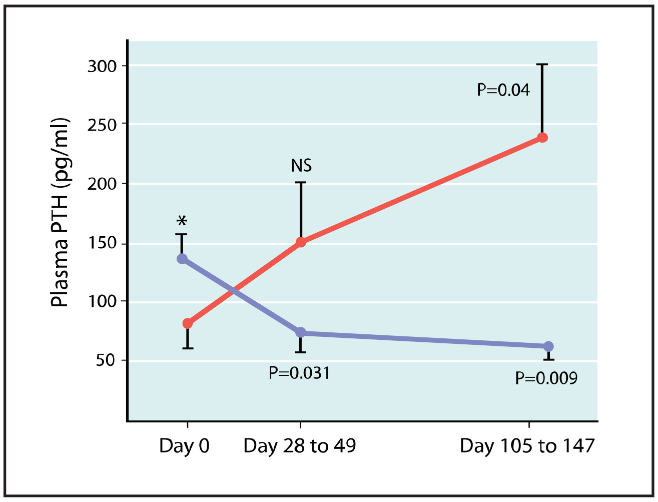

Figure 37-9. Plasma parathyroid hormone (PTH) concentrations in cats with chronic kidney disease that were fed either a veterinary therapeutic renal food with decreased phosphorus (blue line) (n=14) or a maintenance food with higher phosphorus (red line) (n=8). Results expressed as mean ± SEM. NS = not significant.
P values represent statistical significance of each value compared with pre-treatment value (Day 0).
*No significant difference between groups at baseline (Day 0).

Survival rate was significantly higher in the low-phosphorus group (75%) compared with the high-phosphorus group (33%) (**Figure 37-11**). Kidney function also deteriorated at a more rapid rate in the high-phosphorus group. Decrements of renal function were more closely related to nephrocalcinosis and tubulointerstitial lesions than to glomerular abnormalities (Brown et al, 1991). Specifically, in this study, progression and death were associated with interstitial fibrosis, tubular atrophy and dilatation and mineralization of cortical basement membranes, tubular epithelia and vascular and tubular lumina. The association of progression with tubulointerstitial lesions and nephrocalcinosis, however, does not necessarily establish a causal role for nephrocalcinosis. A similar study was conducted by investigators in the same laboratory to evaluate effects of dietary phosphorus restriction (0.48 vs. 1.46% DM) when a higher protein food (32% DM) was fed (Finco et al, 1992). In contrast to the previous study, improved survival was not observed in the group fed low-phosphorus food. An additional study compared the effects of feeding four foods of varying phosphorus and protein content (low phosphorus/low protein; high phosphorus/low protein; low phosphorus/high protein; high phosphorus/high protein) to four groups of dogs with CKD (remnant kidney model). In this study, survival was significantly increased by feeding either of the low-phosphorus foods (0.44 to 0.49% DM phosphorus) and was not affected by the amount of dietary protein (16.7 to 32% DM) (Finco et al, 1992a).

Beneficial effects of limiting dietary phosphorus intake, by feeding a veterinary therapeutic renal food, have also been demonstrated in cats and dogs with naturally occurring CKD (Elliott et al, 2000; Barber et al, 1999; Jacob et al, 2002; Ross et al, 2006). In one study, feeding a dry or moist veterinary therapeutic renal food[e] with low phosphorus (0.29 or 0.41% DM) was associated with significantly decreased plasma phosphorus and PTH concentrations compared with results from cats fed a typical maintenance food with higher phosphorus (1.9% DM) (Barber et al, 1999). In three additional studies, dogs and cats managed by feeding a veterinary therapeutic renal food with decreased phosphorus had significantly prolonged survival times compared with patients that were fed a higher phosphorus maintenance food (Elliott et al, 2000; Jacob et al, 2002; Ross et al, 2006) (**Box 37-3**).

The minimum recommended allowance for dietary phosphorus is 0.3% DM in foods for healthy adult dogs and 0.26% DM for healthy adult cats (NRC, 2006). The mean DM phosphorus contents of several grocery brand dog and cat foods were 1.39 and 1.54%, respectively (Allen et al, 2000). To achieve beneficial effects, the recommended phosphorus levels for foods used to manage CKD are 0.2 to 0.5% DM for dogs and 0.3 to 0.6% DM for cats.

Sodium and Chloride

As renal function deteriorates, fractional sodium excretion increases to maintain sodium balance and preserve extracellular fluid volume. The fractional excretion of sodium must change markedly to maintain sodium balance when dietary sodium intake changes (Klahr and Slatopolsky, 1973). Patients with decreased renal function can only vary sodium excretion over a limited range, which narrows progressively as GFR declines. Thus, patients with CKD may not tolerate excessively high or low dietary sodium levels. If excessive sodium is ingested, sodium retention with expansion of extracellular fluid volume can occur and produce or worsen preexisting hypertension, fluid

overload and edema. If sodium intake is inadequate, negative sodium balance develops with resultant declines in extracellular fluid volume, plasma volume and GFR. Also, excessive dietary sodium intake may increase the absorptive workload on surviving nephrons, increasing oxygen consumption and contributing to hypoxia and increased production of damaging ROS. (See Antioxidants below.)

Limiting dietary sodium intake has been recommended for patients with CKD because of its potential to help manage concomitant hypertension; however, this has not been critically evaluated in dogs and cats with CKD. Systemic hypertension has been reported in 9 to 93% of dogs and 19 to 65% of cats with CKD (Elliott et al, 2001; Syme et al, 2002; Brown et al, 2007). The mechanism for hypertension in renal parenchymal disease is not well understood. It has been postulated that reduced intrarenal blood flow activates the renin-angiotensin-aldosterone system, which leads to chronic expansion of the extracellular fluid and elevations in blood pressure. Other possible mechanisms include secondary renal hyperparathyroidism and reduced levels of renal vasodilators such as prostaglandins.

Kidney disease may cause hypertension, and the kidneys may suffer the consequences of uncontrolled hypertension. The mechanism by which hypertension damages the kidney is not completely understood (Klahr, 1989). Canine CKD patients with major reduction of functional renal mass have impaired renal autoregulation as evidenced by increased renal arterial pressure. Dysfunctional autoregulation may result in further renal damage during hypertensive episodes, which contribute to a progressive decline in kidney function (Brown et al, 1995). Dogs with surgically induced CKD with more pronounced hypertension had significantly lower GFR values, higher UPC ratios and increased renal lesions (Finco, 2004). Hypertension has been associated with increased risk of uremic crisis and death in dogs with naturally occurring CKD (Jacob et al, 2003). In cats with CKD, however, hypertension has not been associated with decreased survival (Elliott et al, 2001; Syme et al, 2006; Jepson et al, 2007). Based on other studies, increased dietary sodium intake has not been associated with increased blood pressure in healthy cats, dogs, cats with induced kidney disease, or cats with naturally occurring CKD (Buranakarl et al, 2004; Greco et al, 1994; Luckschander et al, 2004; Kirk et al, 2006).

Currently, the role of sodium intake in progression of CKD is a topic of considerable interest in human medicine and has been mentioned in dogs and cats with CKD (Polzin, 2007; Chandler, 2008). Sodium may be directly nephrotoxic and restricting sodium intake may be beneficial in CKD, independent of its effect on blood pressure (Cianciaruso et al, 1998; Ritz et al, 2006; Jones-Burton et al, 2006; Sanders, 2004; Weir and Fink, 2005; Verhave et al, 2004). Potential mechanisms for the negative effects of salt in patients with CKD include: 1) increased TGF-β expression in renal endothelial cells, which may lead to renal fibrosis, 2) increased oxidative stress and 3) increased proteinuria. Angiotensin II or increased dietary salt intake may independently increase production of TGF-β (Sanders, 2004). Increased production of TGF-β, in turn, results in increased renal oxidative stress by production of ROS

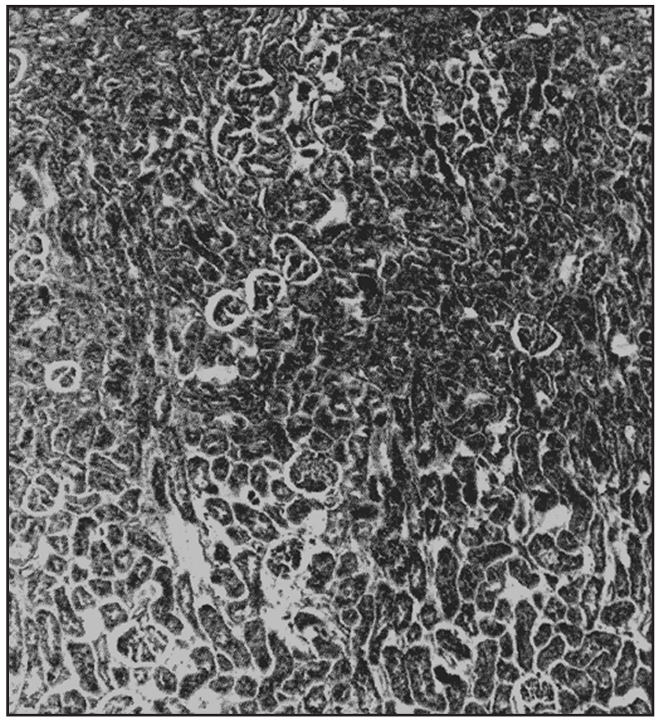

Figure 37-10. Photomicrographs of the renal cortex from cats with experimentally induced chronic kidney disease. (Above) Renal tissue from a cat fed a low-phosphorus food (0.42% DM phosphorus). Mineralized foci are not seen in this kidney (hematoxylin-eosin stain). (Below) Renal tissue from a cat fed a food with normal phosphorus levels (1.56% DM phosphorus). Mineralization (black foci), fibrosis and mononuclear cell infiltrates are extensive compared with that seen on a renal photomicrograph from a cat eating the lower phosphorus food (von Kossa's stain). American Journal of Veterinary Research 1982; 43: 1023-1026.)

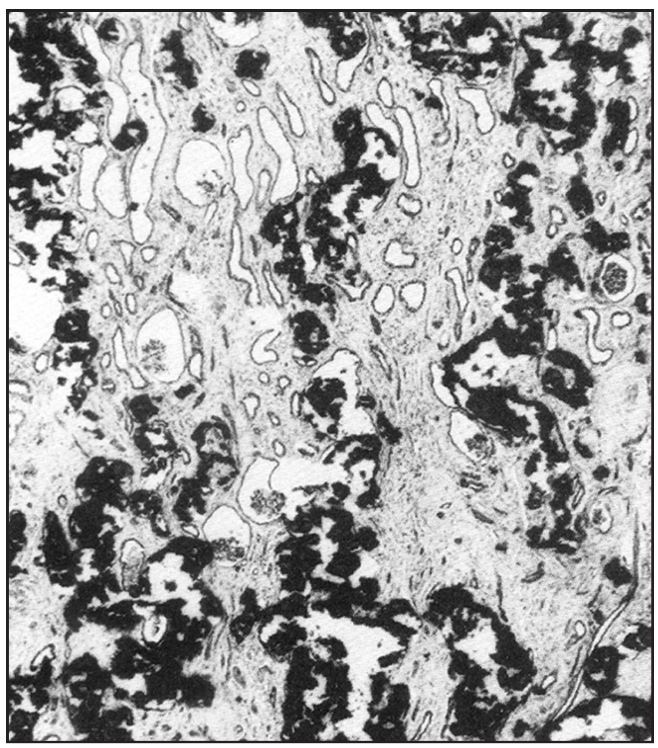

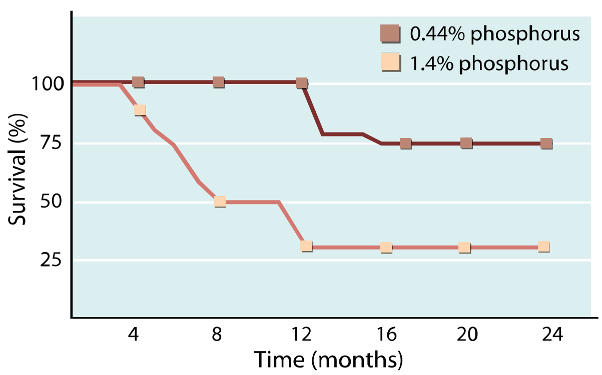

Figure 37-11. Survival of dogs with experimentally induced chronic kidney disease fed low-protein foods with different levels of phosphorus. Note that survival was much improved in dogs consuming the low-phosphorus food. (Adapted from Brown SA, Crowell WA, Barsanti JA, et al. Beneficial effects of dietary mineral restriction in dogs with marked reduction of functional renal mass. Journal of the American Society of Nephrology 1991; 1: 1169-1179.)

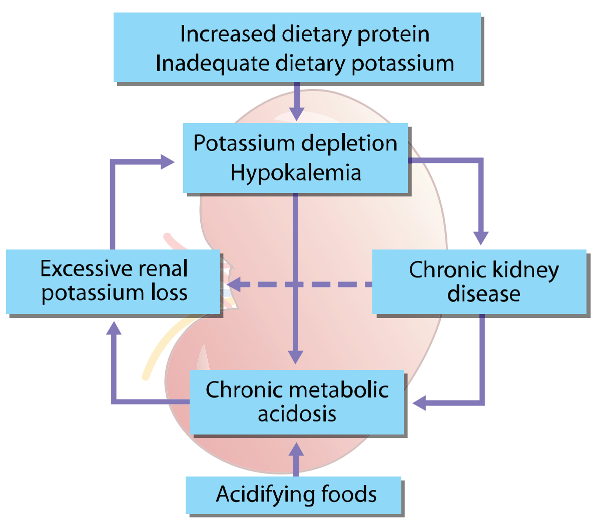

Figure 37-12. Proposed relationship between dietary potassium intake, excessively acidifying foods and feline chronic kidney disease.

(**Figure 37-7**). In human patients with CKD, the anti-proteinuric effect of angiotensin-converting enzyme (ACE) inhibition was strongly dependent on dietary sodium restriction; increased sodium intake virtually abolished the anti-proteinuric effect of the ACE inhibitor lisinopril (Heeg et al, 1989). Administration of ACE inhibitors has been associated with decreased proteinuria in dogs and cats (Grauer et al, 2000; King et al, 2006; Mizutani et al, 2006). The role of dietary sodium on beneficial effects of ACE inhibition has not been evaluated in dogs and cats; however, most patients in these studies were also fed veterinary therapeutic renal foods, which likely contained decreased amounts of sodium. Additional clinical studies are needed to evaluate the role of salt in progression of CKD; however, until results of such studies are available, it has been recommended that modest dietary avoidance of salt be encouraged in human patients with CKD, especially if they have hypertension and/or proteinuria (Jones-Burton et al, 2006).

The long-term effects of altering dietary sodium intake alone in cats and dogs with naturally occurring CKD have not been reported. Feeding veterinary therapeutic renal foods with decreased sodium (0.18 to 0.3% DM sodium in cats and 0.17% DM sodium in dogs) has been associated with increased survival time compared with feeding maintenance foods that contain more sodium (0.4 to 1.1% DM sodium in cats and 0.4% DM sodium in dogs) (Ross et al, 2006; Jacob et al, 2002; Elliott et al, 2000). Several reports describe short-term effects (seven days to six months) of feeding differing amounts of sodium on renal function in dogs and cats (Buranakarl et al, 2004; Greco et al, 1994; Luckschander et al, 2004; Kirk et al, 2006; Xu et al, 2009). In healthy adult cats (mean age = seven years), feeding foods containing 1.11% DM sodium was not associated with increased serum concentrations of urea nitrogen, creatinine or phosphorus, compared with feeding foods containing 0.55% DM sodium for six months (Xu et al, 2009). In this study, data from nine cats with serum creatinine values >1.5 mg/dl were evaluated; there were no significant differences between groups based on dietary sodium intake. Urine concentrating ability for these nine cats was not reported; however, mean urine specific gravity for all cats at the beginning of the study ranged from 1.049 to 1.053. In a study in cats with induced kidney disease, three different amounts of sodium (0.34, 0.68 and 1.35% DM) were fed for seven days (Buranakarl et al, 2004). Feeding the lowest amount of sodium was associated with increased urinary potassium loss and reduced GFR (Buranakarl et al, 2004). The effects of high salt intake (1.19% DM sodium) for three months were evaluated in six cats with naturally occurring CKD (azotemia with urine specific gravity <1.035) (Kirk et al, 2006). The CKD cats fed the high-salt food had significant and progressive increases in blood urea nitrogen, serum creatinine and serum phosphorus compared with results from cats consuming food with 0.37% DM sodium (Kirk et al, 2006). Two of the cats were removed from the study after beginning the high-sodium food due to decreased food intake; this did not affect results of statistical analysis or study conclusions.

A number of studies examined the interaction of dietary sodium with other ions, including chloride. The full expression of sodium chloride-sensitive hypertension in people depends on the concomitant administration of both sodium and chloride (Kurtz et al, 1987; Boegehold and Kotchen, 1989; Luft et al, 1990). In experimental models using rodents with sodium chloride-sensitive hypertension and in clinical studies with small numbers of hypertensive people, blood pressure and volume were not increased by a high dietary sodium intake provided with anions other than chloride. Furthermore, high chloride intake without sodium has less effect on blood pressure than does sodium chloride intake (Kurtz et al, 1987; Boegehold and Kotchen, 1989; Kotchen et al, 1981). The failure of non-chloride sodium salts to produce hypertension or hypervolemia may be related to their failure to expand plasma volume because the

renal tubular signal for renin release is responsive to renal tubular chloride (Boegehold and Kotchen, 1989; Luft et al, 1990; Kotchen et al, 1981, 1987). Chloride may also act as a direct renal vasoconstrictor (Boegehold and Kotchen, 1989). These findings suggest that both sodium and chloride are nutrients of concern in patients with hypertension and CKD.

Based on current information, dietary DM sodium intakes for patients with CKD are 0.3% or less for dogs and no more than 0.4% for cats. For comparison, the minimum recommended DM allowances for sodium in foods for healthy adult dogs and cats are 0.08 and 0.096%, respectively (NRC, 2006). The mean sodium levels in several moist grocery brand dog foods were 0.87% DM and 0.9% DM in moist cat foods, although some moist foods contain more sodium. In contrast, dry foods contained approximately half those amounts (Allen et al, 2000). The minimum recommended allowances for chloride for foods for healthy adult dogs and cats are 1.5 times the recommended sodium levels (NRC, 2006). That same factor is suggested for chloride content of foods for canine and feline CKD patients. Some patients may have obligatory urinary sodium losses and abruptly changing these patients to a low-sodium food may result in dangerous contraction of the extracellular fluid volume. Therefore, it is recommended that dogs and cats with CKD be gradually transitioned to foods with reduced amounts of sodium.

Potassium

Cats with CKD appear to be particularly predisposed to disorders in potassium homeostasis (**Figure 37-12** and **Case 37-3**). Decreased dietary potassium intake due to inappetence or vomiting and increased urinary losses due to polyuria can contribute to hypokalemia in CKD. Hypokalemia (potassium values <3.5 mEq/l) has been reported to occur in 19 to 20% of cats with CKD and was moderate to severe (potassium <3.1 mEq/l) in more than half of the cases in one study (DiBartola et al, 1987; Elliott and Barber, 1998). Conversely, hyperkalemia was observed in 9 to 13% of these cats. Hyperkalemia was observed in oliguric and polyuric kidney disease and was most common (22%) in cats with endstage CKD.

Potassium depletion leads to functional and morphologic changes in the kidneys of dogs and cats. Functional changes include reduced GFR and urine concentrating ability. Chronic potassium depletion stimulates renal ammonia synthesis. In hypokalemic rats, increased renal ammoniagenesis contributed to chronic lymphoplasmacytic tubulointerstitial nephritis (Nath et al, 1985). Studies in cats demonstrated that potassium depletion may result from feeding acidifying foods that are high in protein and low in potassium. CKD was observed in three of nine adult cats fed a food high in protein (40% DM) and low in potassium (0.32% DM) content for two years. Lymphoplasmacytic interstitial nephritis and interstitial fibrosis were detected in these cats and in two other cats without laboratory abnormalities (DiBartola et al, 1993).

The minimum recommended allowances for foods for healthy adult dogs and cats are 0.4% DM, and 0.52% DM, respectively (NRC, 2006). The potassium requirement for cats is proportional to the protein content of the food. Using purified foods, 0.3% potassium was required for growth in kittens fed a 33% protein food; however, 0.5% potassium was required with a 68% protein food (Hills et al, 1982). Acidifying foods and chronic metabolic acidosis may contribute to hypokalemia (**Figure 37-12**) (Dow et al, 1990).

The recommended range for potassium for foods for dogs with CKD is 0.4 to 0.8% DM and for cats 0.7 to 1.2% DM. For cats with hypokalemia, oral supplementation with potassium gluconate should be considered if diet alone does not maintain serum potassium concentration above 4.0 mEq/l (Polzin, 2007). Oral administration is safest and is the preferred route unless a critical emergency exists or if oral administration is impossible or contraindicated. Oral potassium gluconate appears to be tolerated well; the initial recommended dose is 2 to 6 mEq potassium gluconate/cat/day, depending on the size of the cat and severity of clinical signs. The potassium gluconate dose should be adjusted based on clinical response and serial analyses of serum potassium concentration. During initial treatment, serum potassium concentration should be checked every two to four days. Later, serum potassium should be checked every two to four weeks. Additional studies are needed to determine whether routine potassium supplementation is indicated in all cats with CKD, regardless of serum potassium concentration (Polzin et al, 2000).

Omega-3 Fatty Acids

The specific dietary fatty acid content of a food can influence progression of CKD by affecting: 1) renal hemodynamics, 2) platelet aggregation, 3) lipid peroxidation, 4) systemic blood pressure, 5) proliferation of glomerular mesangial cells and 6) plasma lipid concentration. Appropriate levels of omega-3 (n-3) fatty acids (e.g., eicosapentaenoic acid [EPA] and docosahexaenoic acid) in foods compete with arachidonic acid in several ways to alter eicosanoid production. These alterations are considered to be renoprotective (Brown et al, 1998).

Specific ingredients (e.g., menhaden fish oil) contain increased levels of omega-3 fatty acids; therefore, animals fed menhaden fish oil have decreased levels of 2-series eicosanoids, which are normally derived from arachidonic acid, and increased levels of 3-series eicosanoids, derived from omega-3 fatty acids. The 3-series eicosanoids are less potent at inducing vasoconstriction and platelet aggregation than the 2-series eicosanoids. Saturated fatty acids found in animal fat do not serve as precursors for eicosanoid production.

In dogs with a remnant kidney model of CKD, dietary omega-3 fatty acid supplementation reduced proteinuria, prevented glomerular hypertension and decreased production of proinflammatory eicosanoids (Brown et al, 1998, 2000). Dietary fat composition altered the rate of CKD progression in dogs following 15/16 nephrectomy (**Figure 37-13**). A low-fat food (<1% DM fat) was supplemented with one of three different fat sources (menhaden fish oil, beef tallow or safflower oil) to achieve a total DM fat concentration in the food of 15%. Dogs were assigned to dietary treatment two months following nephrectomies and followed for 20 months. Compared with

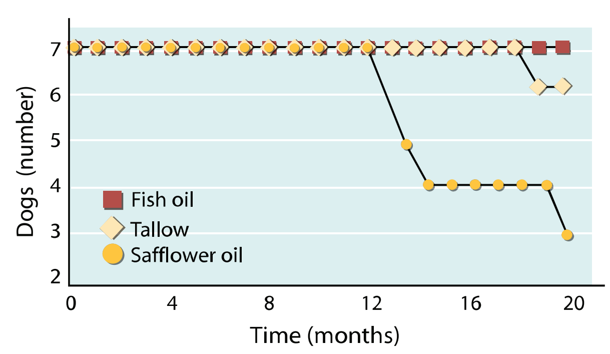

Figure 37-13. Survival of dogs with experimentally induced chronic kidney disease fed foods with three different fat sources (fish oil, tallow, safflower oil). Note that survival was increased in those dogs consuming foods with either tallow or fish oil compared to safflower oil. Dietary fatty acid composition appears to affect hemodynamic adaptations to renal disease in dogs. (Adapted from Brown SA, Brown CA, Crowell WA, et al. Dietary lipid composition alters chronic course of canine renal disease (abstract). Journal of Veterinary Internal Medicine 1996; 10: 168.)

the other two groups, the group receiving the food supplemented with safflower oil had greater glomerular enlargement and mean glomerular capillary pressure. Dietary fatty acid composition appeared to alter hemodynamic responses to renal insufficiency. Final mean exogenous creatinine clearance was 1.3 ml/min./kg body weight for the menhaden fish oil group, 0.9 ml/min./kg body weight for the beef tallow group and 0.5 ml/min./kg body weight for the safflower oil group. Mean UPC ratios were 0.6 in the menhaden fish oil group, 1.5 in the beef tallow group and 2.1 in the safflower oil group. Survival was similar in groups receiving menhaden oil and beef tallow; however, four of seven dogs in the safflower oil group were euthanized. In other studies in dogs with a remnant kidney model of CKD, dietary supplementation with either omega-3 fatty acids or antioxidants was renoprotective and their effects were additive when used together (Brown, 2008).

However, in normal and CKD dogs fed foods supplemented with safflower and menhaden fish oil, the oil supplement had no significant effect on the ratio of urinary eicosanoids (Crocker et al, 1996). The ratio of the urinary eicosanoids thromboxane B_2 (a stable urinary metabolite of thromboxane A_2) and prostaglandin E_2 has been used as an index of renal vascular tone in normal and CKD dogs. Failure to demonstrate a change in the ratio may be related to the length of the washout period (three weeks) and uncertain stability of lipid supplements in this study.

A retrospective CKD study was conducted to evaluate survival times in 146 cats fed one of seven commercial veterinary therapeutic renal foods, compared with survival times in 175 cats fed regular maintenance foods (Plantinga et al, 2005). The median survival time for cats fed maintenance foods was seven months whereas the median survival time for cats fed veterinary therapeutic renal foods was 16 months. The group with the longest median survival time (23 months) was fed the food with the highest reported content of EPA. However, because of study design and differences between groups (e.g., age of cats, plasma creatinine concentrations) and foods (e.g., potassium, phosphorus) used, it is not possible to conclude that differences in survival times were due to increased amounts of EPA. In addition, EPA content was not determined for all foods used in the study.

Although the recommended amount of omega-3 fatty acids for foods for CKD patients has not been definitively determined, the amounts in the aforementioned studies in dogs (Brown et al, 1998, 2000; Brown, 2008) ranged from 0.41 to 4.37% DM. With a 5:1 omega-6:omega-3 fatty acid ratio, the lower end of the range (0.41%) was effective in reducing the magnitude of glomerular hypertension and renal generation of inflammatory eicosanoids (Brown, 2008). The omega-6:omega-3 ratio was not reported in the earlier studies (Brown et al, 1998, 2000). To date, studies like these have not been done in cats but it seems likely that similar levels would be effective. Based on results of canine studies described above, the recommended range for total omega-3 fatty acid content in foods for canine and feline CKD patients is 0.4 to 2.5% DM. Until there is definitive work, a somewhat broad range for the omega-6:omega-3 fatty acid ratio is recommended (1:1 to 7:1). These recommendations are similar to omega-3 fatty acid content and omega-6:omega-3 ratios recommended for dogs and cats with cancer, osteoarthritis and inflammatory skin diseases.

Dietary omega-3 fatty acid supplementation in combination with antioxidants (See Antioxidants below.) can further reduce renal oxidant injury. In a study in dogs with the remnant model of CKD, dietary supplementation with omega-3 fatty acids and antioxidants (vitamin E, carotenoids and lutein), both were independently renoprotective; when combined, their effects were additive (Brown, 2008). In this model, addition of antioxidants reduced proteinuria, glomerulosclerosis and interstitial fibrosis independent of the ratio of dietary omega-6 to omega-3 fatty acids (Brown, 2008).

Antioxidants: Vitamins E and C

Oxidative damage is a component in the progression of renal injury in several types of kidney disease (**Figure 37-7**) (Diamond et al, 1986; Agarwal, 2003; Vasavada and Agarwal, 2005). Unquenched ROS may damage proteins, lipids, DNA and carbohydrates, resulting in structural and functional abnormalities and progressive renal injury. Renal oxidative stress occurs when production of ROS exceeds quenching capacity of antioxidant defense mechanisms (Brown, 2008). As previously discussed (See Etiopathogenesis above.), increased renal oxidative stress has been linked to proteinuria as a potential mediator of tubulointerstitial damage and to progression of CKD (Brown, 2008; Agarwal, 2003; Agarwal et al, 2004; Vasavada and Agarwal, 2005). Specifically, overloading tubular mechanisms for resorption of filtered albumin by proximal tubular cells can stimulate production of proinflammatory and profibrotic cytokines by activation of the redox-sensitive gene nuclear factor-κB thereby contributing to tubulointerstitial damage (Agarwal, 2003; Rossert and Froissart, 2006).

Numerous antioxidant defense mechanisms are designed to

minimize damage by ROS including several nutritional antioxidants: vitamins E and C and carotenoids (Brown, 2008). Supplementation of foods with these antioxidants has been evaluated in dogs and cats with naturally occurring CKD. In a canine study, 10 patients with CKD (IRIS stage 2 to 3) and 10 healthy dogs were evaluated to determine effects of supplementation of vitamins E (1,200 IU/kg DM) and C (150 mg/kg DM), and β-carotene (1.6 mg/kg DM) in a dry veterinary therapeutic renal food (Yu et al, 2006). Levels of vitamins E and C and β-carotene in the control food were not reported. The antioxidant supplementation reduced oxidative stress as measured by significantly reduced plasma malondialdehyde concentration. The antioxidant-supplemented renal food significantly reduced serum creatinine concentration and resulted in increased body weight and activity (eight of 10 dogs) in the CKD dogs compared with dogs receiving the unsupplemented commercial maintenance-type food (Yu et al, 2006).

Similarly, effects of antioxidants on renal oxidative stress were studied in 10 cats with CKD compared with healthy cats (Yu and Paetau-Robinson, 2006). Supplementation of vitamins E (742 mg/kg DM) and C (84 mg/kg DM) and β-carotene (2.1 mg/kg DM), compared with the control food containing 166 mg/kg DM vitamin E, less than 5 mg/kg DM vitamin C and 1.4 mg/kg DM β-carotene, resulted in reduced markers of oxidative injury. Antioxidant supplementation significantly reduced DNA damage in cats with CKD as evidenced by reduced serum 8-hydroxy-2'-deoxyguanosine (8-OHdG) and comet assay parameters (Yu and Paetau-Robinson, 2006). Based on these studies, supplementation with vitamins E and C and β-carotene as antioxidants may benefit dogs and cats with CKD.

Dietary supplementation with antioxidants in combination with increased omega-3 fatty acids (discussed above) reduces renal oxidant injury. Supplementation with vitamin E suppressed renal oxidative stress in rats with 5/6 nephrectomy (Tain et al, 2007). Also, as mentioned above in dogs with a remnant kidney model of CKD, dietary omega-3 fatty acid supplementation reduced proteinuria, prevented glomerular hypertension and decreased production of proinflammatory eicosanoids (Brown et al, 1998, 2000). In other studies in dogs with a remnant kidney model of CKD, dietary supplementation with omega-3 fatty acids and antioxidants (vitamin E, carotenoids and lutein) both independently were renoprotective and their effects were additive when used together (Brown, 2008). In this model, addition of antioxidants reduced proteinuria, glomerulosclerosis and interstitial fibrosis independent of the ratio of dietary omega-6 polyunsaturated fatty acids to omega-3 polyunsaturated fatty acids (Brown, 2008).

The DM requirement of vitamin E in foods for adult dogs is 30 IU/kg (NRC, 2006). An upper limit of 1,000 to 2,000 IU/kg food DM has been suggested for dogs (AAFCO, 2007). One antioxidant biomarker study in dogs indicated that for improved antioxidant performance, foods should contain at least 500 IU vitamin E/kg DM (Jewell et al, 2000). Besides helping to prevent chronic diseases associated with oxidative stress, increasing dietary intake of vitamin E, up to 2,010 mg/kg food DM in older dogs improved immune function (Hayes et al, 1969; Hall et al, 2003; Meydani et al, 1998). Based on the above studies, foods for canine CKD patients should contain at least 400 IU vitamin E/kg DM and higher levels are probably better. In one report, dietary supplementation of food for dogs with induced CKD, 5 IU/kg body weight was effective; this amount translates to approximately 450 IU/kg food DM (Brown, 2008).

The minimum recommended allowance of vitamin E in foods for healthy adult cats is 38 IU/kg DM (NRC, 2006). No safe upper limit has been established for cats. One antioxidant biomarker study suggested that cat foods should contain 600 IU/kg DM for improved antioxidant function (Jewell et al, 2000). A study in aged cats showed that increasing dietary intake of vitamin E to 272 and 552 IU/kg of food DM improved immune function (Hayes et al, 1969; Hall et al, 2003). Based on these data and studies in cats with CKD discussed above, foods for cats with CKD should contain at least 500 IU/kg DM and, as with dogs, higher levels are probably better. Foods high in polyunsaturated fatty acids (e.g., those containing fish oils), may require increased amounts of vitamin E (four or more times levels in typical foods) to prevent steatitis (NRC, 2006).

Healthy dogs can synthesize required amounts of vitamin C for normal maintenance conditions (Innes, 1931; Naismith, 1958; Chatterjee et al, 1975) and they can rapidly absorb supplemental vitamin C (Wang et al, 2001). However, in vitro studies indicate that dogs and cats have from one-quarter to one-tenth the ability to synthesize vitamin C as other mammals (Chatterjee et al, 1975). Foods for canine and feline CKD patients should contain at least 100 and 100 to 200 mg vitamin C/kg DM, respectively. This recommendation is based on the aforementioned vitamin E levels in foods for dogs and cats with CKD and data indicating that vitamin C regenerates vitamin E at about a 1:1 molar ratio (Barclay et al, 1985). This range is not a risk factor for urinary oxalate production in cats (Yu and Gross, 2005).

Other Nutritional Factors

β-carotene

β-carotene is a carotenoid like lutein and lycopene. As mentioned above, the carotenoids have antioxidant properties. β-carotene can be absorbed by dogs and cats. β-carotene is also a precursor for vitamin A. Dogs, but not cats, are able to convert β-carotene to vitamin A. β-carotene can be pro-oxidant at high levels in people and laboratory animals (Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study Group, 1994). β-carotene values in foods typically are difficult to obtain from manufacturers. For these reasons, at this time, β-carotene is not considered a key nutritional factor for foods for dogs or cats with CKD.

Acidifiers and Buffers

Metabolic acidosis is a common finding in patients with CKD. Decreased venous blood pH and plasma bicarbonate or total CO_2 concentrations are common, particularly in cats

with uremic signs or endstage disease (Lulich et al, 1992; Elliott and Barber, 1998; Elliott et al, 2003, 2003a). The kidneys play an important role in regenerating bicarbonate and excreting dietary acids, which may be derived from several sources. Sulfuric acid is formed when sulfur-containing amino acids (i.e., methionine and cysteine) are oxidized to sulfate. In general, animal-source proteins are higher in sulfur-containing amino acids than are plant-source proteins. Exogenous- and endogenous-source proteins are equally important. Insufficient energy intake results in protein catabolism and increased hydrogen ion production. Urinary urea production and total urinary hydrogen ion excretion are directly proportional. Organic acids are produced from partial oxidation of carbohydrates, fats, proteins and nucleic acids. Phosphoric acid can be ingested in the food or it can be produced endogenously. Phosphoric acid is used in some cat foods as a palatability enhancer, either separately or as a component of topically applied animal digests. Phosphoric acid can be derived from hydrolysis of phosphate esters in proteins and nucleic acids, if they are not neutralized by mineral cations (e.g., sodium, potassium and magnesium). The contribution of dietary phosphate to acid production depends on the type of protein ingested. Some proteins generate phosphoric acid, whereas others generate only neutral phosphate salts. Hydrochloric acid is generated when positively charged cationic amino acids (e.g., lysine and arginine) are broken down into neutral products.

Some commercial veterinary therapeutic renal foods are formulated with combinations of ingredients that will alkalinize the urine and blood, which minimizes dietary acid load (Burkholder et al, 2000). These foods are limited in protein ingredients, particularly those that are high in sulfur-containing amino acids. For patients with CKD, the serum total CO_2 should be maintained within the reference range for healthy patients. Ideally, blood gas analysis should be done to more accurately confirm the presence of metabolic acidosis. As CKD progresses and acidosis becomes more severe, alkali therapy (e.g., sodium bicarbonate, potassium citrate) should be considered in addition to nutritional management. Although urinary pH may be used as an indirect assessment of acid/base status, monitoring venous blood gases is a more sensitive method to evaluate effectiveness of alkalinization therapy.

Vitamin D
Calcitriol (1,25-dihydroxyvitamin D) plays an important role in the pathogenesis of secondary renal hyperparathyroidism. Patients with severe CKD have decreased circulating levels of 1,25-dihydroxyvitamin D because of decreased synthesis by the kidney. Hyperphosphatemia and the progressive loss of renal epithelial cells inhibit conversion of 25-hydroxyvitamin D to calcitriol by renal 1-α-hydroxylase. At earlier stages of CKD, circulating levels of 1,25-dihydroxyvitamin D may be normal due to the compensatory effect of increased concentrations of PTH on renal 1-α-hydroxylase activity and tubular synthesis of 1,25-dihydroxyvitamin D.

Calcitriol is an important regulator of parathyroid chief-cell function. Calcitriol acts by decreasing PTH messenger RNA expression, increasing expression of vitamin D receptors and controlling the "set point" of chief cells, which determines responsiveness to negative feedback by ionized serum calcium concentrations. Decreased circulating calcitriol levels in CKD lead to chief-cell hyperplasia and increased secretion of PTH. Increased PTH levels have been suggested to play a role in the severity of clinical signs and progression of CKD (Nagode and Chew, 1992).

Avoiding excessive dietary phosphorus and using phosphate binders reduce the inhibitory effects of hyperphosphatemia on renal 1-α-hydroxylase activity, thereby increasing calcitriol production by tubular cells. Oral administration of low doses of calcitriol is associated with decreased serum PTH concentrations. Strong evidence supports the use of calcitriol therapy for slowing progression of CKD in dogs but not in cats (Polzin et al, 2005a; Polzin, 2007). The effect of varying vitamin D levels in foods has not been studied; therefore, it is not included as a key nutritional factor.

B Vitamins
Limited information exists concerning vitamin nutrition in dogs and cats with CKD; however, these patients are at risk for B-vitamin deficiency because of decreased appetite, vomiting, diarrhea and polyuria. Human patients with CKD apparently are especially prone to pyridoxine and folate deficiency (Gilmour et al, 1993). Thiamin and niacin deficiency may contribute to anorexia associated with renal failure. Empirical administration of vitamins seems appropriate in anorectic patients with CKD. However, care must be taken to avoid excessive amounts of fat-soluble vitamins. Patients eating adequate amounts of commercial veterinary therapeutic renal foods are unlikely to need B-vitamin supplementation.

Trace Minerals
Presumably, CKD alters metabolism of trace minerals. For example, nutrients such as copper and zinc that are highly bound to protein may be lost with severe proteinuria. Aluminum may accumulate in human patients with CKD who are treated with aluminum-containing phosphate binders. Aluminum toxicity can cause metabolic bone disease, encephalopathy and anemia. However, exact data are not available to support making a routine recommendation for dietary trace mineral modification for dogs and cats with CKD. There are no reports of trace mineral problems in dogs and cats with CKD that eat commercial veterinary therapeutic renal foods.

Soluble Fiber
It is well established that soluble fiber causes bacterial proliferation in the colon. Bacterial growth requires a source of nitrogen. Although dietary protein provides some nitrogen, blood urea is the largest and most available source of nitrogen for bacterial protein synthesis in the colon (Younes et al, 1995). Urea is the major end product of protein catabolism in mammals. When blood urea diffuses into the large bowel it is broken

Canine Urolithiasis: Definitions, Pathophysiology and Clinical Manifestations

Carl A. Osborne
Jody P. Lulich
Lisa K. Ulrich

"If the patient you treat is harmed more than helped, then best leave the stones alone. But by taking a look at the thoughts in this book, ways to treat stones by how patients eat you'll be shown."
Carl A. Osborne, 1999

CLINICAL IMPORTANCE

Urolithiasis is a common disorder of the urinary tract in dogs. However, the incidence (annual rate of appearance of new cases among the entire population at risk for the disease) of canine urolithiasis has not been established. Urolithiasis was diagnosed in 3,628 of 676,668 dogs (0.53%) admitted to veterinary teaching hospitals in North America between 1980 and 1993. The proportion of dogs with urolithiasis admitted to veterinary hospitals in Germany was similar (Lulich et al, 1995).

Clinical signs of urolithiasis may be the first indication of underlying systemic disorders, or defects in the structure or function of the urinary tract (**Table 38-1**). Uroliths may pass through various parts of the excretory pathway of the urinary tract, they may dissolve, they may become inactive or they may continue to form and grow. If uroliths associated with clinical signs are allowed to remain untreated, they may result in serious sequelae. Despite urolith removal by voiding, dissolution protocols, or surgery, uroliths frequently recur if risk factors associated with their formation are not suppressed or corrected.

Urolithiasis should not be viewed as a single disease, but rather as a sequela of one or more underlying abnormalities. The fact that urolith formation is often erratic and unpredictable indicates that several interrelated complex physiologic and pathologic factors are involved. Therefore, detection of uroliths is only the beginning of the diagnostic process. Determination of urolith composition narrows etiologic possibilities. Knowledge of the patient's food and how it is fed and serum and urine concentrations of lithogenic minerals, crystallization promoters, crystallization inhibitors and their interactions aids in the diagnosis, treatment and prevention of urolithiasis (**Box 38-1**).

FORMATION OF UROLITHS

Initiation and Growth

Urolith formation is associated with two complementary but separate phases: initiation and growth. It appears that initiating events are not the same for all types of uroliths. In addition, factors that initiate urolith formation may be different from those that allow urolith growth.

The initial step in urolith formation is formation of a crystal nidus (or crystal embryo). This initiation phase of urolith for-

Rupture of the outflow tract
Uroperitoneum
Inflammation of tissues adjacent to various portions of the urinary tract
Formation of inflammatory bladder polyps

mation, called nucleation, is dependent on supersaturation of urine with lithogenic crystalloids. The inciting factor and the precise sequence of events that lead to the formation of most types of stones are still unknown. The degree of urine supersaturation may be influenced by the magnitude of renal excretion of crystalloids, urinary pH and/or crystallization inhibitors or promoters in urine. Noncrystalline proteinaceous matrix substances may also play a role in nucleation in some instances.

Three theories have been proposed to explain initiation of lithogenesis: 1) supersaturation-crystallization theory, 2) matrix-nucleation theory and 3) crystallization-inhibition theory (Osborne and Kruger, 1984). Each theory emphasizes a single factor. The supersaturation-crystallization theory incriminates excessive supersaturation of urine with urolith-forming crystalloids as the primary event in lithogenesis. In this hypothesis, crystal nucleation is considered to be a physiochemical process involving precipitation of crystalloids from a supersaturated solution. Urolith formation is thought to occur independently of preformed matrix or crystallization inhibitors.

The matrix-nucleation theory incriminates preformed organic matrix (thought to be a mucoprotein with mineral-binding properties) as the primary determinant in lithogenesis. This theory is based on the assumption that preformed organic matrix forms an initial nucleus that subsequently permits urolith formation by precipitation of crystalloids. The role of organic matrix in lithogenesis has not been defined with certainty; however, the similarity of the overall composition of matrix from human uroliths of various mineral composition supports this hypothesis.

The crystallization-inhibition theory proposes that reduction or absence of organic and inorganic inhibitors of crystallization is the primary determinant of calcium oxalate and calcium phosphate lithogenesis. This theory is based on the fact that several lithogenic substances in urine are maintained in solution at concentrations significantly higher than is possible in water (i.e., driving forces for crystal precipitation of normally saturated urine are minimized by crystallization inhibitors). Similarly, inhibitors are important in minimizing crystal growth and aggregation. These three theories are not mutually exclusive. In fact, supersaturation of urine with the crystal's components is a prerequisite for each theory of nucleation.

Further growth of the crystal nidus depends on: 1) whether or not it remains in the lumen of the excretory pathway of the urinary system, 2) the degree and duration of supersaturation of urine with crystalloids identical or different from those in the nidus and 3) physical characteristics of the crystal nidus. Crystals that are compatible with other crystalloids may align themselves and grow on the surface of other crystals. This is called epitaxial growth. Epitaxy may represent a heterogeneous form of nucleation, and may account for some mixed and compound uroliths. For example, in people, the structural similarities of uric acid and calcium oxalate permit urolith growth by epitaxy (Coe, 1977).

Nucleation

Nucleation refers to the initial event in the formation (or precipitation) of uroliths and is characterized by the appearance of submicroscopic molecular aggregates of crystalloids. Initially, the aggregates are approximately 100 molecules in size and represent potential crystal embryos (or a nidus). Crystals represent an orderly arrangement of atoms in a periodic pattern or lattice. To become a urolith, crystal embryos must have a lattice arrangement that allows continued growth. They must also be large enough to prevent dispersion back into the dissolved phase (Pak, 1976).

Nucleation has been classified as homogeneous (also called self nucleation or generalized nucleation) or heterogeneous (also called localized nucleation) (Lyon and Vermeulen, 1965). Homogeneous nucleation occurs spontaneously in highly supersaturated urine in the absence of foreign substances (**Figure 38-1**). Therefore, the nidus is composed of identical crystalloids. Heterogeneous nucleation is catalyzed by foreign material such as suture material, indwelling catheters, tissue debris, crystal embryos of different composition, etc. (**Figure 38-2**). Urine contains many impurities that might promote heterogeneous nucleation and initiate crystal formation at a concentration of crystalloids below the formation concentration.

Box 38-1. Urolithiasis Terms and Concepts.

UROLITHIASIS

The urinary system is designed to dispose of waste products in soluble form. However, some waste products are sparingly soluble and occasionally precipitate out of solution to form crystals. Growth or aggregation of microscopic crystals may lead to formation of macroscopic uroliths. Urolithiasis may be conceptually defined as the formation of uroliths anywhere in the urinary tract from less soluble crystalloids of urine as a result of multiple congenital and/or acquired physiologic and pathologic processes. If such crystalloids become trapped in the urinary system, they may grow to sufficient size to cause clinical signs.

Urolithiasis should not be thought of as a single disease, but rather as a sequela of one or more underlying abnormalities. The fact that urolith formation is often erratic and unpredictable indicates that several interrelated complex physiologic and pathologic factors are involved. Therefore, detection of uroliths is only the beginning of the diagnostic process. Determination of urolith composition narrows etiologic possibilities. Knowledge of the patient's food, and serum and urine concentrations of lithogenic minerals, crystallization promoters, crystallization inhibitors and their interactions aids in the diagnosis, treatment and prevention of urolithiasis.

UROLITHS

Uroliths are polycrystalline concretions that typically contain more than 95% organic or inorganic crystalloids, and less than 5% organic matrices (weight vs. weight ratio). (The exception to this generality is infection-induced uroliths which contain as much as 50% matrix). Uroliths may also contain a number of minor constituents. A variety of different types of uroliths may occur in dogs (**Figure 1**). Uroliths are typically composed of organized crystal aggregates with a complex internal structure. Cross sections of uroliths frequently reveal nuclei and laminations, and less frequently radial striations. Urine that bathes uroliths varies in composition (and probably in degree of saturation with lithogenic crystalloids) from day to day and perhaps from hour to hour. This phenomenon is of conceptual importance in understanding the physical characteristics of uroliths.

The incidence and composition of uroliths may be influenced by a variety of factors including: 1) species, 2) breed, 3) gender, 4) age, 5) geography, 6) food, 7) anatomic abnormalities, 8) physiologic abnormalities, 9) urinary tract infection and 10) urinary pH. Uroliths may be named according to mineral composition, location (i.e., nephroliths, ureteroliths, cystoliths, vesical calculi, urethroliths) or shape (i.e., smooth, faceted, pyramidal, laminated, mulberry, jackstone, staghorn or branched). Characteristic shapes of crystals and uroliths are influenced primarily by the internal structure of crystals and the environment in which they form. Crystals of calcium oxalate monohydrate tend to fuse, producing smoothly rounded or mammillated uroliths. Local factors that influence the size and shape of uroliths include: 1) number of uroliths present, 2) mobility or fixation of uroliths, 3) flow characteristics of urine and 4) anatomic configuration of the structure in which uroliths grow.

MINERAL

A mineral is a naturally occurring, inorganically formed substance that has a characteristic chemical composition and usually has an ordered atomic arrangement that may influence its external geometric form. Minerals commonly found in uroliths often have a chemical name and a crystal (or mineral) name. Even though a particular mineral usually predominates, the mineral composition of many uroliths may be mixed. Occasionally, the center of a urolith may be composed of one type of crystalloid (e.g., silica), whereas outer layers are composed of a different crystalloid (especially struvite). Detection, treatment and prevention of the underlying causes of urolithiasis depend on knowledge of the composition and structure of all portions of uroliths.

MATRIX

The nondialyzable portion of uroliths that remains after crystalline components have been dissolved with mild solvents is organic matrix. Uroliths consistently contain variable quantities of organic matrix substances in addition to crystalloids. Organic matrix substances identified in human uroliths and experimentally produced in animals include matrix substances A, Tamm-Horsfall glycoprotein, uromucoid, serum albumin and alpha and gamma globulins. Of these, matrix substance A, Tamm-Horsfall glycoprotein and uromucoid appear to be quantitatively more significant than alpha and gamma globulins.

The complex of diverse mucoprotein compounds composing matrix substances may represent the skeleton of uroliths. Although the physical characteristics of uroliths suggest organized relationships between the matrix skeleton and crystalline building blocks, the role of each of these components in formation, retention and growth of uroliths is still poorly understood.

Organic matrix may affect urolith formation by one or more of several mechanisms including: 1) sites of heterogeneous nucleation, 2) templates for organizing and modifying growth of crystals 3) binding agents that cement urolith particles together and promote retention of crystals and 4) protective colloids that prevent further growth of uroliths. Organic matrix may also be composed of passive substances that have no effect on urolith formation or growth.

NUCLEI AND LAMINATIONS

Examination of cross sections of uroliths often reveals a nucleus and adjacent peripheral laminations. Laminated uroliths may be detected by radiography. Nuclei are focal points (or cores) that differ in appearance from more peripheral portions of the urolith. Nuclei are usually but not invariably located in the center of uroliths. Nuclei may be of crystalline composition or they may be composed of foreign material, tissue debris, blood clots, bacteria, etc. The mineral composition of crystalline nuclei may be identical or different from the remainder of the urolith. Nuclei surrounded by well-defined layers (or lamellae) of solid material suggest an early phase of urolith evolution. However, crystalline nuclei large enough to be detected visually are too large to represent an initial crystalline nidus for crystal nucleation in the physiochemical sense. Centrally located nuclei imply that the urolith was freely accessible to urine from all sides and that growth proceeded at a similar rate on all sides.

Laminated uroliths are common and may represent: 1) alternating bands of different mineral types, 2) periods during which urolith

Box 38-1 continued

growth occurred without interruption or 3) alternating periods of precipitation of minerals and gel. Although a difference in appearance between two consecutive layers should prompt suspicion of differences in composition, this is not always the case.

MATRIX CONCRETIONS
By definition, a urolith must contain some minerals. However, concretions composed primarily (more than 65%) of matrix may occur. These concretions, commonly called matrix stones, often occur in the urethra of male cats and sheep, and sometimes occur in dogs and people. They may form a cast of that portion of the excretory pathway in which they are formed (e.g., urethral plugs), implying a rapid rate of formation. In dogs, matrix concretions usually occur secondary to bacterial infections.

COMPOUND UROLITHS
Compound uroliths have one or more layers of mineral composition (e.g., struvite) different from minerals identified in the nucleus (e.g., calcium oxalate).

MIXED UROLITHS
Mixed uroliths contain more than one mineral, neither of which composes at least 70% of the urolith, but without a nucleus or well-defined laminations.

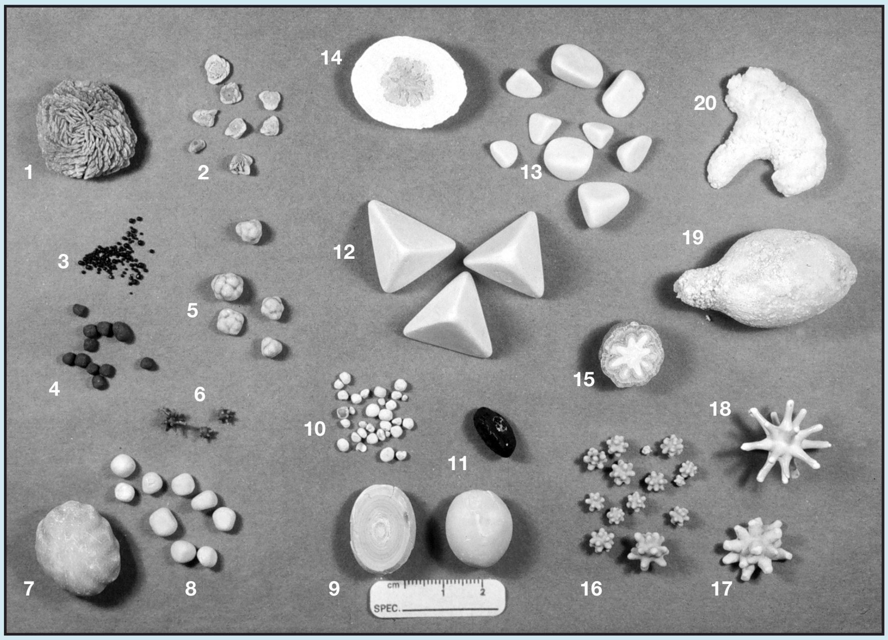

Figure 1. Different mineral types of canine uroliths illustrating common sizes, shapes and surface characteristics. 1) Calcium oxalate dihydrate; 2) Calcium oxalate dihydrate; 3) Calcium oxalate monohydrate; 4) Calcium oxalate monohydrate; 5) Calcium oxalate monohydrate; 6) Calcium oxalate dihydrate; 7) Cystine; 8) Cystine; 9) Ammonium urate (left urolith has been bisected to illustrate laminations); 10) Ammonium urate; 11) Ammonium urate; 12) Struvite; 13) Struvite; 14) Compound urolith with a nidus of calcium oxalate monohydrate surrounded by a shell of struvite and calcium carbonate apatite; 15) Compound urolith with a nidus of silica surrounded by shells containing a mixture of calcium oxalate, silica and ammonium urate; 16) Silica; 17) Silica; 18) Silica; 19) Struvite that has the shape of the urinary bladder and proximal urethra; 20) Struvite that has the shape of the renal pelvis and proximal ureter.

The Bibliography for **Box 38-1** can be found at www.markmorris.org.

These substances may be thought of as facilitators or potentiators of crystallization. Any crystal type may be a potential nidus for nucleation of another crystal type. A greater degree of supersaturation (i.e., a higher formation product) is required for homogeneous nucleation than for heterogeneous nucleation. Once nucleation has occurred, however, crystal growth can occur at any degree of supersaturation (even at metastability).

Undersaturated Solutions
An undersaturated solution contains a sufficiently low concentration of a crystalloid to permit dissolution of additional quantities of the crystalloid. Urine is undersaturated when the solute concentration (or activity product) is less than the solubility of the solute in question. Formation of urine that is undersaturated with lithogenic crystalloids may permit varying degrees of urolith dissolution.

Saturated Solutions
Saturated solutions are in equilibrium with undissolved solute at a given temperature. Saturated solutions contain so much dissolved substances that no more can be dissolved at a given temperature. With respect to urine, the saturation concentration is that concentration of a crystalloid that remains unchanged when the urine is mixed with uroliths (or the solid phase) containing that crystalloid. The saturation of salts in urine is influenced by several variables including pH, ionic strength and temperature.

Supersaturated Solutions
A supersaturated solution is more saturated with a substance at a given temperature than would be normally expected (i.e., it is any concentration greater than the saturation concentration). Supersaturated urine contains a greater concentration of a crystalloid (cystine, phosphate, calcium, ammonium, etc.) than the associated solvent (water) would be predicted to be able to normally hold in solution. Supersaturation can vary in degree. Urine is metastable at lower levels of supersaturation. At higher levels of supersaturation, however, urine becomes unstable

with regard to its capacity to keep lithogenic substances in solution (**Figure 38-3**). Factors that increase the saturation of crystalloids in urine predispose patients to precipitation of crystals and thus urolith formation. Spontaneous precipitation will occur if the concentration of the crystalloid is greater than its formation product.

Metastable Region

The metastable region refers to the degree of supersaturation of a crystalloid that lies between the solubility product and the formation product. Metastability applies to those liquids (e.g., urine) that have the capacity to retain more of a compound in solution than would be predicted by knowledge of its true solubility in water. The term "metastable" is appropriate because it implies a condition subject to change. A metastable solution is thermodynamically unstable, but does not contain enough energy to initiate crystal formation. However, crystals already present may grow. The region of metastability varies with the type of lithogenic crystalloid. For example, in people, it has been estimated that the difference between the solubility product and the formation product of calcium oxalate in urine is a multiple of about 8.5 to 10.0 (Coe, 1978).

Oversaturated Solutions

An oversaturated solution is one in which the degree of supersaturation of a crystalloid is greater than the formation product (**Figure 38-3**). Recall that supersaturated urine exceeds the solubility product, but does not exceed the formation product. Oversaturated urine is no longer metastable. Nucleation will take place in the absence of heterogeneous factors. Oversaturation of urine is thought to cause crystals observed by microscopic examination of urine sediment.

Inhibitors and Promoters of Crystal Formation

Urine is a complex solution containing a variety of substances that can inhibit or promote crystal formation and growth. Inhibitors include molecules that reduce calcium oxalate and calcium phosphate supersaturation. Some inhibitors (e.g., citrate, magnesium, pyrophosphate) form soluble salts with calcium, oxalic acid or phosphoric acid, thereby reducing the quantity of these metabolites available for precipitation. Other inhibitors (e.g., nephrocalcin, uropontin, glycosaminoglycans, Tamm-Horsfall glycoprotein, other inert ions) interfere with the ability of calcium and oxalic acid to combine, thereby minimizing crystal formation and growth. Also, glycosaminoglycans act as protectors by preventing crystals from adhering to the urinary tract mucosa.

Clinical Concepts of Urine Supersaturation

Salts (crystals) are neutral compounds derived from the reversible interaction of a cation (e.g., calcium) and an anion (e.g., oxalic acid). The ability of a salt to dissolve in solution depends on the concentration of its ions in solution, and its interaction with other ions and neutral molecules in the same solution. For example, the state of urine saturation for any specific crystal system is the product of urine solute concentration, pH, ionic strength, tem-

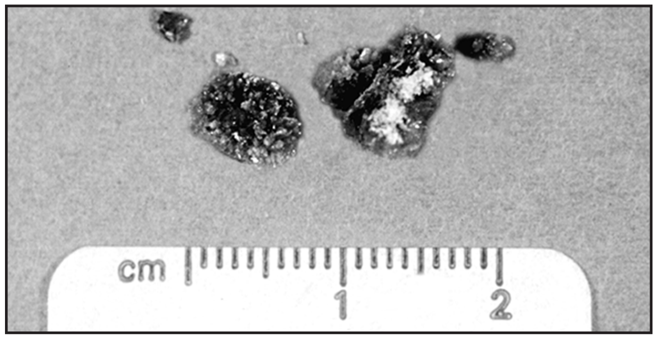

Figure 38-1. Layered urocystolith composed of 100% calcium oxalate dihydrate removed from an adult male miniature schnauzer. The difference in color of the center of the urolith vs. the outer layer is due to the large quantity of blood in the matrix of the outer layer.

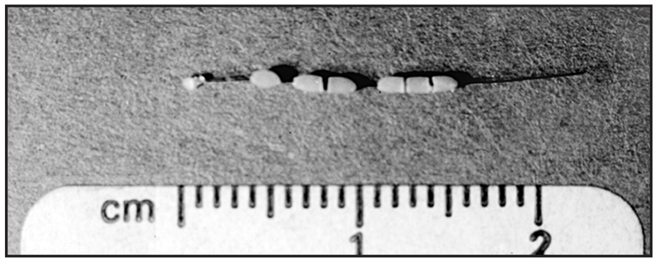

Figure 38-2. Struvite uroliths that have formed on a hair shaft.

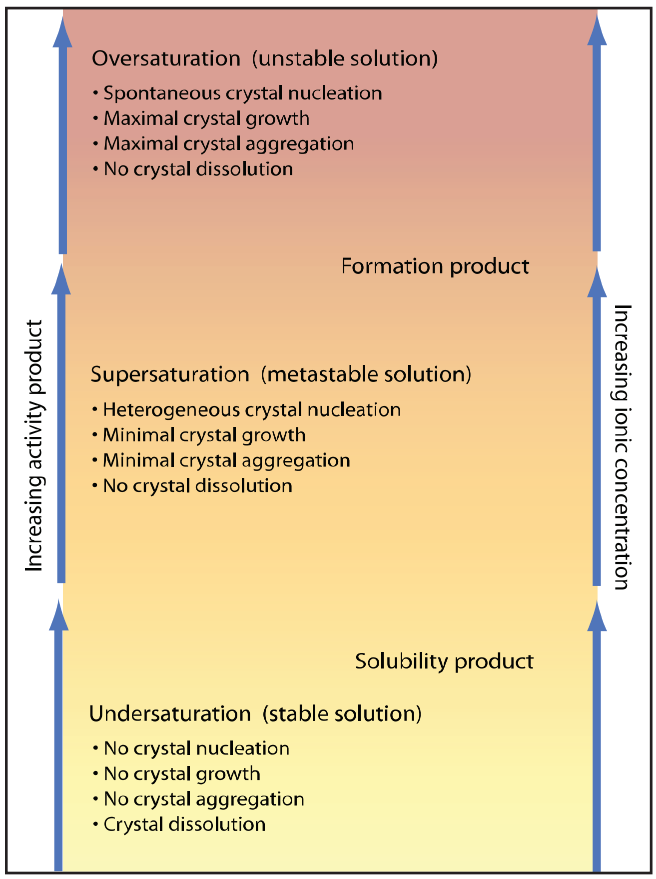

Figure 38-3. Probable events in formation of crystals in urine. A variety of factors influence the solubility of minerals in urine including concentration of lithogenic and non-lithogenic minerals, the concentration of crystallization inhibitors and crystallization promoters, urine temperature, urinary pH and urine ionic strength.

perature and preformed chemical complexes.

To illustrate these principles, consider pure water as a solution and calcium oxalate as a salt. Small amounts of calcium oxalate added to water dissolve completely because water is undersaturated with calcium and oxalic acid ions. As more calcium oxalate is added, the water's capacity to dissolve additional calcium oxalate is decreased until the solution becomes saturated. In this context, saturation of the solution with calcium and oxalic acid ions occurs when no additional calcium oxalate can be dissolved at a given pH and temperature of the solution. If additional calcium oxalate is added, it will appear as a solid.

As in water, calcium oxalate can also be dissolved in undersaturated urine. However, unlike water, urine is a complex solution containing a unique combination of ionic and nonionic molecules that may increase the solubility of calcium oxalate. Therefore, calcium oxalate added beyond the point of saturation will remain in solution. Thus, the solution becomes supersaturated with calcium and oxalic acid ions. Supersaturation is conceptually significant because the solution contains enough energy to form solids from dissolved ions (i.e., it is thermodynamically unstable). When supersaturated, the solution must "struggle" to maintain the homogeneous nature between the ions it contains. One method by which the solution returns to thermodynamic stability is by concentrating excess calcium and oxalic acid ions as solids or crystals on pre-existing surfaces or templates (e.g., other crystals or foreign material). This phenomenon is called heterogeneous nucleation. However, if the solution becomes oversaturated by addition of more calcium and oxalic acid ions, calcium oxalate crystals will form without an existing template (so-called homogeneous nucleation). After crystals have formed, available thermodynamic energy favors crystal growth whereby free ions become incorporated into the crystals. Crystal growth continues until ions in solution become depleted, allowing the solution to return to thermodynamic stability (or saturation). Crystals retained in the urinary tract may grow (the second phase of urolith formation).

Urine is a complex solution containing "inert" ions (i.e., sulfate, sodium, potassium, magnesium) unlikely to chemically bond with calcium and oxalic acid. In this way, they increase calcium oxalate solubility. The negative ions (e.g., sulfate) surround positive calcium ions, and the positive ions (e.g., sodium, potassium, magnesium) surround negative oxalic acid ions. The net effect is a decrease in attraction between calcium and oxalic acid ions. Because calcium and oxalic acid ion interaction is required for crystal formation, the solubility of calcium oxalate increases as the concentration of "inert" ions increases.

Supersaturation of urine with certain lithogenic ions also depends on another group of substances called "crystallization inhibitors." These include citric acid and pyrophosphates that chelate calcium but remain dissolved in solution. Likewise, certain mucoproteins, glycosaminoglycans, glycoproteins (e.g., nephrocalcin) and other poorly identified substances may interact with calcium. The result is a decrease in the amount of calcium available to bind with oxalic acid (and phosphoric acid). It is of significance that these inhibitors have been found to be deficient or abnormal in some calcium oxalate urolith-forming patients.

Activity Product
The product of the chemical activities of two ionic materials is called the activity product. It is a mathematical expression used to estimate the degrees of saturation (i.e., undersaturation, supersaturation or oversaturation) of a dog's urine with lithogenic minerals (**Figure 38-3**). In addition to concentration of minerals, it encompasses other variables including urinary pH and ionic strength of the solution (Pak et al, 1977). Activity product encompasses solubility product and formation product. Activity products are calculated by measuring total concentrations of major ionizable solutes in urine. For efficiency, computer programs are commonly used to aid calculation of ion concentrations and activity products (Brown et al, 1994).

Solubility Product
The solubility product is a type of activity product reflecting the urine's ability to dissolve a known concentration of lithogenic ions at variable but known pH and temperature. It is constant for each mineral component at a given temperature and pH. Urine is saturated when the solubility product value is reached. Below this value, urine is undersaturated with lithogenic ions; above this value urine is supersaturated. When devising dietary and medical protocols to dissolve or prevent urolith formation, the goal is to achieve an activity product less than the solubility product (or a state of undersaturation) (**Figure 38-3**).

Formation Product
The formation product is a type of activity product reflecting the concentration of ions at which precipitation of solute (homogeneous nucleation and eventually crystal formation) occurs at a given pH and temperature. It is the upper limit of metastability. Urinary pH may affect the ionization of some urine constituents and thus their solubility. If urinary pH varies during the day, urine may be intermittently supersaturated or oversaturated. Ion activities above the formation product are associated with an unstable state of oversaturation resulting in spontaneous crystal formation and rapid crystal growth. Because this condition may be influenced by the product of several factors (including the time of incubation, a crystallizable matrix and inhibitors of nucleation) in addition to the concentration of lithogenic crystalloids, it is commonly called the formation product. In people, as mentioned above, the formation product for calcium oxalate is approximately 8.5 to 10 times greater than its solubility product (Coe, 1978). This indicates that urine, because of the addition of a variety of crystallization inhibitors, must be saturated at least eight times above the solubility product before crystals will form. In general, urine of urolith formers is more supersaturated with respect to the constituents of their uroliths than is the urine of normal subjects.

PATIENT ASSESSMENT

History and Physical Examination
The history of dogs with urolithiasis depends on: 1) anatomic location(s) of uroliths, 2) duration of uroliths in specific loca-

tion(s), 3) physical characteristics of uroliths (size, shape, number), 4) secondary urinary tract infection (UTI) and virulence of infecting organism(s) and 5) presence of concomitant diseases in the urinary tract and other body systems. After a diagnosis of urolithiasis has been confirmed, the history and physical examination should focus on detection of any underlying illness that may predispose the dog to urolith formation.

A dietary history should also be obtained for all patients with urolithiasis, with the objective of identifying risk factors that predispose the patient to specific mineral types. Likewise, owners should be questioned about vitamin-mineral supplements, previous illnesses and medications that may predispose the patient to various types of uroliths.

Signs typical of lower urinary tract disease include dysuria, pollakiuria, hematuria, urge incontinence, paradoxical incontinence and voiding small uroliths during micturition. Signs of uremia may occur if urine flow has been obstructed for a sufficient period, or if there is extravasation of urine into the peritoneal cavity due to rupture of the excretory pathways.

Signs of upper tract disease include painless hematuria and polyuria if sufficient nephrons have impaired function. Abdominal pain may occur if there is overdistention of the renal pelvis with urine due to outflow obstruction (**Table 38-2**). Many patients with uroliths have no clinical signs. Absence of signs is especially common in patients with nephroliths.

If gross hematuria is present, determining when during the process of micturition it is most severe may be of value in localizing its source. If hematuria occurs throughout micturition, lesions (including uroliths) may be present in the kidneys, ureters, urinary bladder, prostate gland and/or urethra. If hematuria occurs primarily at the end of micturition, lesions of the ventral bladder wall or intermittent renal hematuria should be suspected. If hematuria occurs at the beginning or is independent of micturition, lesions in the urethra or genital tract should be suspected.

Digital palpation of the entire urethra, including evaluation by rectal examination, may reveal urethroliths or uroliths lodged in the bladder neck. A firm, non-yielding mass may be palpated in the urinary bladder if a solitary urolith is present; a grating sensation confined to the bladder may be detected if multiple uroliths are present. It may be impossible to palpate small or solitary urocystoliths if the bladder wall is contracted and/or thickened due to inflammation. Likewise, it may be impossible to palpate uroliths in a distended or overdistended bladder. In this situation, the bladder should be repalpated after urine has been eliminated by voiding, manual compression of the bladder, cystocentesis or catheterization. One should suspect urethroliths when urethral catheters cannot be advanced into the bladder. However, inability to advance a catheter through the urethra may also be associated with urethral strictures or space occupying lesions that partially or totally occlude the urethral lumen.

In the absence of infection or outflow obstruction, abnormalities are usually not associated with nephroliths unless bilateral nephroliths are associated with sufficient renal damage to cause uremia. If infection or obstruction is present, there may be pain in the area of the kidneys and/or palpable enlargement of the affected kidney(s). Concomitant bacterial pyelonephritis may be associated with polysystemic signs due to sepsis.

Table 38-2. Clinical signs of uroliths that may be associated with urinary system dysfunction.

Urethroliths
Asymptomatic
Dysuria, pollakiuria, urge incontinence and/or periuria
Gross hematuria
Palpable urethral uroliths
Spontaneous voiding of small uroliths
Partial or complete urine outflow obstruction
- Overflow incontinence
- Anuria
- Palpation of an overdistended and painful urinary bladder
- Urinary bladder rupture, abdominal distention and abdominal pain
- Signs of postrenal azotemia (anorexia, depression, vomiting and diarrhea)
- Signs associated with concurrent urocystoliths, ureteroliths and/or renoliths

Urocystoliths
Asymptomatic
Dysuria, pollakiuria and urge incontinence
Gross hematuria
Palpable bladder uroliths
Palpably thickened urinary bladder wall
Partial or complete urine outflow obstruction of bladder neck (See Urethroliths.)
Other signs associated with concurrent urethroliths, ureteroliths and/or renoliths

Ureteroliths
Asymptomatic
Gross hematuria
Constant abdominal pain
Unilateral or bilateral urine outflow obstruction
- Palpably enlarged kidney(s)
- Signs of postrenal azotemia (See Urethroliths.)

May have other signs associated with concurrent urethroliths, urocystoliths and/or nephroliths

Nephroliths
Asymptomatic
Gross hematuria
Constant abdominal pain
Signs of systemic illness if generalized renal infection is present (anorexia, depression, fever and polyuria)
Palpably enlarged kidney(s)
Signs of postrenal azotemia (See Urethroliths.)
Other signs associated with concurrent urethroliths, urocystoliths and/or ureteroliths

Diagnostic Studies

Urinalysis

Results of urinalysis are usually characterized by abnormalities typical of inflammation (pyuria, proteinuria, hematuria and increased numbers of epithelial cells), which may or may not be associated with infection. Whereas urease-producing microbes (staphylococci, *Proteus* spp., ureaplasmas) may cause infection-induced struvite (magnesium ammonium phosphate) uroliths to form, opportunistic bacteria that are not lithogenic (e.g., *Escherichia coli* and streptococci) may colonize the urinary tract as a result of urolith-induced alterations in local host defenses. Quantitative urine culture of all patients with uroliths is recom-

mended because knowledge of bacterial type is important in predicting the mineral composition of uroliths, and in selecting an appropriate antimicrobial agent for treatment.

The pH of urine obtained from patients with uroliths is variable; however, it may become persistently alkaline if secondary infection with urease-producing bacteria occurs. The significance of a single urinary pH measurement should be interpreted cautiously because there are significant fluctuations throughout the day, especially with respect to the time, amount and types of food consumption. In general, magnesium ammonium phosphate and calcium phosphate uroliths are associated with alkaline urine, whereas ammonium urate, sodium urate, uric acid, calcium oxalate, cystine and silica uroliths tend to be associated with acidic urine.

The advent of effective dietary and medical protocols to dissolve and prevent uroliths in dogs and cats has resulted in renewed interest in detection and interpretation of crystalluria. Evaluation of urine crystals may aid in: 1) detection of disorders predisposing animals to urolith formation, 2) estimation of the mineral composition of uroliths and 3) evaluation of the effectiveness of dietary and medical protocols initiated to dissolve or prevent uroliths.

Crystals form only in urine that is or recently has been supersaturated with lithogenic substances. Therefore, crystalluria represents a risk factor for urolithiasis. However, detection of urine crystals is not synonymous with urolithiasis and clinical signs associated with uroliths. Nor are urine crystals irrefutable evidence of a urolith-forming tendency. For example, crystalluria that occurs in individuals with anatomically and functionally normal urinary tracts is usually harmless because the crystals are eliminated before they aggregate or grow to sufficient size to interfere with normal urinary function. In addition, crystals that form after elimination or removal of urine from the patient often are of no clinical importance. Identification of crystals that have formed in vitro does not justify therapy.

Detection of some types of crystals (e.g., cystine and ammonium urate) in clinically asymptomatic patients, frequent detection of large aggregates of crystals (e.g., calcium oxalate or magnesium ammonium phosphate) in apparently normal individuals, or detection of any form of crystals in fresh urine collected from patients with confirmed urolithiasis may be of diagnostic, prognostic and therapeutic importance. Large crystals and aggregates of crystals are more likely to be retained in the urinary tract, and therefore may be of greater clinical significance than small or single crystals.

Although there is not a direct relationship between crystalluria and urolithiasis, detection of crystals in urine is proof that the urine sample is oversaturated with lithogenic substances. However, oversaturation may occur as a result of in vitro events in addition to or instead of in vivo events. Therefore, care must be used not to overinterpret the significance of crystalluria. In vivo variables that influence crystalluria include: 1) the concentration of lithogenic substances in urine (which in turn is influenced by their rate of excretion and the volume of water in which they are excreted), 2) urinary pH (**Table 38-3**), 3) the solubility of lithogenic substances and 4) excretion of diagnostic agents (e.g., radiopaque contrast media) and medications (e.g., sulfonamides).

In vitro variables that influence crystalluria include: 1) temperature, 2) evaporation, 3) urinary pH and 4) the technique of

Table 38-3. Common characteristics of selected urine crystals.

Crystal types	Appearances	Urinary pH at which crystals commonly form: Acidic	Neutral	Alkaline
Ammonium urate	Yellow-brown spherulites, thorn apples	+	+	+
Amorphous urates	Amorphous or spheroidal yellow-brown structures	+	±	-
Bilirubin	Reddish-brown needles or granules	+	-	-
Calcium carbonate	Large yellow-brown spheroids with radial striations, or small crystals with spheroidal or dumbbell shapes	-	±	+
Calcium oxalate dihydrate	Small colorless envelopes (octahedral form)	+	+	±
Calcium oxalate monohydrate	Small spindles “hempseed” or dumbbells	+	+	±
Calcium phosphate	Amorphous or long thin prisms	±	+	+
Cholesterol	Flat colorless plates with corner notch	+	+	-
Cystine	Flat colorless hexagonal plates	+	+	±
Hippuric acid	Four- to six-sided colorless elongated plates or prisms with rounded corners	+	+	±
Leucine	Yellow-brown spheroids with radial and concentric laminations	+	+	-
Magnesium ammonium phosphate	Three- to six-sided colorless prisms	±	+	+
Sodium urate	Colorless or yellow-brown needles or slender prisms, sometimes in clusters or sheaves	+	±	-
Sulfa metabolites	Sheaves of needles with central or eccentric binding, sometimes fan-shaped clusters	+	±	-
Tyrosine	Fine colorless or yellow needles arranged in sheaves or rosettes	+	-	-
Uric acid	Diamond or rhombic rosettes, or oval plates, structures with pointed ends, occasionally six-sided plates	+	-	-
Xanthine	Yellow-brown amorphous, spheroidal or ovoid structures	+	±	-

Key: + = crystals commonly occur at this pH, ± = crystals may occur at this pH, but are more common at the other pH, - = crystals are uncommon at this pH.

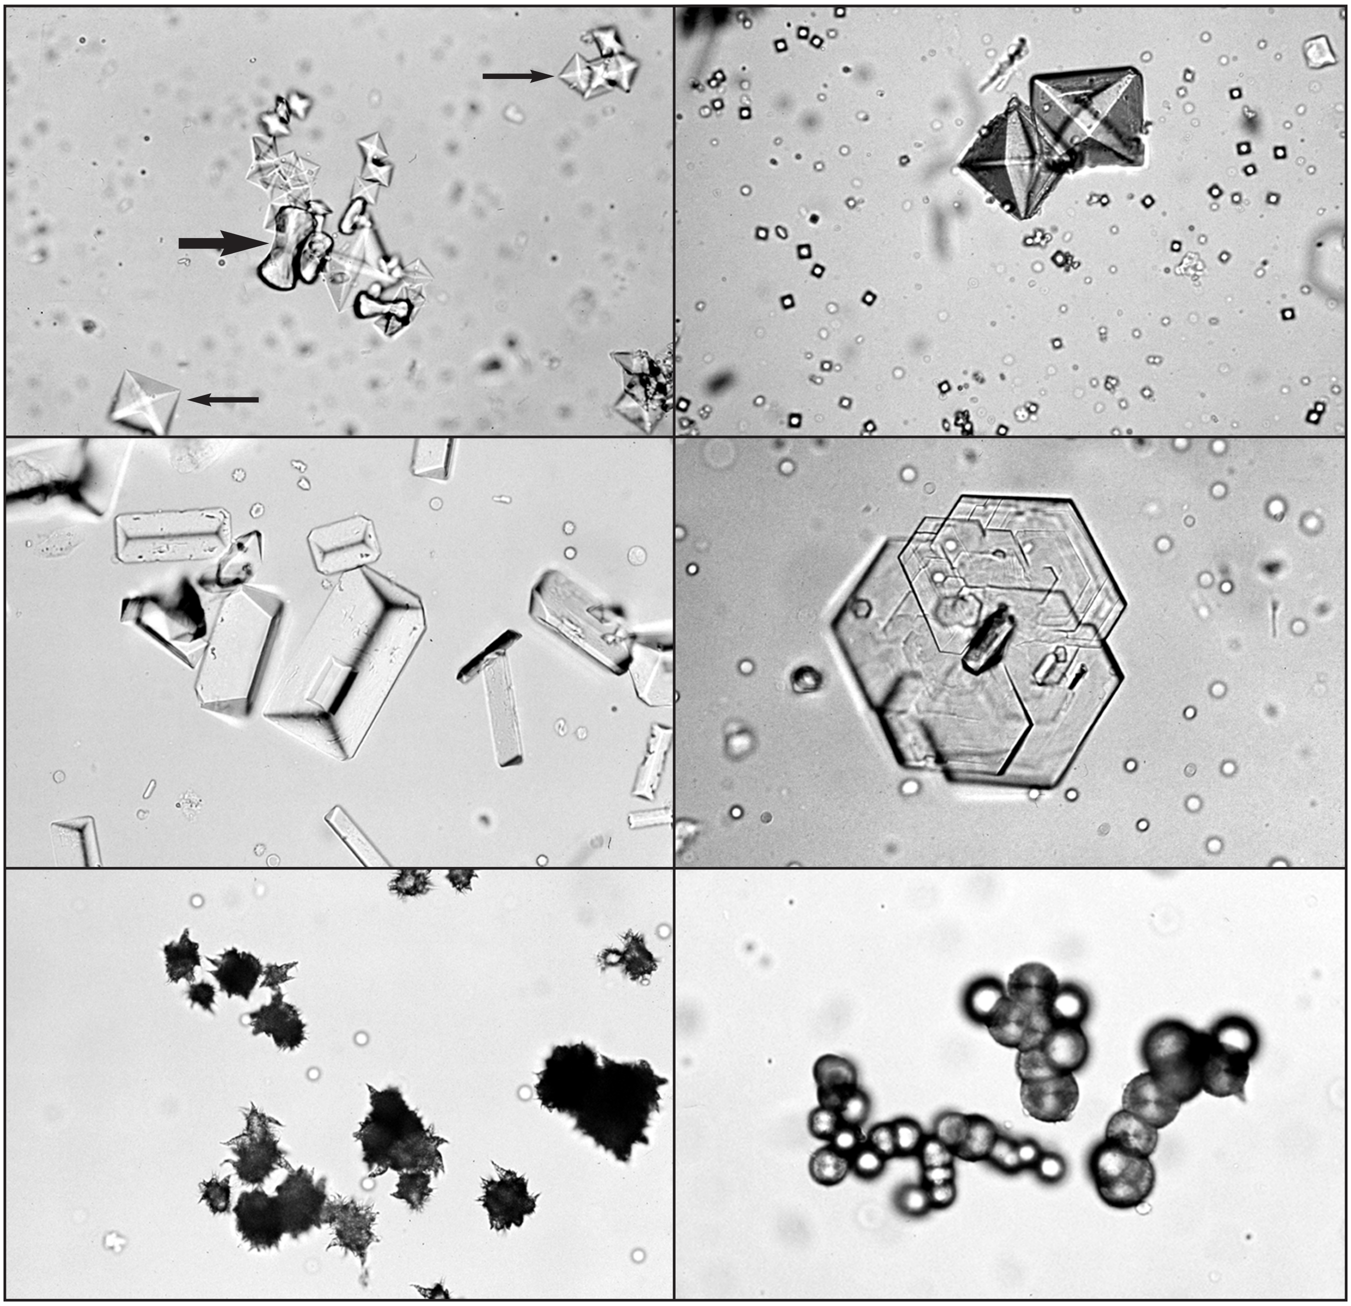

Figure 38-4. Photomicrographs of common crystals found in urine sediment. Calcium oxalate monohydrate (dumbbell form, large arrow) and calcium oxalate dihydrate (octahedral form, small arrows) (Top, Left). Calcium oxalate dihydrate; octahedral form (Top, Right). Magnesium ammonium phosphate (struvite); prisms (Middle, Left). Cystine; flat, colorless hexagonal plates (Middle, Right). Ammonium urate; thorn apple form (Bottom, Left). Amorphous xanthine; spheroids (Bottom, Right).

specimen preparation (e.g., centrifugation vs. noncentrifugation and volume of urine examined) and preservation. As mentioned above, in vitro changes that occur after urine collection may enhance formation or dissolution of crystals. Although in vitro changes may be used to enhance detection of certain types of crystals (e.g., acidification to cause precipitation of cystine), in vitro crystal formation may have no clinical relevance to in vivo formation of crystals in urine. When knowledge of in vivo urine crystal type is especially important, fresh, warm specimens should be serially examined. The number, size and structure of crystals should be evaluated, as well as their tendency to aggregate.

Urinary pH influences the formation and persistence of several types of crystals. Therefore, it is often useful to consider pH when interpreting crystalluria (**Table 38-3**). Different crystals tend to form and persist in certain urinary pH ranges, although there are exceptions. Exceptions may be related to large concentrations of lithogenic substances in urine or recent in vivo or in vitro changes in urinary pH.

Refrigeration is an excellent method to preserve many phys-

Table 38-4. Advantages and disadvantages of survey radiography, double-contrast radiography and ultrasonography in assessing uroliths.

Parameters	**Survey radiography**	**Double-contrast radiography**	**Ultrasonography**
Assessment of urethroliths	Yes, if radiodense	Indirectly*	Poor
Assessment of radiolucent urocystoliths	Unreliable	Yes	Yes
Distinguishing blood clots from urocystoliths	No	Probably	Yes
Assessment of laminated urocystoliths	Best of the three methods	Probably	No
Assessment of other bladder disorders	Unreliable	Yes	Sometimes
Assessment of urocystolith number	Yes (>3 mm)	Yes (>1 mm)	Equipment and observer dependent
Assessment of urocystolith size	Yes (>3 mm)	Yes (>1 mm)	Equipment and observer dependent
Assessment of urocystolith density	Yes (>3 mm)	No	No
Assessment of urocystolith shape	Yes (>3 mm)	Yes (>1 mm)	No
Immediate postsurgical assessment for uroliths	Yes	Not recommended**	No (air artifacts)
Risk of air artifact in bladder	No	Yes	No
Risk of iatrogenic bacterial urinary tract infection	No	Yes	No
Exposure to ionizing radiation	Yes	Yes	No
Necessary to remove hair	No	No	Often
Authors' overall choice	**Screening**	**Investigation**	**Third choice**

*During transurethral catheterization.
**Due to risk of iatrogenic bacterial urinary tract infection.

Table 38-5. Comparison of relative densities of common uroliths detected by survey radiography.*

Mineral types	**Relative atomic number****
Water	**7.7**
Urate	6.9-7.7
Struvite	9.81
Cystine	10
Silica	11.6
Calcium oxalate dihydrate	13
Calcium oxalate monohydrate	13.6
Cortical bone	**15**
Calcium phosphate	15.9

**Effective atomic numbers (Zeff), which is the sum of different elements in the urocystolith and is related to its mass.

ical, chemical and morphologic properties of urine sediment. However, refrigeration must be used with caution when evaluating crystalluria from qualitative and quantitative standpoints. Although refrigeration of urine samples is likely to enhance formation of various types of crystals, this phenomenon may have no relationship to events occurring in the patient's body.

Crystalluria may also be influenced by food, including water intake. Dietary influence on crystalluria is of diagnostic importance because urine crystal formation that occurs while patients are consuming hospital foods may be dissimilar to urine crystal formation that occurs when patients are consuming foods fed at home.

Microscopic evaluation of urine crystals should not be used as the sole criterion to predict the mineral composition of macroliths in patients with confirmed urolithiasis (**Table 38-3** and **Figure 38-4**). Only quantitative analysis can provide definitive information about the mineral composition of the entire urolith. However, interpretation of crystalluria in light of other clinical findings often allows the clinician to tentatively identify the mineral composition of uroliths, especially their outermost layers. Subsequent reduction or elimination of crystals by therapy provides a useful index of the efficacy of medical and dietary protocols designed to dissolve or prevent uroliths.

Radiography and Ultrasonography

The primary objective of radiographic or ultrasonographic evaluation of patients suspected of having uroliths is to determine the site(s), number, density and shape of uroliths. However, the size and number of uroliths are not a reliable index of the probable efficacy of therapy. After urolithiasis has been confirmed, radiographic or ultrasonographic evaluation also aids in detection of predisposing abnormalities (**Table 38-4**).

The size, number, location and mineral composition of uroliths influence their radiographic and ultrasonographic appearance. Most uroliths greater than 3 mm in diameter have varying degrees of radiodensity, and therefore can be detected by survey abdominal radiography or ultrasonography (Osborne et al, 1995). Very small uroliths (<3 mm in diameter) may not be visualized by survey radiography or ultrasonography. Uroliths greater than 1 mm in diameter can usually be detected by double-contrast cystography, provided excessive contrast medium is not used (Feeney et al, 1999). **Table 38-5** lists relative densities of common uroliths based on survey radiography (Feeney et al, 1999). Because of significant variation, the radiodensity of uroliths is not by itself a reliable index of mineral composition.

Uroliths greater than 3 mm in diameter are not commonly radiolucent. An exception to this generality is uroliths composed of 100% ammonium or sodium urate or uric acid. However, in our experience many ammonium urate uroliths of dogs are marginally radiodense. This finding may be related to a variable quantity of phosphates and other minerals in urate uroliths of dogs.

Matrix uroliths may be radiolucent or have some radiodensi-

ty. Blood clots are radiolucent and may be mistaken for radiolucent uroliths. Radiolucent uroliths may be readily distinguished from blood clots when evaluated by two-dimensional, gray-scale ultrasonography. Uroliths are usually in the dependent portion of the bladder lumen, produce sharply marginated shadows containing few echoes and are associated with acoustic shadowing. Blood clots may be located anywhere in the bladder lumen, typically have an irregular outline and indistinct margins and are not associated with acoustic shadowing.

Uroliths that are radiodense on survey radiographs may appear to be radiolucent when evaluated by positive-contrast radiography. This finding is related to the fact that many uroliths are more radiodense than body tissue, but less radiodense than the contrast material. A diagnosis of radiolucent uroliths should be based on their radiodensity compared with soft tissues, and not their radiodensity compared with positive-contrast medium.

A urolith may be larger than that depicted by its radiodensity if only a portion of it contains radiodense minerals. This phenomenon is most likely to occur with rapidly growing struvite uroliths that contain large quantities of matrix.

Hematology and Serum Chemistry

Hemograms of dogs with uroliths are usually normal unless there is concomitant generalized infection of the kidneys or prostate gland associated with leukocytosis. Microcytosis, anemia, target cells and leukocytosis have occasionally been associated with portal vascular anomalies in dogs with and without urate uroliths (Cornelius et al, 1975; Ewing et al, 1974; Griffiths et al, 1981; Rothuizen and van den Ingh, 1980).

Serum chemistry values are usually normal in patients with infection-induced magnesium ammonium phosphate, cystine and silica uroliths unless obstruction of urine outflow or generalized renal infection leads to changes characteristic of renal failure. Although most patients with calcium oxalate and calcium phosphate uroliths are normocalcemic, some are hypercalcemic.

Calcium phosphate and sterile struvite uroliths may be associated with distal renal tubular acidosis characterized by hyperchloremic (normal anion gap) metabolic acidosis, urinary pH values consistently greater than approximately 6 and hypokalemia.

A variety of biochemical alterations may exist in patients with urate urolithiasis. The following changes may be observed in patients with urate uroliths due to congenital or acquired hepatic disorders (Rothuizen and van den Ingh, 1980; Barrett et al, 1976; Marretta et al, 1981): 1) decreased urea nitrogen concentrations, 2) decreased total protein and albumin concentrations, 3) abnormal bile acid concentrations, 4) increased concentrations of total bilirubin and fasting blood ammonia and 5) increased serum alanine aminotransferase and serum alkaline phosphatase enzyme activities. Dogs with portal vascular anomalies typically have reduced hepatic functional mass and altered portal blood flow evidenced by abnormally elevated bile acid concentrations, prolonged sulfobromophthalein retention times and abnormal ammonia tolerance tests (Griffiths et al, 1981; Rothuizen and van den Ingh, 1980; Barrett et al, 1976; Marretta et al, 1981; Center et al, 1985).

Urine Chemistry

Detection of the underlying causes of specific types of urolithiasis is often linked to evaluation of the biochemical composition of urine. For best results, at least one and preferably two consecutive 24-hour urine samples should be collected because determination of fractional excretion of many metabolites in "spot" urine samples does not accurately reflect 24-hour metabolite excretion (**Table 38-6**).

Water consumption and hydration status must be considered when interpreting laboratory results. Decreased water consumption and dehydration are associated with several alterations, including decreased renal clearance of metabolites and increased urine specific gravity and urine solute concentrations (Taburu et al, 1993). Caution must be used in interpreting 24-hour excretion of solutes in the diagnosis and therapy of urolithiasis if hospitalized animals consume less water than in the home environment.

Urine concentrations of potentially lithogenic metabolites are also influenced by the amount and composition of food consumed, and whether urine was collected during conditions of fasting or food consumption (Lulich et al, 1991, 1991a). Aldosterone secretion increases following food deprivation. Increased aldosterone secretion promotes renal tubular sodium reabsorption and potassium excretion. As a consequence, plasma potassium concentration decreases, urinary potassium excretion increases and urinary sodium and chloride excretion decrease (Lulich et al, 1991a). Urinary calcium, magnesium and uric acid excretions are reduced during fasting. However, urinary excretion of phosphorus, oxalate and citrate are apparently unaffected by fasting (Lulich et al, 1991a). In dogs, urinary ammonia, titratable acid and hydrogen ion excretion decrease and urinary pH values increase when food is withheld (Lulich et al, 1991a; Lemieux and Plante, 1968). Therefore, values for 24-hour urinary solute excretion may differ when measured following food consumption vs. values obtained when food is withheld.

Consumption of food stimulates gastric secretion of hydrochloric acid. As a result, concentrations of chloride decrease and bicarbonate increase in venous blood draining the stomach. Total serum concentration of carbon dioxide increases. The resulting metabolic alkalosis is commonly called the postprandial alkaline tide. Urinary pH will increase unless acidifying substances are contained in the food. In a study of healthy beagles, eating was associated with increased urinary excretion of hydrogen ions, ammonia, sodium, potassium, calcium, magnesium and uric acid (Lulich et al, 1991a).

Laboratory results may be markedly affected by changes in foods fed in a home environment vs. different foods fed in a hospital environment. For example, urinary excretion of potentially lithogenic metabolites while animals consume foods fed in the hospital may be different from those excreted by animals eating at home. To determine the influence of home-fed foods on laboratory test results, consider asking clients to bring

Table 38-6. Protocol for measuring 24-hour urinary excretion of various substances associated with urolithiasis.

Technique

1. To allow for food acclimation, feed the patient either the food it was consuming just before urolith formation or a standard food at home for 10 to 14 days. We commonly use Prescription Diet k/d Canine* as the standard food.
2. If possible, house and feed the dog in the urine collection cage for at least one day before urine collection. As dogs become acclimated to their new environment, they are more likely to consume quantities of food and water similar to that consumed in their home environment.
3. Begin each 24-hour urine collection period by removing urine from the urinary bladder by transurethral catheterization. This urine is discarded. Record the actual time that urine collection is initiated.
4. Weigh the dog.
5. Then feed the dog its food as if at home. Water should be continuously available for consumption.
6. Begin administering a broad-spectrum antibiotic that achieves high concentrations in urine to prevent catheter-induced urinary tract infection. The dosage, dosing interval and route of administration should be based on manufacturer recommendations.
7. Keep the patient in the collection cage during urine collection. When using metabolism cages designed for urine collection, catheterization of the urinary tract is unnecessary except at the end of the 24 hours. House-trained dogs may not voluntarily void in their cage. Bladder catheterization may be necessary to obtain urine from these dogs. Dogs may be catheterized as often as necessary to keep them comfortable (usually every six to eight hours).
8. Catheterize the urinary bladder at the end of 24 hours to remove all urine. Save this urine.
9. Record the exact time of collection termination.
10. Pool all urine collected during the 24-hour period in a single container and measure its volume.
11. Thoroughly mix the pooled urine before removing aliquots for analysis.

Preservation

1. Preservatives have different roles, but are often used to minimize bacterial growth, reduce chemical decomposition, solubilize constituents that might otherwise precipitate out of solution, or decrease atmospheric oxidation of unstable compounds.
2. The method of preservation may vary depending on the substances being measured and the tests used to measure them. Consult the laboratory to determine the recommended method of preservation.
3. Preservatives should not be added to some specimens because of possible interference with analytical methods.
4. Refrigeration is a common method for preserving urine collected for analysis. Urine removed by intermittent catheterization can be stored in a refrigerator in clean containers with screw top lids. Containers used for continuous collection beneath metabolism cages can be surrounded by ice packs and then insulated. Refrigeration causes some minerals to precipitate out of solution.
5. Specimens can be acidified (add 10 ml of 1 N hydrochloric acid per liter to achieve a pH of 3 or less) to preserve oxalate and calcium for analysis. However, acidified urine is unsuitable for measuring uric acid because it precipitates in acidic solutions.

Storage of selected analytes in urine

1. No single preservative is ideal if multiple substances in urine are to be analyzed. To minimize degradation, we routinely collect urine under conditions of refrigeration. Immediately following urine collection, preservatives are added to appropriate aliquots of urine for storage until analysis.
2. Uric acid and xanthine: Aliquots of urine should be diluted (1 ml of urine with 19 ml of distilled water) to preserve uric acid and xanthine. This mixture can then be frozen.
3. Ammonia: Aliquots of urine (3 to 5 ml) may be frozen for up to 30 days.
4. Oxalate: Aliquots of urine (2 ml) are diluted with 1 N hydrochloric acid (1.66 ml) and then frozen.

Calculations

1. Calculating 24-hour urine volume
   a. Although 24-hour urine specimens are recommended to minimize the effects of short-term biologic variations in mineral excretion, collecting perfectly timed 24-hour samples may be difficult. The following formula can be used to adjust actual urine volume to a 24-hour period: 1,440 ÷ actual time interval (minutes) x urine volume (1,440 = number of minutes in 24 hours).
   b. Example: A 24-hour urine collection was started at 9:30 a.m. and ended the following day at 8:30 a.m. A total of 350 ml of urine were collected during this period. What is the 24-hour urine volume? 1,440 ÷ 1,380 x 350 = 356.2 ml.
2. Converting mmol/l to mg/dl
   a. Scientists are striving to adopt a uniform system of measurement termed the *System International d 'Unites* to standardize measurements. In this system, concentration is often expressed as moles, millimoles or micromoles of a substance per liter of fluid. Most normal values in the United States are expressed as mg/dl. The following formula can be used to convert mmol/l to mg/dl: mmol/l x atomic weight of substance ÷ 10. The atomic weights of elements can be found in the periodic tables of general chemistry books.
   b. Example: The concentration of calcium from a 24-hour urine sample was 1.35 mmol/l. Convert this value to mg/dl for comparison with normal values. The atomic weight of calcium is 40.08. 1.35 mmol/l x 40.08 ÷ 10 = 5.4 mg/dl.
3. Calculating mg/kg/24-hour or mEq/kg/24-hour excretion
   a. Excretion of metabolites is often expressed on a per kg basis to standardize excretion for dogs of different weights. The following formula can be used to standardize excretion rates: Concentration of substance x 24-hour urine volume ÷ body weight in kg. The units used to express the volume of urine and the concentration of the substance evaluated must be the same.
   b. Example: The concentration of calcium in a 24-hour urine sample was 5.4 mg/dl. A total of 356.2 ml of urine was collected. The dog weighed 10 kg. What is the daily calcium excretion on a per kg basis? First, express the volume of urine collected in the same units as the concentration of the substance measured. The 356.2 ml = 3.562 dl; therefore, 5.4 mg/dl x 3.562 dl ÷ 10 kg = 1.92 mg/kg/24 hours.

Additional considerations

1. Midpoint blood samples. Evaluation of blood during the midpoint of a 24-hour urine collection may help determine if changes in urine concentration reflect changes in serum or plasma concentration of analytes. This information can help detect underlying causes and mechanisms of abnormal mineral excretion. Likewise, evaluation of blood concentrations of some hormones (i.e., parathyroid hormone, calcitriol, etc.) may be helpful in determining the role of hormones in the regulation of mineral excretion.

Table 36-6 continued

2. Antimicrobials
   a. Antimicrobials are administered to prevent iatrogenic urinary tract infection during catheterization of the urinary bladder. The dosage, dosing interval and route should be based on the recommendations of the manufacturer. We recommend that antimicrobial administration be continued for three to five days after urine collection. This represents the time required for normal urothelial repair and replacement.
   b. Select antimicrobials that are primarily excreted in the urine and that minimally affect urine concentrations of minerals, promoters and inhibitors associated with urolith formation. Because some antimicrobials are formulated as salts of sodium or potassium, high concentrations of sodium or potassium may be excreted in urine. We routinely use cephalosporins when collecting urine for amino acid evaluation (i.e., cystine urolithiasis), and ampicillin when collecting urine from dogs with calcium oxalate or urate uroliths.
3. Fasting urine collection
   a. Fasting urine collections have been evaluated to characterize the pathophysiologic mechanism of hypercalciuria in dogs with calcium oxalate uroliths. Dogs that absorb excessive amounts of calcium from their food and subsequently excrete large quantities of calcium in their urine have intestinal hypercalciuria. Hypercalciuria primarily occurs during food consumption; normal or lower quantities of urine calcium are excreted when food is withheld. In addition, dogs with intestinal hypercalciuria have normal serum concentrations of calcium and normal or low serum concentrations of parathyroid hormone. In contrast, urinary calcium excretion during fed and nonfed conditions is similar in dogs with primary hyperparathyroidism (resorptive hypercalciuria) or impaired renal tubular absorption of calcium (renal-leak hypercalciuria).
   b. Fasting urine collections are initiated immediately following collection of urine during standard feeding.
4. Urinary pH. The solubility of mineral salts is influenced by urinary pH. Determination of urinary pH from 24-hour urine samples may be helpful in understanding crystal formation, and can also be used to calculate activity products for several mineral salts commonly found in uroliths. We use an ion selective electrode and pH meter to accurately measure urinary pH.
5. Activity products
   a. The activity product of urine is a mathematical expression used to estimate the degree of saturation of urine with mineral salts. Activity products are calculated by measuring concentrations of major ionizable solutes in urine. For efficiency, computer programs are commonly used to aid in calculating activity products.
   b. Urine in which the activity product exceeds the solubility product is saturated for that particular mineral salt. Although crystals may not form at this degree of saturation, uroliths already present are likely to grow.
   c. Urine in which the activity product exceeds the formation product for a particular mineral salt is associated with an unstable state of oversaturation. Crystal nucleation and rapid crystal growth are likely at this urine concentration.

*Hill's Pet Nutrition, Inc., Topeka, KS, USA.

home-fed foods for use during periods of diagnostic hospitalization (Osborne et al, 1990).

Urolith Analysis

Small uroliths in the urinary bladder or urethra are commonly voided during micturition by female dogs and occasionally by male dogs. Uroliths with a smooth surface (e.g., those composed of ammonium urate or calcium oxalate monohydrate) are more likely to pass through the urethra than uroliths with a rough surface (e.g., those composed of calcium oxalate dihydrate or silica). Commercially manufactured tropical fish nets designed for household aquariums facilitate retrieval of uroliths during voiding (Osborne et al, 1992). They are much less expensive than collection cups with wire mesh bottoms designed for people and available from medical supply houses. Urocystoliths may also be obtained by voiding urohydropropulsion (**Figure 38-5** and **Table 38-7**). If the unaided eye can detect a urolith, it will usually be sufficient size for quantitative analysis.

CATHETER-ASSISTED RETRIEVAL OF UROCYSTOLITHS

Small urocystoliths may be retrieved for analysis by aspirating them through a urethral catheter into a syringe (Osborne et al, 1992; Lulich and Osborne, 1992). Urocystoliths detected by survey radiography may be too large to be removed with the aid of a urethral catheter. However, large urocystoliths are often associated with small ones that may be detected by double-contrast cystography. The diameter of uroliths retrieved is limited by the size of openings or "eyes" in the proximal portion of the catheter and by the diameter of the catheter lumen. It is best to select the largest-diameter catheter that can be advanced into the bladder lumen without traumatizing the urethral mucosa.

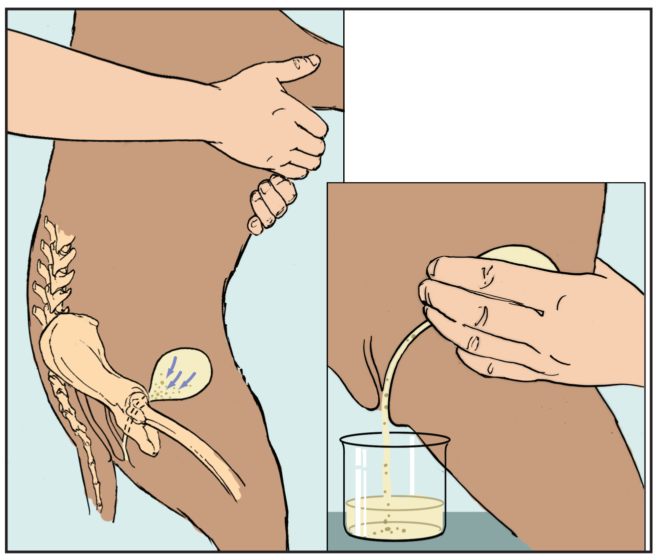

Figure 38-5. To remove urocystoliths by voiding urohydropropulsion, position the patient so that its vertebral column is approximately vertical (Left). The urinary bladder is then gently agitated to promote gravitational movement of urocystoliths into the bladder neck. To expel urocystoliths (Right), voiding is induced by applying steady digital pressure to the urinary bladder. (Adapted from Lulich JP, Osborne CA, Carlson M, et al. Nonsurgical removal of uroliths from dogs and cats by voiding urohydropropulsion. Journal of the American Veterinary Medical Association 1993; 203: 660-663.)

Table 38-7. Voiding urohydropropulsion: A nonsurgical technique for removing small urocystoliths.

1. Perform appropriate diagnostic studies, including complete urinalysis, quantitative urine culture and diagnostic radiography. Determine the location, size, surface contour and number of urocystoliths.
2. Anesthetize the patient, if needed.
3. If the urinary bladder is not distended with urine, moderately distend it with a physiologic solution (e.g., saline, Ringer's, etc.) injected through a transurethral catheter. To prevent overdistention, palpate the bladder per abdomen during infusion. Remove the catheter.
4. Position the patient such that the vertebral spine is approximately vertical.
5. Gently agitate the urinary bladder, with the objective of promoting gravitational movement of urocystoliths into the bladder neck.
6. Induce voiding by manually expressing the urinary bladder. Use steady digital pressure rather than an intermittent squeezing motion.
7. Collect urine and uroliths in a cup. Compare urolith number and size to those detected by radiography and submit them for quantitative analysis.
8. If needed, repeat Steps 3 through 7 until the number of uroliths detected by radiography are removed or until uroliths are no longer voided.
9. Perform double-contrast cystography to ensure that no uroliths remain in the urinary bladder. Repeat voiding urohydropropulsion if small urocystoliths remain.
10. Administer prophylactic antimicrobials for three to five days, or longer if needed.
11. Monitor the patient for adverse complications (i.e., hematuria, dysuria, bacterial urinary tract infection and urethral obstruction with uroliths).
12. Formulate appropriate recommendations to minimize urolith recurrence or to manage uroliths remaining in the urinary tract on the basis of quantitative mineral analysis of voided urocystoliths.

Well-lubricated, soft, flexible catheters are preferable to less flexible ones. The size of openings in the proximal portion of the catheter may be enlarged with a scalpel, razor blade or scissors to facilitate retrieval of urocystoliths. However, care must be used not to weaken the catheter to the point where it could break while being inserted into or removed from the urethra and urinary bladder.

Uroliths may be retrieved by catheter aspiration as follows (**Figure 38-6**). With the patient in lateral recumbency, a well-lubricated catheter should be advanced through the urethra into the bladder lumen. The tip of the catheter should be positioned so that it will not interfere with movement of the bladder wall as fluid is aspirated from the bladder lumen. If the urinary bladder is not distended with urine, it should be partially distended with physiologic (0.9%) saline solution. As a rule of thumb, a normal, empty canine or feline urinary bladder can be partially distended by injecting 3 to 4 ml of fluid per kg body weight. However, the urinary bladder should be palpated per abdomen during the time it is distended with saline solution to ensure that it is not overdistended.

The next step is crucial to successful retrieval of urocystoliths. While urine (and saline solution) is aspirated into the syringe,

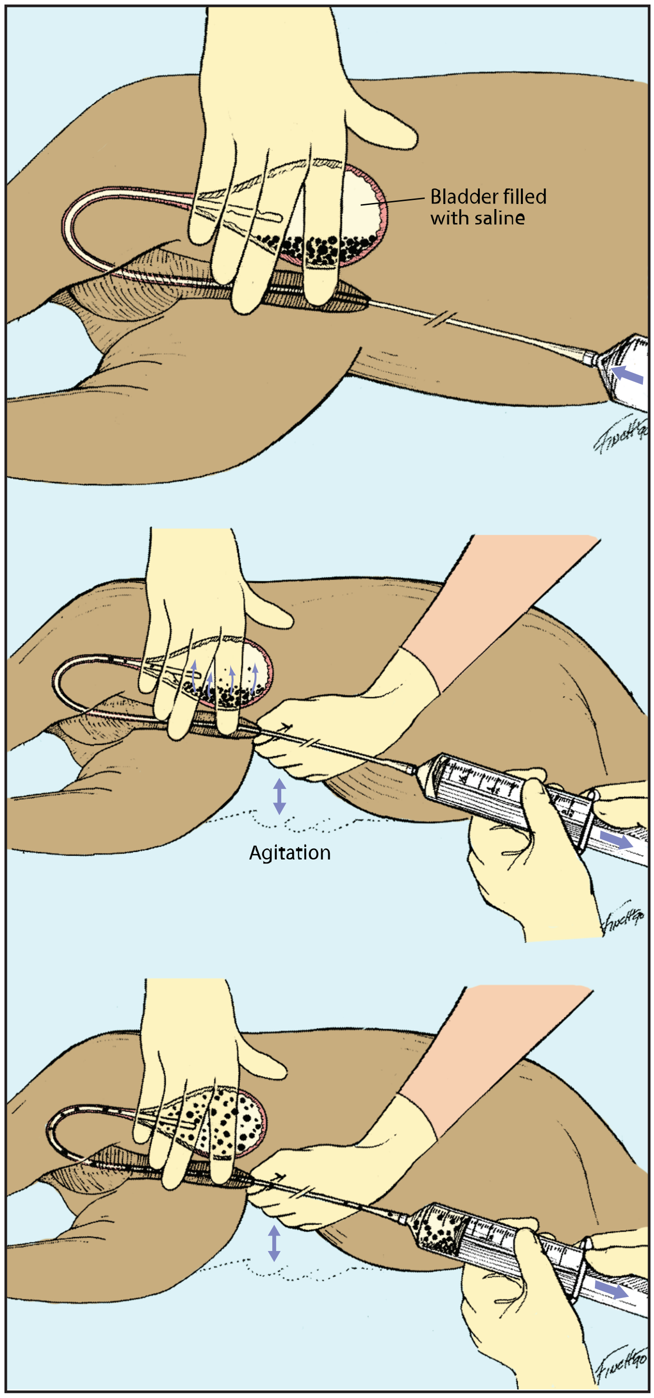

Figure 38-6. Illustration of catheter-assisted retrieval of urocystoliths. With the patient in lateral recumbency, uroliths have gravitated to the dependent portion of the urinary bladder (Top). The bladder lumen has been distended by injection of 0.9% saline solution. Vigorous movement of the abdomen in an up-and-down motion disperses uroliths throughout fluid in the bladder lumen (Middle). Aspiration of fluid from the urinary bladder during movement of the abdominal wall (Bottom) may result in movement of one or more small uroliths into the catheter and syringe. (Adapted from Lulich JP, Osborne CA. Catheter assisted retrieval of canine and feline urocystoliths. Journal of the American Veterinary Medical Association 1992; 201: 111-113.)

an assistant should vigorously and repeatedly move the patient's abdomen in an up-and-down motion. This maneuver disperses uroliths located in the dependent portion of the bladder throughout fluid in the bladder lumen. Small uroliths in the vicinity of the catheter tip may then be aspirated into the catheter along with the urine-saline mixture. It may be necessary to repeat this sequence of steps several times before a sufficient number of uroliths are retrieved. The bladder lumen should be redistended with saline solution each time. Difficulty in aspirating urine and saline solution into the syringe may be caused by poor positioning of the catheter tip or by partial occlusion of the catheter lumen with one or more uroliths. Flushing saline solution through the catheter after it has been removed from the patient often results in the retrieval of uroliths that occlude the catheter lumen.

Care must be used not to overdistend the urinary bladder with saline solution because this will increase the space in which the uroliths are suspended. Because patients with uroliths are predisposed to catheter-induced bacterial UTIs, antimicrobial therapy should be considered immediately before this procedure and for an appropriate period afterward. Proper selection, insertion and positioning of urethral catheters minimize iatrogenic trauma to the lower urinary tract.

COLLECTION AND QUANTITATIVE ANALYSIS OF URINE CRYSTALS

If available data do not indicate the probable mineral composition of uroliths and if uroliths cannot be retrieved with the aid of a urethral catheter, consider preparing a large pellet of urine crystals by centrifugation of urine in a conical-tip centrifuge tube (Osborne et al, 1992, 1995). The quantity of crystalline sediment available for analysis may be increased by repeatedly removing the supernatant after centrifugation, adding additional noncentrifuged urine to the tube containing sediment and again centrifuging the preparation. If the conditions that caused urolith formation are still present, evaluation of the pellet formed from crystalline sediment by quantitative methods designed for urolith analysis may provide meaningful information about the mineral composition of a patient's uroliths. However, crystals identified by this method may only reflect the outer portions of compound uroliths. Therefore, results of quantitative urine crystal analysis should be interpreted in conjunction with other pertinent clinical data.

QUANTITATIVE ANALYSIS OF UROLITHS

The location, number, size, shape, color and consistency of uroliths removed from the urinary tract should be recorded. All uroliths should be saved in a container (preferably a sterile one) and submitted for analysis. Do not give uroliths to owners before analysis. If multiple uroliths are present, one may be placed into a container of 10% buffered formalin for demineralization and microscopic examination. However, formalin should not be used to preserve uroliths for mineral analysis because formalin may alter the results. Because many uroliths contain two or more mineral components, it is important to examine representative portions. The mineral composition of crystalline nuclei may be identical or different from outer layers of uroliths (**Figure 38-7**). The nuclei of uroliths should be analyzed separately from outer layers because knowledge of the mineral composition of the nuclei may suggest the initiating cause of the urolith. Uroliths should not be broken before submission because the central core may be distorted or lost.

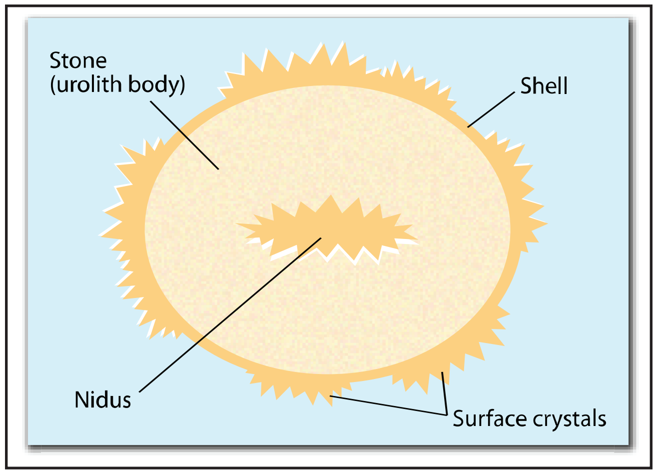

Figure 38-7. Schematic demonstrating the different components that may be observed on the cut surface of a bisected urolith. (Adapted from Osborne CA, Lulich JP, Polzin DJ, et al. Analysis of 77,000 canine uroliths: Perspectives from the Minnesota Urolith Center. Veterinary Clinics of North America: Small Animal Practice 1999; 29: 23.)

Routine analysis of uroliths by qualitative methods of chemical analysis is not recommended. The major disadvantage of this procedure is that only some of the chemical radicals and ions can be detected. In addition, the proportion of the different chemical constituents in the urolith cannot be quantified. In contrast to chemical methods of analysis, physical methods have proved to be far superior in identification of crystalline substances. Physical methods also permit detection of silica and drugs and drug metabolites. They also permit differentiation of various subgroups of minerals (e.g., calcium oxalate monohydrate and calcium oxalate dihydrate, or uric acid, ammonium acid urate and xanthine) and allow semiquantitative determination of various mineral components. Physical methods commonly used by laboratories that specialize in quantitative urolith analysis include a combination of polarizing light microscopy, x-ray diffractometry and infrared spectroscopy (Osborne et al, 1983; Zinn et al, 1986; Ulrich et al, 1996). Some laboratories also are equipped to perform elemental analysis with an energy dispersive x-ray microanalyzer or by neutron activation. Occasionally, chemical methods of analysis and paper chromatography may be used to supplement information provided by physical methods. Chapter 46 lists selected laboratories that perform quantitative urolith analysis.

UROLITH CULTURE

Bacterial culture of the interior of uroliths is indicated if: 1) urine obtained from the patient has not been previously cultured, 2) culture of urine obtained from patients suspected of having struvite uroliths yields no growth or 3) the patient has a

UTI with bacteria that do not produce urease. Bacteria harbored inside uroliths are not always the same as those present in urine. Bacteria detected within uroliths probably represent those present at the time they were formed, and may serve as a source of recurrent UTI. Bacteria may remain viable within uroliths for long periods. In a pilot study, we cultured viable staphylococci from struvite uroliths removed from a miniature schnauzer up to three months following surgery. If all the uroliths have not been removed from the patient, knowledge of the type and antimicrobic susceptibility of bacteria inside uroliths that have been voided or removed may be of therapeutic significance. Procedures for culture of microbes from the inner portions of uroliths have been developed and can be performed by most veterinary diagnostic laboratories (Osborne et al, 1983; Ruby and Ling, 1986).

GUESSTIMATION OF UROLITH COMPOSITION

Formulation of effective dietary and medical protocols for urolith dissolution depends on knowledge of the mineral com-

Table 38-10. Problem-specific and therapeutic-specific database for diagnosis and management of urolithiasis.

1. Obtain appropriate history and perform physical examination, including a rectal examination of the urethra.
2. Perform complete urinalysis; save aliquots of urine for possible determination of mineral concentration.
3. Obtain quantitative urine culture and determine urease activity; test for antimicrobial susceptibility if bacterial pathogens are identified. Consider attempts to isolate ureaplasmas if urease-positive urine is bacteriologically sterile.
4. Perform a complete blood cell count.
5. Freeze an aliquot of serum collected at the time the sample was obtained for the complete blood cell count for possible determination of urea nitrogen, creatinine, calcium and/or uric acid concentrations.
6. Obtain radiographs.
   a. Take survey radiographs of the entire urinary system.
   b. Consider intravenous urography for patients with renal or ureteral uroliths.
   c. Consider intravenous urography or contrast cystography for patients with bladder uroliths.
   d. Consider contrast urethrography for patients with urethral uroliths.
   e. Ultrasonography is recommended if equipment is available.
7. Determine mineral composition of uroliths.
   a. Submit uroliths passed during micturition or retrieved during diagnostic procedures for quantitative analysis.
   b. Use results obtained from the history, physical examination, laboratory examination and radiography to determine probable mineral composition of uroliths.
8. Initiate therapy to eradicate urinary tract infection, if present.
9. Initiate therapy for urolithiasis.
   a. Initiate therapy to promote dissolution of uroliths if amenable to dietary and medical therapy.
      Formulate followup protocol to monitor dissolution of uroliths.
      Formulate alternative treatment options if uroliths do not dissolve or if problems such as recurrent outflow obstruction occur.
      b. Remove uroliths by voiding urohydropropulsion.
      c. Remove uroliths by nephrotomy or cystotomy.
      Obtain bladder or kidney biopsy specimens for microscopic examination during surgical procedure.
      Correct any anatomic defects, if present.
      Compare number of uroliths removed during surgery with the number identified by radiography.
      Obtain postsurgical radiographs to evaluate completeness of urolith removal.
      Submit uroliths for quantitative analysis.
10. After uroliths are surgically removed or medically dissolved, initiate therapy to prevent recurrence.
11. Formulate followup protocol with clients.

Box 38-2. Principles of Urolith Treatment and Prevention.

OVERVIEW

Surgery has been the time-honored method of managing all types of urolithiasis in dogs. Although surgery has been an effective method that provides immediate elimination of uroliths, it is associated with several limitations, including: 1) persistence of underlying causes and a high rate of recurrence of uroliths despite surgery, 2) patient factors that enhance adverse consequences of general anesthesia or surgery and 3) inability to remove all uroliths or fragments of uroliths during surgery. In addition, situations occasionally arise in which owners of companion animals will not consent to surgical therapy but will consider dietary and medical therapy. Dietary and medical dissolution of uroliths may be considered for these and other reasons (i.e., the urolith is asymptomatic).

Results of several experimental and clinical investigations have confirmed the efficacy of dietary and medical dissolution of canine uroliths. Despite the feasibility of dissolution of uroliths, however, this form of therapy is associated with potential hazards. Uroliths always predispose patients to urinary tract infection (UTI) and obstructive uropathy. Risks and benefits of dietary and medical vs. surgical and dietary and medical therapy must be considered for each patient.

Detailed descriptions of nonsurgical and surgical methods for reestablishing urine outflow are beyond the scope of the discussion but are available elsewhere. Likewise, details pertaining to surgical removal of uroliths, endoscopic and percutaneous manipulation of uroliths, chemolysis via nephrostomy, disintegration of renal and ureteral uroliths via ultrasound and shockwave lithotripsy have been reviewed.

DIETARY AND MEDICAL DISSOLUTION OF UROLITHS

Therapy should not be initiated before appropriate samples have been collected for diagnosis. The objectives of dietary and medical management of uroliths are to arrest further growth and to promote urolith dissolution by correcting or controlling underlying abnormalities. For therapy to be effective, it must induce undersaturation of urine with lithogenic crystalloids by: 1) increasing the solubility of crystalloids in urine, 2) increasing the volume of urine in which crystalloids are dissolved or suspended and 3) reducing the quantity of lithogenic crystalloids in urine. For example, attempts to increase the solubility of crystalloids in urine often include administration of medications designed to change urinary pH to create a less favorable environment for crystallization. Likewise, diuresis is commonly induced to increase the volume of urine in which crystalloids are dissolved or suspended. A dietary change is an example of a method to reduce the quantity of lithogenic crystalloids in urine.

In general, dietary and medical treatment should be formulated in stepwise fashion, with the initial goal of reducing the urine concentration of lithogenic substances. Medications that have the potential to induce a sustained alteration in body composition of metabolites, in addition to urine concentration of metabolites, should be reserved for patients with active or frequently recurrent uroliths. Caution must be used so that the side effects of treatment are not more detrimental than the effects of the uroliths.

Results of experimental and clinical studies have revealed that the size and number of uroliths do not dictate the likelihood of response to therapy. We have had success in dissolving uroliths that are small and large, single and multiple. However the rate of dissolution is related to size and surface area of the urolith exposed to urine. Just as one large ice cube dissolves more slowly than an equal volume of crushed ice, one large urolith will dissolve more slowly than an equal volume of many smaller uroliths. Rate of dissolution is influenced by surface area of the urolith exposed to undersaturated urine.

Difficulty in inducing complete dissolution of uroliths by creating urine that is undersaturated with the suspected lithogenic crystalloid should prompt consideration that: 1) the wrong mineral component was identified, 2) the nucleus of the urolith is of different mineral composition than outer portions and/or 3) the owner or the patient is not complying with therapy.

SURGICAL REMOVAL OF UROLITHS

Detection of uroliths is not in itself an indication for surgery. However, along with dietary and medical management, surgical intervention may play an important role in therapy of urolithiasis.

position of uroliths. Because a variety of different types of uroliths and nephroliths occur in dogs (**Tables 38-8** and **38-9**), veterinarians should use a protocol that facilitates determination of the mineral composition of uroliths based on probability (**Tables 38-10** and **38-11**). Formulation of dietary and medical therapy based on the mineral composition of uroliths determined by this protocol is usually associated with a high degree of success in dissolving uroliths or arresting their growth.

Attempts to induce dissolution of uroliths may be hampered if the uroliths are heterogeneous in composition. This has not been a significant problem in dogs with uroliths composed primarily of magnesium ammonium phosphate with small quantities of calcium apatite because the solubility characteristics of the two minerals are similar. Veterinarians have encountered difficulty in dissolving uroliths composed primarily of struvite with an outer shell composed primarily of calcium apatite. Difficulty will also be encountered in attempting to induce complete dissolution of a urolith with a nucleus of calcium oxalate, calcium phosphate, ammonium urate or silica and a shell of struvite because the solubility characteristics of this combination of minerals are dissimilar. These phenomena should be considered if dietary and medical therapy seems to be ineffective after initially reducing the size of uroliths (**Box 38-2**).

REFERENCES

The references for **Chapter 38** can be found at www.markmorris.org.

Surgical candidates include patients: 1) with urolith-induced obstruction to urine outflow that cannot be corrected by nonsurgical techniques, especially in patients with concomitant UTI, 2) with uroliths that are refractory to current methods of dietary and medical dissolution (e.g., silica, calcium oxalate and calcium phosphate uroliths), 3) with uroliths that are increasing in size or number despite dietary and medical therapy designed to inhibit their growth or cause their dissolution (especially if they are obstructing urine outflow or causing progressive deterioration in renal function), 4) with nephroliths and renal dysfunction of such a nature that the time required to induce dietary and medical dissolution is likely to be associated with more renal dysfunction than that associated with surgical procedures, 5) with anatomic defects of the urogenital tract that predispose patients to recurrent UTI and urolithiasis and are amenable to surgical correction at the time uroliths are removed and 6) unable to respond to dietary and medical management because of poor client compliance with therapeutic recommendations.

Complete obstruction to urine outflow caused by uroliths in patients with concomitant UTI should be regarded as a surgical emergency. In this situation, rapid spread of infection and associated damage to the urinary tract, especially the kidneys, are likely to induce septicemia and peracute renal failure caused by a combination of obstruction and pyelonephritis.

Unilateral nephroliths and ureteroliths that cause outflow obstruction and markedly impair function of the associated kidney should be managed by surgical intervention or (if possible) percutaneous nephropyelolithotomy. Dietary and medical therapy designed to induce urolith dissolution over several weeks in patients with poorly draining kidneys is unlikely to be effective because the urolith(s) will not be continuously bathed with newly formed urine modified to induce litholysis. The same concept applies to urethroliths that cannot be removed by nonsurgical methods.

Surgical removal of uroliths followed by dietary and medical litholytic protocols may be of value in some patients. Examples include patients in which uroliths or fragments of uroliths remain after surgery, and patients with crystalluria of a character and magnitude that indicate rapid recurrence is likely. Surgical incisions should be repaired using meticulous technique if protein-restricted canine litholytic foods are used.

PREVENTION OF UROLITH RECURRENCE

Uroliths tend to recur. Prevention of recurrent uroliths, which reduces the need for dietary and medical therapy and surgery, is therefore cost effective. In general, preventive strategies are designed to eliminate or control the underlying causes of various types of uroliths. When causes cannot be identified, preventive strategies encompass efforts to minimize risk factors associated with lithogenesis. These strategies commonly include dietary modification.

Carroll Weiss

"We should provide the type of medical care that we would desire if we were the patient rather than the doctor."
Carl A. Osborne

TERMINOLOGY

Purines are catabolites derived from DNA and RNA. They include adenine, guanine, hypoxanthine, xanthine, anhydrous uric acid, uric acid monohydrate, uric acid dihydrate, salts of uric acid (e.g., ammonium urate, sodium urate, calcium sodium urate) and in most mammals, allantoin. Each of these catabolites may behave differently.

PREVALENCE AND MINERAL COMPOSITION

Purine uroliths (ammonium urate, sodium urate, calcium urate, uric acid, xanthine, etc.) accounted for 6.4% (22,412 of 350,803) of all canine uroliths submitted to the Minnesota Urolith Center from 1981 to 2007 (Table 38-8), and 4.97% (2,020 of 40,612) of all canine uroliths analyzed in 2007. Purines accounted for 13.3% of all upper tract uroliths analyzed at the Minnesota Urolith Center from 1981 to 2006 (Table 38-9). Most dogs with xanthine uroliths had a history of treatment with allopurinol. Purines composed 23% of uroliths retrieved from dogs less than 12 months old. The mean age of dogs at the time of ammonium urate urolith retrieval was approximately four years (range one month to 17 years). The mean age of dogs at the time of sodium urate and calcium urate urolith retrieval was also approximately four years (range six months to 14 years). The mean age of dogs at the time of uric acid urolith retrieval was three years (range one month to 12 years). The mean age at the time of xanthine urolith retrieval was approximately five years (range one and one-half to nine years). Males were affected more often than females with ammonium urate (90 vs. 10%), sodium and calcium urate (99 vs. 1%), uric acid (88 vs. 12%) and xanthine (81 vs. 19%) uroliths.

In our series, 66 different breeds were affected with ammonium urate uroliths including Dalmatians (61%), miniature schnauzers (7%), Yorkshire terriers (5%), Shih Tzus (4%) and English bulldogs (4%). Twelve different breeds had sodium and

Table 39-1. Common characteristics of canine purine uroliths.

Chemical names	**Formulas**
Ammonium acid urate	$C_5H_3N_4O_3NH_4 \bullet H_2O$
Sodium acid urate	$C_5H_3N_4O_3Na \bullet H_2O$
Uric acid	$C_5H_4N_4O_3 \bullet 2H_2O$
Xanthine	$C_5H_4N_4O_2$

Some variations in mineral composition
Ammonium urate only
Sodium calcium urate
Sodium urate only
Uric acid only
Xanthine only
Ammonium urate mixed with variable quantities of sodium urate, or sodium and calcium urate, magnesium ammonium phosphate and/or calcium oxalate
Sodium and calcium oxalate
Xanthine and uric acid

Physical characteristics
Color: Light or dark brown, brown-green
Shape: Variable. Usually round or ovoid in urinary bladder, may assume shape of renal pelvis (funnel shaped), may assume jackstone appearance. Usually smooth, occasionally irregular or rough.
Nuclei: Nuclei and concentric laminations are common.
Density: Usually dense and brittle. Radiographically, purine uroliths have marginal radiodensity compared with soft tissue. Some may be radiolucent.
Number: Single or multiple
Location: May be located in kidneys, ureters, urinary bladder (most common) and/or urethra.
Size: Usually small (1 mm to 1 cm in diameter), occasionally large (more than 1 cm)

Prevalence
Approximately 5 to 6% of all canine uroliths. Approximately 13% of canine nephroliths.
May be recurrent.

Characteristics of affected canine patients
In Dalmatian dogs, most common in males.
Mean age at diagnosis is four years (range <1 to >17 years).
Most commonly observed in Dalmatian dogs, English bulldogs, miniature schnauzers, Yorkshire terriers and Shih Tzus.

calcium urate uroliths; however, these uroliths were primarily encountered in Dalmatians (92%) and English bulldogs (4%). Six different breeds had uric acid uroliths; Dalmatians were affected most commonly (80%). Five different breeds had xanthine uroliths, including Dalmatians (56%) and English bulldogs (35%). Ammonium urate (97%), sodium and calcium urate (96%), uric acid (100%) and xanthine (94%) uroliths were more commonly removed from the lower urinary tract than the upper urinary tract.

Ammonium urate, sodium and calcium urate and uric acid uroliths typically appear as multiple, small, smooth, hard, round or ovoid structures with a characteristic brown-green color (**Table 39-1**). However, the physical appearance of urate uroliths may vary depending on the presence and quantity of different mineral components, the quantity of matrix they contain, the site(s) of their formation and growth and whether or not they are associated with concurrent urinary tract disorders. Rarely, they form jackstones. Examination of cross sections of urate uroliths frequently reveals concentric laminations and nuclei located in the geographic center of the urolith.

ETIOPATHOGENESIS AND RISK FACTORS

Applied Biochemistry: Uric Acid Metabolism

Uric acid is one of several biodegradation products of purine nucleotide metabolism (**Figure 39-1**) (Foreman, 1984; Gutman, 1964; Greene et al, 1969; Williams and Wilson, 1990; Wyngaarden and Holmes, 1978). Purines are made up of three groups of compounds: 1) oxypurines (hypoxanthine, xanthine, uric acid and allantoin), 2) aminopurines (adenine, guanine) and 3) methylpurines (caffeine, theophylline and theobromine). In most dogs and cats, allantoin is the major metabolic end product, and it is the most soluble of the purine metabolic products excreted in urine (Bartges et al, 1992; Cohen et al, 1965; Giesecke and Stangassinger, 1990; Roch-Ramel and Peters, 1978). Whereas uric acid provides a means for nitrogen excretion in some animals (reptiles, birds, etc.), mammals excrete nitrogen in the form of urea (ureotelics). Because people and apes lack the enzyme uricase (urate oxidase), they cannot metabolize uric acid into allantoin. It has been estimated that the serum uric acid level of people is up to 100 times greater than serum creatinine concentrations in other mammals (Rafey et al, 2003).

The serum concentration of uric acid is derived from two sources: 1) exogenously from food and 2) endogenously from de novo purine biosynthesis, involving nucleic acid turnover and production from non-purine precursors. Purine synthesis occurs in the liver and involves recycling of guanine and hypoxanthine. In people, excess nucleotides are converted to xanthine and then uric acid via xanthine oxidase (Asplin, 1996). In most dogs and cats, excess uric acid is converted to allantoin via the hepatic enzyme uricase. Allantoin is highly soluble in urine, whereas uric acid and xanthine are not. Therefore, people are at greater risk for uric acid urolithiasis than most dogs and cats (Cameron and Sakhaee, 2007). Tissue catabolism or consumption of foods high in purine content may increase purine catabolism. In people, consumption of high-purine foods can cause as much as a 50% increase in urinary excretion of uric acid compared to consumption of a purine-free diet (Fellstrom et al, 1983).

In people, it has been estimated that approximately one-third of excess uric acid is eliminated by way of the intestinal tract (Sorensen, 1965). The kidneys eliminate the remainder. Although the mechanisms involved in glomerular filtration, renal tubular absorption and renal tubular secretion of uric acid have not yet been completely defined, it appears that all three mechanisms are involved (Cameron and Sakhaee, 2007). It has been proposed that glomeruli freely filter uric acid. The proximal tubules actively reabsorb approximately 99% of filtered uric acid. Subsequently, the renal tubules secrete approximately 50% of the filtered uric acid, followed by 40% postsecretory reabsorption. The final uric acid excretion is approximately 10% (Cameron and Sakhaee, 2007).

Uric acid is a weak organic acid with an ionization constant (pKa) of 5.5. At a temperature of 37°C (98.6°F), human urine has a pKa of 5.35. Uric acid is less soluble than its base (urate) (Cameron and Sakhaee, 2007).

Uroliths composed of uric acid (anhydrous uric acid, uric acid dihydrate, sodium urate, ammonium urate) or xanthine form because urine is oversaturated with these substances (Brown and Purich, 1992; Finlayson, 1978; Porter, 1963; Smith, 1990). Ammonium urate (also known as ammonium acid urate and ammonium biurate) is the monobasic ammonium salt of uric acid. It is the most common naturally occurring purine urolith form observed in dogs (Osborne et al, 1995). Other naturally occurring purine uroliths include sodium urate (also known as sodium acid urate or monosodium urate), sodium calcium urate, potassium urate and uric acid dihydrate (Osborne et al, 1995).

Uric Acid, Sodium Urate and Ammonium Urate

Risk factors for urate lithogenesis in dogs include: 1) increased renal excretion and urine concentration of uric acid, 2) increased renal excretion or renal production of ammonium ions, 3) increased microbial production of ammonium ions, 4) aciduria, 5) formation of highly concentrated urine and 6) presence of promoters or absence of inhibitors of urate urolith formation (Kruger and Osborne, 1986). Genetic factors may be important because urate uroliths are common in certain breeds of dogs. For example, Dalmatian dogs and English bulldogs have an inherent predisposition to forming urate uroliths (See sections about Dalmatian and non-Dalmatian dogs below.) (Case et al, 1993; Sorenson and Ling, 1993). Dietary components may promote urate urolith formation in predisposed dogs because dietary purines may be digested, absorbed, incorporated into the body's purine pool and eventually excreted in urine (**Tables 39-2** and **39-3**). Thus, metabolism of dietary purines may result in oversaturation of urine with urate lithogenic substances (e.g., other related metabolites of uric acid). In studies of normal dogs, consumption of high-protein foods was associated with greater urine uric acid excretion and increased urine saturation with uric acid, sodium urate and ammonium urate, when compared with consumption of low-protein foods (Bartges et al, 1995, 1995a, 1995b). The same association was found in Dalmatian dogs (Giesecke and Tiemeyer, 1984; Lulich et al, 1995).

Xanthine

Xanthine is a product of purine metabolism and is converted to uric acid by the enzyme xanthine oxidase (Bartges et al, 1992; Parks and Granger, 1986). Hereditary xanthinuria is a rarely recognized disorder of people characterized by a deficiency of xanthine oxidase (Fildes, 1989; Holmes et al, 1974; Kario et al, 1991; Kawachi et al, 1990; Landas et al, 1989; Mateos, 1987). Consequently, abnormal quantities of xanthine are excreted in urine as a major end product of purine metabolism. Because xanthine is the least soluble of the purines naturally excreted in urine, xanthinuria may be associated with formation of uroliths (Bartges et al, 1992; Fildes, 1989; Kario et al, 1991; Ling et al, 1991; Pyrah, 1979).

Naturally occurring xanthinuria and xanthine urolithiasis have been reported to occur in a few dogs (Kidder and Chivers, 1968; Kucera et al, 1997). Xanthine urolithiasis was reported in a family of cavalier King Charles spaniels (van Zuilen et al, 1997).

Uroliths whose composition was at least 70% xanthine

accounted for less than 0.1% (362 of 373,612) of all canine uroliths submitted to the Minnesota Urolith Center from 1998 to 2007. Almost all canine xanthine uroliths in our series were obtained from dogs treated with varying doses of allopurinol given orally.

At the Minnesota Urolith Center, the mean age of dogs at the time of xanthine urolith retrieval was five years (range = three to 168 months). In this regard, the cavalier King Charles spaniel breed is an exception inasmuch that naturally occurring xanthine uroliths have been recognized when these dogs were less than one year of age.

Male dogs (86%) were affected more often than females (9%) in our series (5% were of unknown gender). Of these dogs, 190 were castrated males (53%), 122 were intact males (34%), 23 were spayed females (6%), 11 were intact females (3%) and 16 were of unknown gender (4%). With the apparent exception of cavalier King Charles spaniels (six dogs in our series), the predominance of allopurinol-induced xanthine uroliths in males has also been observed by others (Bartges et al, 1993; Ling et al, 1991). In a report of 38 xanthine-containing uroliths, 36 occurred in males and two occurred in females (Ling et al, 1991).

At our center, 40 different breeds were affected including Dalmatians (50%), mixed breed (12%), English bulldogs (4%), miniature schnauzers (4%), German shepherd dogs (2%), boxers (2%) and cavalier King Charles spaniels (six dogs = 2%). Similar observations have been made by others (Ling et al, 1991). In one report, of 38 xanthine-containing uroliths, 30 were found in Dalmatians, two were found in miniature/toy poodles and one was retrieved from a Shih Tzu (Ling et al, 1991). The affected breeds for five xanthine specimens were apparently unknown. Of the 362 uroliths composed of xanthine in our series, 316 dogs were given allopurinol, 10 were given fluoroquinolones and two received sulfadiazine (34 uroliths were submitted without a drug history).

The most common cause of xanthine uroliths in dogs is formation secondary to therapy with allopurinol. Allopurinol rapidly binds to and inhibits the action of xanthine oxidase, thereby decreasing conversion of hypoxanthine to xanthine and xanthine to uric acid. The result is a reduction of serum and urine concentrations of uric acid with a reciprocal increase in serum and urine concentrations of xanthine (**Figure 39-2**). Administration of allopurinol at high doses, especially with concurrent consumption of high purine foods, will result in formation of xanthine uroliths (**Figure 39-3**).

Dalmatian Dogs

Dalmatian dogs are predisposed to urate uroliths because their ability to oxidize uric acid to allantoin is intermediate between that of people and many non-Dalmatian dogs (Bartges et al, 1994; Duncan and Curtiss, 1971; Friedman and Byers, 1948). This characteristic is due to an autosomal recessive trait (Safra et al, 2005). People normally have a serum uric acid concentration of approximately 3 to 7 mg/dl, and excrete approximately 500 to 700 mg of uric acid in their urine per day (Williams and Wilson, 1990). Of all non-Dalmatian dogs studied to date, most have a serum uric acid concentration of less than 0.5 mg/dl, and excrete approximately 10 to 60 mg of uric acid in their urine per day. Dalmatian dogs have a serum uric acid concentration that is two to four times that of non-Dalmatian dogs and excrete more than 400 to 600 mg of uric acid in their urine per day (Bovee, 1984; Ling et al, 1997).

Studies of the fate of uric acid in Dalmatian dogs have revealed unique hepatic and renal pathways of metabolism (Friedman and Byers, 1948; Duncan and Curtiss, 1971). Of these two metabolic sites, reciprocal allogenic renal and hepat-

ic transplantations between Dalmatian and non-Dalmatian dogs indicate that the hepatic mechanism is quantitatively the more significant (Cohn et al, 1965; Kuster et al, 1972). The liver of Dalmatian dogs does not completely oxidize available uric acid, even though it contains sufficient concentrations of uricase. Compared with non-Dalmatian dogs, Dalmatian dogs convert uric acid to allantoin at a reduced rate (Benedetti et al, 1997; Kocken et al, 1996; Kuster et al, 1972). It has been hypothesized that their hepatic cellular membranes are partially impermeable to uric acid (Harvey and Christensen, 1964; Tiemeyer et al, 1986).

The proximal renal tubules of Dalmatian dogs reabsorb less uric acid than those of non-Dalmatian dogs; a small amount is secreted by the distal tubules (Kessler et al, 1959). In non-Dalmatian dogs, 98 to 100% of the uric acid in the glomerular filtrate is reabsorbed by the proximal tubules and returned to the liver for further metabolism (Kessler et al, 1959; Roch-Ramel et al, 1978). The distal tubules are thought to secrete uric acid in the urine of non-Dalmatian dogs (Foreman, 1984; Mudge et al, 1968; Nolan and Foulkes, 1971; Tiemeyer et al, 1986).

The definitive mechanism(s) of urate urolith formation in Dalmatian dogs is unknown. Increased urinary excretion of uric acid is a risk factor rather than a primary cause. Urate uroliths are recognized 13 times more commonly in males than females; the average age of dogs when uroliths are diagnosed is 4.5 years (Albasan et al, 2005; Case et al, 1993). Although all Dalmatian dogs excrete relatively high quantities of uric acid in their urine, apparently only a small percentage forms urate uroliths (Case et al, 1993; Albasan et al, 2005). At one time, it was thought that urolith-forming Dalmatian dogs did not excrete greater quantities of uric acid in their urine than non-urolith-forming Dalmatian dogs. However, further studies revealed that insensitive methods for measuring urine uric acid concentration were responsible for this erroneous conclusion. When steps are taken to ensure that urine uric acid remains in solution, differences in urine uric acid concentrations between non-urolith-forming Dalmatian and urolith-forming Dalmatian dogs may be expected (Felice et al, 1990; Schaible, 1986).

Urate uroliths commonly affect Dalmatian dogs; however, not all uroliths formed by Dalmatian dogs are composed of ammonium urate. For example, of 2,020 uroliths formed by Dalmatian dogs, 93% were composed of purines (ammonium urate, sodium urate, uric acid and xanthine), 3% were of mixed composition, 1% were struvite, 1% were calcium oxalate, 2% were compound uroliths and less than 1% were cystine.

Non-Dalmatian Dogs

Comparatively little is known about urate lithogenesis in non-Dalmatian dogs that do not have portal vascular anomalies. Many breeds of dogs are affected with urate urolithiasis. Although urate uroliths are commonly encountered in Dalmatian dogs, approximately 30 to 60% of all canine urate uroliths analyzed by quantitative methods are found in other breeds (Bovee and Mcquire, 1984; Kruger and Osborne, 1986; Osborne et al, 1995). English bulldogs have a significantly higher incidence of urate urolithiasis compared with other breeds (Bartges et al, 1994). Clinical evaluation of eight male English bulldogs with confirmed ammonium urate urocystoliths revealed mild elevations in serum uric acid concentration. The size of their livers was normal, as was the serum concentration of hepatic enzymes, blood concentration of ammo-

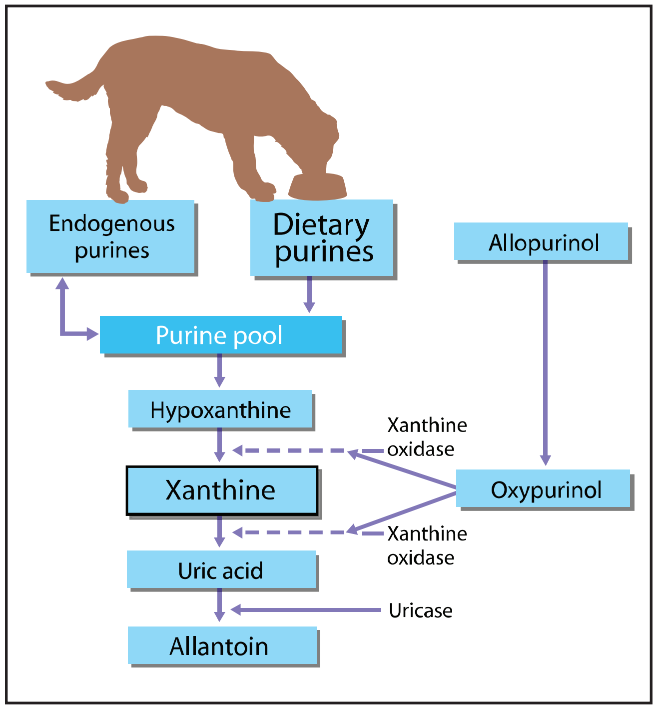

Figure 39-2. Diagram of purine degradation in dogs fed a maintenance food and given allopurinol.

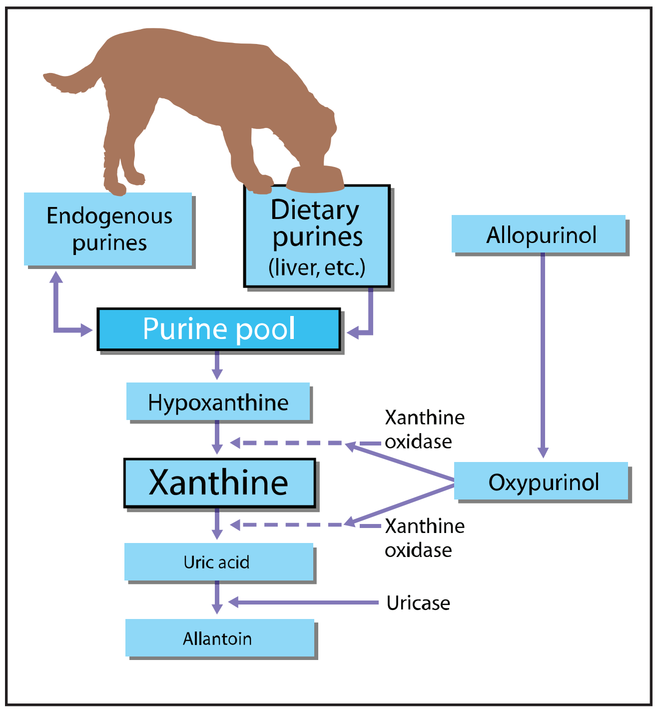

Figure 39-3. Diagram of purine metabolism in dogs that consume a purine-rich food and are given allopurinol.

nia and bromsulphalein retention. Other non-Dalmatian breeds that appear to have a significantly higher incidence of urate urolithiasis based on quantitative urolith analyses are miniature schnauzers, Shih Tzus and Yorkshire terriers (Osborne et al, 1995).

Urate uroliths from non-Dalmatian dogs have been recognized most frequently in males. Uroliths have been detected throughout the lifespan of affected dogs; however, they were most frequently detected in dogs three to six years of age.

Regardless of cause, severe hepatic dysfunction may predispose dogs to urate lithogenesis, especially ammonium urate uroliths. Observations and evidence derived from experimental models suggest that prolonged consumption of foods with markedly restricted levels of protein may be associated with formation of urate uroliths in dogs (Kruger and Osborne, 1986). Biochemical and histologic evaluation of these dogs suggests that long-term consumption of foods severely restricted in protein may induce hepatocellular dysfunction and concomitant hyperuricemia. Hepatic cirrhosis has also been associated with urate uroliths in dogs and other species (Rothuizen and van den Ingh, 1980). However, foods with severely restricted protein levels and other causes of hepatic dysfunction have been uncommon causes of ammonium urate urolithiasis. Nonetheless, their significance relative to ammonium urate lithogenesis deserves further study.

Dogs with Portal Vascular Anomalies or Hepatic Microvascular Dysplasia

Ammonium urate uroliths have frequently been observed in dogs with portal vascular anomalies. These uroliths occur in males and females and usually have been detected before dogs reach three years of age (Rothuizen and van den Ingh, 1980; Marretta et al, 1981; Hardy and Klausner, 1983; Kruger and Osborne, 1986).

Direct communication between the portal and systemic vasculature shunts blood around the liver. Severe hepatic atrophy and diminished hepatic function may occur as a result. Hepatic dysfunction in turn is associated with reduced hepatic conversion of uric acid to allantoin and reduced conversion of ammonia to urea. The predisposition of dogs with portal vascular anomalies to urate urolithiasis is probably associated with concomitant hyperuricemia, hyperammonemia, hyperuricuria and hyperammonuria (Kruger and Osborne, 1986; Hardy and Klausner, 1983). Serum uric acid concentrations in 15 dogs with portal vascular anomalies evaluated at the University of Minnesota Veterinary Teaching Hospital were increased (values ranged from 1.2 to 4.0 mg/dl) (Hardy and Klausner, 1983). Concurrent hyperuricuria, hyperammonuria, hyperuricemia and hyperammonemia were observed in an 18-month-old Bernese mountain dog with recurrent ammonium urate uroliths associated with a portal vascular anomaly (Kruger and Osborne, 1986). This dog had a urine uric acid concentration of 42 mg/kg body weight/day and a urine ammonia concentration of 3.2 mM/kg body weight/day while the dog was fed a protein-restricted food. Hyperuricuria, hyperammonuria, hyperuricemia and hyperammonemia were observed in three miniature schnauzers with ammonium urate uroliths associated with portal vascular anomalies. In these dogs, urine uric acid concentrations were approximately 50 mg/kg body weight/day and urine ammonia concentrations were approximately 1.5 mM/kg body weight/day while the dogs consumed a growth-type food. When two of these dogs consumed a purine-restricted food, urine uric acid concentrations were approximately 17 mg/kg body weight/day and urine ammonia concentrations were approximately 0.6 mM/kg body weight/day.

Not all dogs with portal systemic anomalies develop concurrent ammonium urate urolithiasis. Definition and characterization of other factors responsible for promoting or inhibiting urate lithogenesis in affected dogs require further investigation.

We have observed urate urocystolith formation in miniature schnauzers and Yorkshire terriers with hepatic microvascular dysplasia. Dogs with this disorder do not have macrovascular shunts. Rather, intrahepatic microvascular shunting apparently occurs. Clinical signs and biochemical abnormalities are similar to those seen in dogs with macroscopic vascular shunts. When affected dogs consumed a growth-type food, urinary uric acid excretion was approximately 30 mg/kg body weight/24 hours, urinary ammonia excretion was approximately 1.25 mmol/kg body weight/24 hours and urinary pH was less than 6.5 pH units. When dogs were fed a purine-restricted food, urinary uric acid excretion was approximately 16 mg/kg body weight/24 hours, urinary ammonia excretion was approximately 0.5 mmol/kg body weight/24 hours and urinary pH was greater than 7.0 pH units.

Not all dogs with portal systemic anomalies or hepatic microvascular dysplasia develop concurrent ammonium urate urolithiasis. Definition and characterization of other factors responsible for promoting or inhibiting urate lithogenesis in affected dogs require further investigation.

Dietary Risk Factors

Concentrations of lithogenic substances in urine depend on urine volume. Because commercial dry foods are associated with production of less urine compared with moist foods, consumption of dry foods is likely a risk factor for urate urolith formation.

Dalmatian dogs consuming foods containing more than 20% dry matter (DM) protein, and protein sources high in purines and purine precursors (**Table 39-3**) are at increased risk for urate lithogenesis. Because urate uroliths associated with portal vascular anomalies are often diagnosed in dogs less than one year of age, it is probable that they were consuming foods with increased protein content.

Urine acidity is a risk factor for urate lithogenesis because the solubility of most purines, especially ammonium urate, is pH-dependent. Therefore, consumption of foods that promote aciduria (e.g., high-protein foods or those with other acidifying ingredients) may be a risk factor.

BIOLOGIC BEHAVIOR

Purine uroliths have the potential to undergo spontaneous dis-

solution, remain active (grow) or become inactive (remain unchanged). Although spontaneous dissolution of non-urate-containing uroliths has occasionally been observed, spontaneous dissolution of urate uroliths has apparently not been reported.

Recurrence of urate uroliths may be influenced by several factors including: 1) persistence of underlying causes, 2) incomplete removal of all uroliths from the urinary tract at the time of lithotripsy or surgery, 3) persistence or recurrence of urinary tract infections (UTIs) with urease-producing bacteria and/or 4) failure to comply with therapeutic or prophylactic recommendations. Frequent recurrence of urate uroliths is not surprising considering the persistence of disorders associated with urate urolithiasis.

A relatively high incidence of recurrence following surgical removal is a unique characteristic of urate urolithiasis in Dalmatian and non-Dalmatian dogs. In several studies using qualitative methods of urolith analysis, recurrence was reported in 33 to 50% of dogs with urate uroliths (Brown et al, 1977; Finco et al, 1970; Weaver, 1970). In these dogs, uroliths generally recurred within one year after diagnosis and treatment. Recurrence of urate urolithiasis in non-Dalmatian dogs with portal vascular anomalies also appears to be similar (Marretta et al, 1981; Hardy and Klausner, 1983). In dogs, recurrence of urolithiasis with uroliths composed of minerals other than those present during the initial episode is uncommon. However, uroliths predominantly composed of minerals other than ammonium urate, sodium urate or uric acid may form in canine patients originally affected with urate uroliths (Porter, 1963; Brown et al, 1977).

KEY NUTRITIONAL FACTORS

The key nutritional factors for foods intended for dissolution and prevention of urate uroliths in dogs are discussed below and summarized in **Table 39-4**.

Water

Concentrations of lithogenic substances in urine depend on urine volume. Augmenting urine volume with the goal of decreasing urine uric acid and ammonium concentrations and enhancing urine flow through the excretory pathway is an important strategy. Feeding moist foods is recommended because commercial dry foods are associated with production of a smaller volume of more concentrated urine. Clients should encourage water intake to achieve a urine specific gravity less than 1.020. (See Assess and Determine the Feeding Method: Urate Urolith Dissolution below.)

Sodium chloride supplementation is sometimes recommended to increase urine volume. However, increased sodium intake poses other risks to urate urolithiasis patients. (See Sodium below.) It is noteworthy that sodium chloride given orally to normal human volunteers for 10 days did not alter urine uric acid concentration (Breslau and Pak, 1983).

Attempts at increasing urine volume through administration of diuretic drugs have been reported in people. Long-term administration (up to three years) of hydrochlorothiazide to human patients with uroliths containing calcium salts resulted in increased serum and urine uric acid concentrations (Pak et al, 1978).

Table 39-4. Key nutritional factors for foods for dissolution and prevention of canine purine uroliths.

Factors	Dietary recommendations
Water	Water intake should be encouraged to achieve a urine specific gravity <1.020
Protein and purines	Restrict dietary protein to 10 to 18% dry matter (DM) Restrict dietary purine: the first three non-water ingredients on product label ingredient panel should be low in purines (**Table 39-3**)
Sodium	Moderate sodium restriction (<0.3% DM) Avoid sodium supplements
Urinary pH	Feed a food that maintains an alkaline urine (urinary pH = 7.1 to 7.5)

Protein and Purines

Dalmatian dogs consuming foods containing more than 20% DM protein and protein sources high in purines and purine precursors (**Table 39-3**) are at increased risk for urate lithogenesis. We have observed formation of purine uroliths in some dogs consuming lesser amounts of dietary purines; therefore, other factors are apparently involved.

The range of dietary protein associated with urate urolith formation in dogs with portal vascular anomalies is unknown. In these dogs, the degree of urine saturation with purines is probably related, at least in part, to the degree of vascular shunting and to dietary protein consumption. Because urate uroliths associated with portal vascular anomalies are often diagnosed in dogs less than one year of age, it is probable that these dogs were consuming foods with increased protein content. Growth-type foods are typically higher in protein than foods formulated for adult maintenance.

High-protein foods, besides being potential sources of urine ammonium, purines and purine precursors, can also induce aciduria. Urine acidity is a risk factor for urate lithogenesis because the solubility of most purines, especially ammonium urate, is pH-dependent. On the other hand, protein restriction, to the degree that would be found in a restricted-protein, urate-litholytic food, can impair urine concentrating ability (by decreasing renal medullary urea concentration), making use of additional diuretic agents unnecessary. Furthermore, feeding low-protein, low-purine foods to patients with ammonium urate uroliths, in combination with appropriate allopurinol therapy, has resulted in urolith dissolution (Bartges et al, 1994; Osborne et al, 1986, 1995). Therefore, for urate litholytic foods, or to aid in the prevention of purine lithogenesis, recommend foods that restrict dietary protein to 10 to 18% DM. The minimum recommended allowance for protein in foods for healthy adult dogs is 10% DM (NRC, 2006). Also, if possible, clients should avoid feeding foods with a high purine content. Ideally,

at least the first three non-water ingredients in the ingredient panel on a food label should be low in purines (**Table 39-3**).

Sodium
Sodium chloride can be added to food to increase thirst and urine volume. However, excess sodium increases urine calcium excretion and therefore is a risk factor for calcium oxalate and calcium phosphate urolithiasis, particularly if the urinary pH is high. Also, for the same reason, if oral urine alkalinizing agents are used, potassium citrate may be a better choice than sodium bicarbonate. Besides these risks, supplemental sodium sources may contribute to hypertension in salt-sensitive dogs.

Moderate restriction of dietary sodium (<0.3% DM) in urate litholytic and prevention foods is unlikely to be harmful and may be helpful. Typically, commercial dog foods contain two to three times this amount. The minimum recommended allowance for sodium in foods for healthy adult dogs is 0.08% DM (NRC, 2006).

Urinary pH
Under physiologic conditions associated with alkaluria, urine contains low concentrations of ammonia and ammonium ions (Hande et al, 1984). The specific goal of treatment with a urate litholytic food or an oral urine alkalinizing agent (e.g., potassium citrate) is to maintain a urinary pH within a range of 7.1 to 7.5. Urinary pH values greater than 7.5 should be avoided until it is determined whether or not they provide a significant risk factor for formation of calcium phosphate uroliths. Deposition of a layer of calcium phosphate crystals around existing urate uroliths may impede urolith dissolution. Potassium citrate apparently prevents acid metabolites from increasing renal tubular production of ammonia.

FEEDING PLAN

Current recommendations for dissolution of canine ammonium urate uroliths include a combination of: 1) feeding a litholytic food, 2) formation of an increased quantity of less concentrated urine, 3) alkalinization of urine, 4) administration of xanthine oxidase inhibitors (i.e., allopurinol) and 5) eradication or control of UTIs (Bartges et al, 1992, 1994; Ling, 1995; Lulich et al, 1995; Osborne et al, 1986). **Table 39-5** summarizes the recommendations for dietary and medical dissolution and prevention of canine ammonium acid urate uroliths.

Assess and Select the Food: Urate Urolith Dissolution
Urate litholytic foods have been used most successfully in patients with normal portal vasculature. However, occasional successes have been reported to occur in patients with portal vascular anomalies (Bartges et al, 1994; Osborne et al, 2000). Consumption of a properly formulated urate litholytic food by healthy and urate urolith forming dogs resulted in marked reductions in urine uric acid and ammonia excretion (Lulich et al, 1995; Bartges et al, 1995). **Table 39-6** lists selected commercial veterinary therapeutic foods used for urate urolith dissolution (and prevention) and compares their key nutritional factor content with recommended levels. Select a food that most closely matches the recommended levels of key nutritional factors. Recommend that clients avoid feeding inappropriate amounts of treats or vitamin-mineral supplements. Check the product label or contact the manufacturer to see if the product is approved by the Association of American Feed Control Officials (AAFCO) or some other credible regulatory agency for long-term feeding to adult dogs (**Box 39-1**).

Encourage clients to increase water consumption of patients with urate urolithiasis. When possible, recommend they feed a moist food. Although understandably difficult in some patients, fluid intake should be encouraged throughout the day to help promote a constantly high urine volume. Clients should ensure water is readily available and is not too cold or warm.

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Dogs Without Portal Vascular Anomalies
At the Minnesota Urolith Center, 25 dogs with ammonium urate uroliths were treated with dietary (urate litholytic food) and allopurinol therapy. Complete dissolution occurred in nine dogs (36%), partial dissolution in eight dogs (32%) and no dissolution in eight dogs (32%). A similar dissolution protocol in seven dogs with sodium urate uroliths resulted in complete dissolution in two dogs (29%), partial dissolution in three dogs (42%) and no dissolution in two dogs (29%) (Bartges et al, 1994). Inability to dissolve urate uroliths was usually associated with formation of xanthine. In some dogs with partial urolith dissolution, the remaining uroliths were completely retrieved using voiding urohydropropulsion (Figure 38-5 and Table 38-7) (Lulich et al, 1993) or catheter-assisted retrieval (Figure 38-6) (Lulich and Osborne, 1992). The mean time for urate urolith dissolution in 11 dogs was 3.5 months (median one month, range one to 18 months). Using the above protocol, a nephrolith presumed to be composed of urate was dissolved in nine months in a six-year-old, neutered female English bulldog.

Dogs with Portal Vascular Anomalies
Few studies have been reported about the biologic behavior of ammonium urate uroliths in dogs with portal vascular anomalies. It is logical to hypothesize that elimination of hyperuricuria and reduction of urine ammonium concentration following surgical correction of anomalous shunts would result in sponta-

Canine Calcium Oxalate Urolithiasis: Changing Paradigms in Detection, Management and Prevention

Jody P. Lulich
Carl A. Osborne
Lori A. Koehler

"A well-defined problem is half solved."
Carl A. Osborne

OVERVIEW

Uroliths composed of calcium oxalate monohydrate and calcium oxalate dihydrate form as a result of the interaction of several different environmental and demographic risk factors, and several different metabolic disturbances. That is, not all calcium oxalate uroliths are "created in the same way." Some of these factors are primary and some are compensatory. Identification of primary and secondary abnormalities associated with calcium oxalate urolithiasis is essential if therapy is to be consistently safe and effective.

Of the biogenic uroliths that affect dogs, cats and people, those composed of calcium oxalate have been the most problematic. However, substantial progress has been made in the last 10 years. We predict that within the next 10 years, we will understand how to identify and safely modify the underlying mechanisms involved with calcium oxalate urolithiasis. That is, within the next decade we will have reached our goal of making the surgical removal of uroliths a treatment of historical interest.

PREVALENCE AND MINERAL COMPOSITION

Calcium oxalate accounted for 38% of all canine uroliths submitted to the Minnesota Urolith Center from 1981 to 2007 (Table 38-8) and 41% (16,761 of 40,612) of all canine uroliths submitted in 2007 (**Figure 40-1**) (Osborne and Lulich, 2007). Calcium oxalate also accounted for 43% of all upper urinary tract uroliths analyzed at our Center from 1981 to 2006 (Table 38-9). From 2000 to 2006 calcium oxalate composed only 1% of uroliths retrieved from dogs less than 12 months old. The mean age of dogs at the time of calcium oxalate urolith retrieval was approximately 8.5 years (range = one to 25 years; median = 8.7 years). Males (74%) were affected more often than females (22%); the age of approximately 4% of affected dogs was not specified. A total of 214 different breeds were affected including miniature schnauzers (18%), mixed breeds (14%), Yorkshire terriers (9%), Bichon Frises (8%), Shih Tzus (7%), Lhasa apsos (5%), Pomeranians (4%), dachshunds (3%), Maltese (3%),

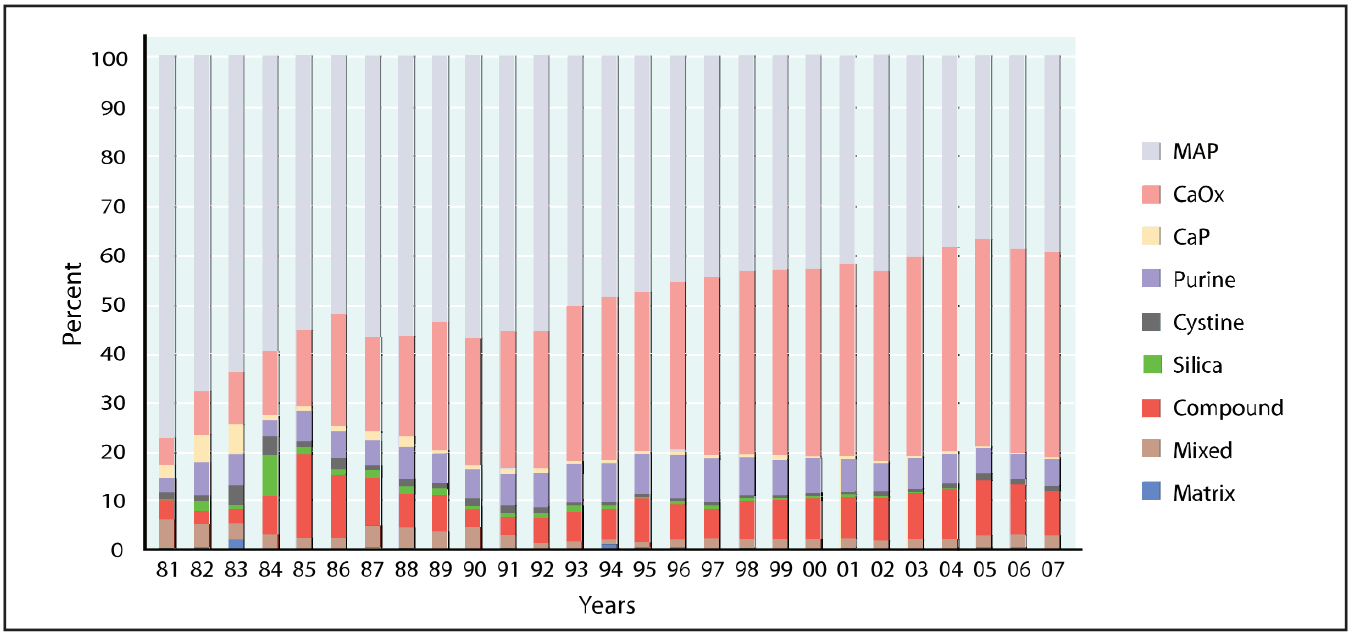

Figure 40-1. Bar graph illustrating increased occurrence of canine calcium oxalate uroliths submitted to the Minnesota Urolith Center from 1981 to 2007. Note the overall decline in struvite urolith submissions and the increase in calcium oxalate submissions. Key: MAP = magnesium ammonium phosphate (struvite), CaOx = calcium oxalate, CaP = calcium phosphate.

miniature poodles (3%), Chihuahuas (2%) and Jack Russell terriers (2%). Calcium oxalate uroliths were more commonly removed from the lower urinary tract (97%) than the upper urinary tract (3%).

Although different combinations of calcium oxalate salts have been identified in canine uroliths, the predominant form encountered has been calcium oxalate monohydrate (whewellite; Table 38-8). Pure calcium oxalate monohydrate has been observed in dogs more frequently than pure calcium oxalate dihydrate (weddelite). A similar observation has been made in cats and people with calcium oxalate uroliths. When calcium oxalate salts occur in combination in human, feline and canine uroliths, the dihydrate salt is usually found surrounding a nucleus of the monohydrate salt (Koide et al, 1982). The significance of this observation has not yet been confirmed, although it has been suggested that calcium oxalate dihydrate may form initially and then be converted to calcium oxalate monohydrate (Leusmann et al, 1984; Otnes, 1983; Schubert and Brien, 1981; Tomazic and Nancollas, 1982). In people, detection of calcium oxalate dihydrate on the outside of a urolith may indicate recent formation, whereas detection of external layers of calcium oxalate monohydrate indicates lack of recent urolith formation (Berenyl et al, 1972). If valid in dogs, this hypothesis would be of clinical significance because it would help to determine if the disorders underlying calcium oxalate urolithiasis were persistent. This in turn would provide evidence of the need for continuous therapy to minimize urolith recurrence. In one study, human patients with calcium oxalate dihydrate uroliths had more recurrences of uroliths than did patients with calcium oxalate monohydrate uroliths (Leusmann et al, 1984).

Calcium oxalate monohydrate and dihydrate uroliths are typically dense and brittle; they have relatively small quantities (~3%) of matrix. Pure calcium oxalate monohydrate and calcium oxalate dihydrate have different colors and shapes (**Table 40-1**). In people, uroliths composed of calcium oxalate monohydrate frequently assume the shape of mulberries or jackstones (Otnes, 1983). To date, only a few canine calcium oxalate jackstones have been observed at the Minnesota Urolith Center.

ETIOPATHOGENESIS AND RISK FACTORS

In order for calcium oxalate uroliths to form, urine must be supersaturated with calcium and oxalic acid. Therefore, increasing the urine concentration of calcium and/or oxalic acid promotes calcium oxalate crystal formation. Hypercalciuria has been documented to occur in dogs with calcium oxalate uroliths (Lulich et al, 1991).

At one time it was thought that increases in urine oxalic acid concentration promoted calcium oxalate urolith formation in people to a greater degree than comparable increases in urine calcium concentration (Smith, 1991). Results of more recent studies, however, indicate that oxalic acid and calcium contribute equally to urine supersaturation with calcium oxalate (Pak et al, 2004). Although hyperoxaluria apparently has not been documented to occur in dogs with calcium oxalate uroliths, the relationship between the concentrations of calcium and oxalic acid within the digestive and urinary tracts is fundamental to understanding calcium oxalate urolithiasis.

Dietary Risk Factors

Dietary ingredients that promote hypercalciuria or hyperoxaluria represent nutritional risk factors for calcium oxalate

urolith formation (**Tables 40-2** and **40-3**). Therefore, reduction of dietary calcium and oxalate appears to be a logical therapeutic goal. However, it is not necessarily harmless. Reducing consumption of only one of these substances (calcium) may increase the availability of the other (oxalic acid) for intestinal absorption and subsequent urinary excretion. To minimize this undesirable shift in the modulation of oxalic acid absorption from the intestine, reduction in dietary calcium should be accompanied by an appropriate reduction in dietary oxalic acid.

Dogs with calcium oxalate urolithiasis frequently consume human food. Calcium oxalate is the most common urolith type recognized in people living in developed countries. As people feed their dogs the same dietary proportions and ingredients they feed themselves, it is logical to postulate that dogs would be exposed to similar nutritional risk factors for urolith formation (**Table 40-2**). Results of epidemiologic studies performed at the Minnesota Urolith Center support this hypothesis.

In addition to human food consumption, an association between calcium oxalate urolithiasis and consumption of commercially available treats has also been recognized. The high sodium content of some commercial dog treats may help explain this association because sodium consumption promotes hypercalciuria (Lulich et al, 1992).

Certain dietary excesses and deficiencies have also been recognized as potential risk factors. Excessive administration of vitamin D, sodium or magnesium promotes hypercalciuria. Because ascorbic acid is a precursor of oxalate, excessive quantities of vitamin C should be avoided. Although dogs with calcium oxalate uroliths have not been evaluated for pyridoxine deficiency, kittens fed pyridoxine-deficient foods exhibited hyperoxaluria (Bai et al, 1989).

Other Risk Factors

Calcium oxalate uroliths have been recognized in many breeds of dogs (see Prevalence and Mineral Composition above). Infrequently encountered breeds include boxers, bloodhounds, coonhounds, Dalmatians, English bulldogs, Newfoundlands, German shorthaired pointers, Skye terriers, wirehaired terriers, golden retrievers, Labrador retrievers and St. Bernards. Approximately 74% of calcium oxalate uroliths have affected male dogs. Most were detected in adults (mean and median age was eight to nine years).

Geographic location has been identified as a risk factor for calcium oxalate urolith formation in people living in the United States (Mandel and Mandel, 1989). In a study of approximately one million people, investigators observed a north-south and west-east gradient such that people living in the southeastern U.S. (Alabama, Arkansas, Florida, Georgia, Louisiana, Mississippi, North and South Carolina, Tennessee and Virginia) had the highest rate of urolith formation (Soucie et al, 1996). Studies evaluating geographic location as a risk factor for calcium oxalate urolith formation in dogs have apparently not yet been reported.

Certain clinical conditions also represent potential risk factors for calcium oxalate urolith formation. Hyperparathyroidism, hyperadrenocorticism, hypervitaminosis D, paraneoplastic hypercalcemia and furosemide administration promote hypercalciuria. In people, intestinal resection, hereditary hyperoxaluria and excessive ascorbic acid administration promote hyperoxaluria (Park and Pearle, 2007).

Table 40-1. Common characteristics of canine calcium oxalate uroliths.

Chemical names	Formulas	Crystal names
Calcium oxalate monohydrate	$CaC_2O_4 \bullet H_2O$	Whewellite
Calcium oxalate dihydrate	$CaC_2O_4 \bullet 2H_2O$	Weddellite

Variations in mineral composition
Calcium oxalate monohydrate only
Calcium oxalate dihydrate only
Combinations of calcium oxalate monohydrate and dihydrate
Calcium oxalate (monohydrate and/or dihydrate) mixed with variable quantities of calcium phosphate. Variable quantities of struvite or ammonium acid urate may also be present.
Calcium oxalate (monohydrate and/or dihydrate) nucleus surrounded by other minerals especially infection-induced struvite

Physical characteristics
Color: Calcium oxalate monohydrate uroliths are usually tan or brown. Calcium oxalate dihydrate uroliths are usually white or cream colored. Surfaces may be red to black if uroliths are coated with blood.
Shape: Variable. Calcium oxalate monohydrate uroliths are usually round or elliptical and have a smooth, polished surface. Occasionally, they may develop a jackstone or mulberry shape. Calcium oxalate dihydrate uroliths and mixed calcium oxalate monohydrate/calcium oxalate dihydrate uroliths are usually round to ovoid and have an irregular surface caused by protrusion of sharp-edged crystals. Occasionally, they may develop a jackstone shape.
Nuclei: Radial striations and concentric laminations may occur.
Density: Very dense and brittle. Survey radiographs reveal that calcium-containing uroliths are radiodense compared with soft tissue.
Number: Single or multiple
Location: May be located in renal pelves, ureters, urinary bladder (most common) and/or urethra.
Size: Sub-visual to several centimeters

Prevalence
Approximately 41% of all canine uroliths. More than 43% of canine upper tract uroliths.
May be recurrent (more than 50% recur by three years after removal)

Characteristics of affected canine patients
More common in males (73%) than females (22%)
Mean age at diagnosis is about eight years (range <1 to >25 years)
Most commonly observed in miniature schnauzers, Lhasa apsos, Yorkshire terriers, Shih Tzus and Bichon Frises

Hypercalciuria

Hypercalciuria can be localized into at least three subtypes according to the primary site of the underlying cause (i.e., intestine, kidney or skeleton): 1) absorptive hypercalciuria is characterized by intestinal hyperabsorption of calcium, 2) renal hypercalciuria is characterized by impaired renal tubular reabsorption of calcium and 3) resorptive hypercalciuria is characterized by bone demineralization.

Available evidence indicates that calcium homeostasis is principally achieved through the actions of parathyroid hormone (PTH) and 1,25-dicholecalciferol (1,25-vitamin D) on the intestines, kidneys and skeleton. For example, states of low

Table 40-2. Some potential risk factors for canine calcium oxalate uroliths.

Diet	Urine	Metabolic status	Drugs
Acidifying potential	Hypercalciuria	Chronic metabolic acidosis	Urine acidifiers
High protein content	Hyperoxaluria	Males	Furosemide
High sodium content	Hypocitraturia?	Breed	Glucocorticoids
Excessive calcium content	Hypomagnesuria?	Miniature schnauzers	Sodium chloride
Excessive restriction of calcium	Hyperuricuria?	Miniature poodles	Vitamin D
Low moisture content	Increased crystal promoters	Lhasa apsos	Ascorbic acid
Excessive phosphorus restriction	Decreased crystal inhibitors	Yorkshire terriers	
Excessive magnesium content	Urine concentration	Shih Tzus	
Excessive magnesium restriction	Urine retention	Bichon Frises	
Excessive vitamin D content		Older age	
Excessive vitamin C content		Hypercalcemia	
Deficient pyridoxine?		Glucocorticoid excess	
High oxalate content		Hypophosphatemia	
		Hyperoxalemia?	
		Osteolysis?

serum ionized calcium concentration result in compensatory PTH- and 1,25-vitamin D-mediated mobilization of calcium from the skeleton, absorption of calcium from the intestine and conservation of calcium by the kidneys. High serum ionized calcium concentrations suppress release of PTH and production of 1,25-vitamin D. The result is decreased skeletal mobilization and intestinal absorption of calcium and enhanced renal calcium excretion. Thus, it is apparent that hypercalciuria can result from increased renal clearance of calcium due to: 1) excessive intestinal absorption of calcium, 2) impaired renal conservation of calcium and/or 3) excessive skeletal mobilization of calcium. Although hypercalciuria can be localized according to the site of the apparent primary defect in calcium transport, compensatory changes typically occur that involve other sites. For example, renal-leak hypercalciuria is associated with secondary hyperparathyroidism, which in turn is associated with varying degrees of bone resorption of calcium and phosphorus and varying degrees of intestinal calcium absorption. Absorptive hypercalciuria results in a positive calcium balance, which in turn suppresses production and release of PTH, decreasing renal tubular reabsorption of calcium.

Hypercalcemic hypercalciuria results from increased glo-

Table 40-4. Summary of distinguishing clinical manifestations for different types of hypercalciuria.

Features	Absorptive hypercalciuria	Renal-leak hypercalciuria	Resorptive hypercalciuria

*Phosphorus is retained in serum as glomerular filtration rate declines.
**Dx food = diagnostic food used in the evaluation of normal dogs and those with calcium oxalate uroliths.

merular filtration of mobilized calcium, which overwhelms normal renal tubular reabsorptive mechanisms. This phenomenon is called resorptive hypercalciuria because excessive bone resorption is associated with increased serum calcium concentrations. In dogs, normocalcemic hypercalciuria is thought to result from either intestinal hyperabsorption of calcium (so-called absorptive hypercalciuria), or decreased renal tubular reabsorption of calcium (so-called renal-leak hypercalciuria) (**Table 40-4**). Absorptive hypercalciuria is characterized by increased urine calcium excretion and urine calcium concentration, normal serum calcium concentration and normal or low serum PTH concentration. Because absorptive hypercalciuria depends on dietary calcium, urine calcium excretion and urine calcium concentration are normal or significantly reduced during the fasting state. However, urine calcium excretion and urine calcium concentration typically increase during non-fasting conditions. Mean 24-hour urine calcium excretion in 33 normal beagles was 0.32 ± 0.2 mg/kg body weight/day during fasting and 0.51 ± 0.3 mg/kg body weight/day when dogs consumed a standard food[a] (Lulich et al, 1991a). By comparison, mean urine calcium excretion in five miniature schnauzers with calcium oxalate urolithiasis and absorptive hypercalciuria was 1.0 ± 0.5 mg/kg body weight/day during fasting and 2.84 ± 0.9 mg/kg body weight/day during non-fasting urine collections (Lulich et al, 1991).

A primary defect observed in people with absorptive hypercalciuria is apparent intestinal hyperabsorption of calcium, which results in increased excretion of excess calcium in urine. In addition to enhanced glomerular filtration of absorbed dietary calcium, decreased PTH secretion results in decreased renal tubular reabsorption of filtered calcium. The same phenomenon appears to occur in dogs with absorptive hypercalciuria.

Primary intestinal abnormalities of calcium absorption, disorders of 1,25-vitamin D production and hypophosphatemia-induced hypervitaminosis D have been recognized as causes of hypercalciuria in people (Park and Pearle, 2007). Absorptive hypercalciuria in people has recently been further subclassified as to whether increased calcium excretion is food unresponsive (Type 1) or food responsive (Type II). The underlying mechanism(s) of absorptive hypercalciuria has not been identified in dogs. However, hypophosphatemia or elevated levels of 1,25-vitamin D were not observed in five dogs with absorptive hypercalciuria.

In human studies, renal-leak hypercalciuria and resorptive hypercalciuria have been documented, but have been recognized less frequently than excessive intestinal absorption of calcium. The defect with renal-leak hypercalciuria is impaired tubular reabsorption of calcium. Patients with renal-leak hypercalciuria have high serum PTH concentrations. Increasing PTH secretion counters the effect of additional calcium lost in urine and maintains normal blood calcium levels. Hypercalcemia associated with calcium oxalate urolithiasis is the hallmark of patients with resorptive hypercalciuria. Hypercalcemia is not a characteristic of patients with excessive intestinal absorption of calcium or renal-leak hypercalciuria. An in-depth review of the pathophysiology of hypercalciuria has recently been published (Park and Pearle, 2007).

Hyperoxaluria

As described above in the discussion about dietary risk factors influencing calcium oxalate urolithiasis, the effect of oxalic acid on calcium oxalate urolithiasis depends on the interactions of calcium and oxalic acid that occur in the lumen of the intestine and in urine. Intestinal hyperabsorption or accelerated endogenous synthesis of oxalic acid can result in hyperoxaluria. In healthy people, the majority of urine oxalic acid is derived from the endogenous metabolism of ascorbic acid, glycine, glyoxylate and tryptophan. The daily quantity of endogenously produced oxalic acid is apparently minimal. In people, hyperoxaluria has been associated with inherited abnormalities of excessive oxalic acid synthesis (primary hyperoxaluria), increased consumption of foods containing high quantities of oxalic acid or oxalic acid precursors (**Table 40-3**), pyridoxine deficiency and disorders associated with fat absorption (Williams and Smith, 1983). We could not find any reports of inherited hyperoxaluria or hyperoxaluria associated with intestinal resection and fat malabsorption in dogs. However, increases in urine oxalic acid excretion have been recognized in kittens fed pyridoxine-deficient foods (Bai et al, 1989).

In people, approximately 10 to 20% of urine oxalic acid is

absorbed from dietary ingredients. Urine oxalic acid excretion is inversely related to dietary intake of calcium. In the intestinal tract, oxalic acid complexes with calcium and is excreted in feces as an insoluble salt. A decrease in the combination of oxalic acid with calcium to form calcium oxalate results in an increased quantity of soluble oxalic acid available for intestinal absorption. Therefore, it is logical to assume that urolith-forming patients with intestinal hyperabsorption of calcium, or those consuming foods with inappropriately low calcium compared with oxalic acid, would be at risk for increased intestinal absorption of dietary oxalic acid, hyperoxaluria and subsequent calcium oxalate urolith formation.

Hypocitraturia

Hypocitraturia is a common physiologic disturbance in people with calcium oxalate urolithiasis. It has been reported to affect 20 to 60% of calcium stone formers (Hamm and Hering-Smith, 2002). Urine citric acid is a negative anion that combines with cationic calcium, thus reducing the quantity of calcium available to complex with oxalic acid. Calcium citrate is more soluble than calcium oxalate. Citrate is also a buffer, and as such, minimizes the formation of calcium phosphate. Citrate also directly inhibits crystallization and aggregation of calcium oxalate and calcium phosphate (Park and Pearle, 2007).

The role of low urine citric acid concentration in the etiology of canine calcium oxalate urolithiasis is not completely resolved. Hypocitraturia has been observed in dogs with calcium oxalate uroliths; however, mechanisms responsible for decreased urine citric acid excretion in dogs are as yet unknown. It is known that acid-base homeostasis influences the quantity of citric acid excreted in urine (Simpson, 1983). In normal dogs, acidosis is associated with decreased urine citric acid formation and excretion, whereas alkalosis promotes urine citric acid formation and excretion.

Several abnormalities associated with acidosis may lead to hypocitraturia. Examples include distal renal tubular acidosis, chronic diarrhea associated with systemic acidosis and excessive consumption of animal protein, which produces excess acid and promotes bone demineralization. A recent study of a high-protein, low-carbohydrate diet typified by the so-called Atkins diet revealed a significant reduction in urinary pH and citrate during the induction and maintenance phases of the diet (Reddy et al, 2002). Hypocitraturia may also occur in association with thiazide-induced hypokalemia, which produces intracellular acidosis. Idiopathic hypocitraturia may also occur independent of acidosis.

The Role of Oxalate-Degrading Bacteria

Recent studies have revealed a correlation between enteric colonization of oxalate-degrading bacteria (ODB), mainly *Oxalobacter formigenes*, and the absence of hyperoxaluria and/or calcium oxalate formation in rats and people (Sidhu et al, 1999; Troxel et al, 2003). Consider the following evidence: 1) Using a rat model, one group of investigators demonstrated a rapid reversal of hyperoxaluria after probiotic administration of *O. formigenes* (Sidhu et al, 2001). 2) Oral administration of *O. formigenes* to people with Type 1 hyperoxaluria reduced the oxalate concentration in plasma and urine (Hoppe et al, 2006). 3) In rats, *O. formigenes* colonization induced colonic secretion/excretion of endogenous oxalate and was associated with reduced oxalate levels in plasma (Hatch et al, 2006). These studies indicate that colonization of ODB in the gastrointestinal (GI) tract can prevent enteric absorption of oxalic acid and increase fecal excretion of endogenously produced oxalate. ODB possess two enzymes, formyl CoA transferase and oxalate CoA decarboxylase, that metabolize oxalic acid to formate and CO_2 (Lung et al, 1994; Sidhu et al, 1997). In addition, *O. formigenes* carries a specialized membrane transporter, oxalate/formate antiporter, to transport the substrate and product across the membrane (Ruan et al, 1992). *O. formigenes*, *Lactobacillus* spp., *Bifidobacterium lactis, Enterococcus faecalis* and *Eubacterium lentum* are major ODB found in mammalian GI tracts (Allison et al, 1986; Federici et al, 2004; Hokama et al, 2000; Ito et al, 1996; Weese et al, 2004). *O. formigenes,* an anaerobe, is solely dependent on oxalate as an energy source. It is considered to efficiently degrade oxalate in the GI tract of rats, sheep, pigs and people (Allison et al, 1985, 1986; Daniel et al, 1987).

There have been few studies reported in which ODB have been evaluated in dogs in context of calcium oxalate uroliths. Oxalate-degrading *Lactobacillus* spp. are present in healthy dogs and cats (Weese et al, 2004). However, the effect of intestinal colonization with ODB on urine oxalate excretion has apparently not been investigated. Oxalate-degrading bacterial activity in canine feces has been demonstrated (Daniel et al, 1987). However, the role of ODB in the pathogenesis of canine and feline calcium oxalate urolithiasis apparently has not been reported.

Considering the current evidence derived from human and rodent models, we hypothesize that decreased concentrations of intestinal ODB are a likely risk factor for calcium oxalate urolith formation in dogs and cats (Lulich et al, 2008). We also hypothesize that the prevalence of ODB in the intestine of dogs with calcium oxalate uroliths is lower than in clinically healthy dogs without uroliths. If our hypothesis is correct, administration of novel probiotics that deliver viable ODB to the intestine and subsequent colonization of the intestinal mucosa with *O. formigenes* should minimize calcium oxalate urolith recurrence.

Macromolecular Crystal Growth Inhibitors

In addition to urine concentration of lithogenic minerals and other ions, large molecular weight glycoproteins in urine profoundly enhance solubility of calcium oxalate. One such protein called nephrocalcin minimizes calcium oxalate crystal growth in human urine (Nakagawa et al, 1983). In studies of nephrocalcin obtained from urolith-forming patients, this crystallization inhibitor lacked appropriate quantities of carboxyglutamic acid residues and was unable to prevent crystal growth. Preliminary studies of urine obtained from dogs with calcium oxalate uroliths have revealed that nephrocalcin also lacks appropriate numbers of carboxyglutamic acid residues com-

pared with nephrocalcin isolated from normal canine urine (Carvalho et al, 2006).

Tamm-Horsfall glycoprotein and glycosaminoglycans inhibit calcium oxalate crystal aggregation. One hypothesis is that the mechanism of action of these proteins is to block growth sites on crystals, thereby inhibiting formation of calcium oxalate uroliths (Deganello, 1993).

BIOLOGIC BEHAVIOR

Calcium oxalate uroliths may be voided in the urine or become lodged in any portion of the urinary tract. Uroliths that remain in the urinary tract may continue to grow slowly or may become inactive (no further growth). Not all persistent uroliths are associated with clinical signs. Unlike infection-induced struvite uroliths, most calcium oxalate uroliths are not associated with urinary tract infection (UTI). Uroliths composed of the dihydrate salt of calcium oxalate appear to be less likely to cause complete urinary obstruction because of their irregular surface contour. Their jagged surface may prevent them from forming a continuous seal within the lumen of the urethra. However, if uroliths remain in the urinary tract, dysuria, UTI, partial or total urinary obstruction and polyp formation are potential sequelae. Spontaneous dissolution of calcium oxalate uroliths in dogs has apparently not been reported.

In a retrospective clinical survey of 438 dogs surgically treated for urolithiasis, 111 patients had 155 known recurrences (Brown et al, 1977). Recurrence was observed in 25% of dogs with calcium oxalate uroliths. We performed two retrospective studies and found that the rate of recurrence of calcium oxalate uroliths increased with the length of time that dogs were evaluated: 3% recurred after three months, 9% after six months, 36% after one year, 42% after two years and 48% after three years (Lulich et al, 1992a). The second study evaluated urolith recurrence in Bichon Frise dogs. After one year, 37% had their first recurrence; after two years, 64% had their first recurrence and 8% had their second recurrence; after three years, 90% had their first recurrence, 15% had their second recurrence and 4% had their third recurrence. Urolith recurrence was detected in 100% of dogs evaluated at or after four years (Lulich et al, 2004). Owner and patient compliance with therapy and persistence of factors responsible for urolith initiation at the time of urolith eradication influence the frequency of urolith recurrence.

KEY NUTRITIONAL FACTORS

Because dissolution of calcium oxalate uroliths in dogs has not been reported, the focus of dietary management is to prevent calcium oxalate urolith recurrence. The goals of dietary prevention include: 1) reducing calcium concentration in urine, 2) reducing oxalic acid concentration in urine, 3) promoting high concentration and activity of inhibitors of calcium oxalate crystal growth and aggregation in urine and 4) reducing concentration of urine.

Certain dietary excesses and deficiencies have been recognized as potential risk factors for calcium oxalate urolithiasis and are the basis of key nutritional factors. **Table 40-5** summarizes the key nutritional factors for calcium oxalate prevention.

Table 40-5. Key nutritional factors for foods for prevention of calcium oxalate uroliths.

Factors	Recommended levels
Water	Water intake should be encouraged to achieve a urine specific gravity <1.020 Moist food will increase water consumption and formation of less concentrated urine
Protein	Avoid excess dietary protein Restrict dietary protein to 10 to 18% dry matter (DM)
Calcium	Avoid excess dietary calcium, especially dietary supplements given independent of diet Restrict dietary calcium to 0.4 to 0.7% DM
Oxalate	Avoid foods high in oxalic acid (**Table 40-3**)
Phosphorus	Avoid phosphorus deficiency and maintain a normal Ca:P ratio (1.1:1 to 2:1) Dietary phosphorus should be in the range of 0.3 to 0.6% DM
Sodium	Recommend moderate dietary sodium restriction Dietary sodium should be <0.3% DM
Magnesium	Avoid excess or deficient dietary magnesium Dietary magnesium should be in the range of 0.04 to 0.15% DM
Ascorbic acid (vitamin C)	Avoid pet foods, supplements or human foods that contain ascorbic acid
Urinary pH	Avoid acidifying foods Foods should produce a urinary pH 7.1-7.5

Water

Dogs consuming dry commercial foods may be at greater risk for urolithiasis than dogs consuming moist foods because dry foods are often associated with higher urine concentrations of calcium and oxalic acid and more concentrated urine. Therefore, consider moist foods, rather than dry foods, to aid in the prevention of recurrence of calcium oxalate uroliths. Water intake should be encouraged to achieve a urine specific gravity less than 1.020. In addition to decreasing urine specific gravity, increased water intake is likely to be associated with increased voiding frequency. Frequent voiding reduces crystal retention time thereby minimizing crystal growth.

Protein

Ingestion of foods that contain high quantities of animal protein may contribute to calcium oxalate urolithiasis by increasing urine calcium excretion and decreasing urine citrate excretion (Breslau et al, 1988; Lekcharoensuk et al, 2002, 2002a). Some of these consequences result from obligatory acid excretion associated with protein metabolism. Hypercalciuria occurs in normal dogs fed high-protein foods (40% dry matter [DM]). Therefore, excessive dietary protein consumption should be avoided in dogs with active calcium oxalate urolithiasis. The recommended range for dietary protein is 10 to 18% DM. The

*Low in oxalate, but not low in calcium content.

minimum recommended allowance for protein in foods for healthy adult dogs is 10% DM (NRC, 2006).

Calcium and Oxalic Acid

Reduction of dietary calcium appears to be a logical therapeutic goal because intestinal hyperabsorption of calcium has been identified as one mechanism promoting hypercalciuria in dogs with calcium oxalate uroliths. However, reducing consumption of calcium may increase the availability of oxalic acid for intestinal absorption and subsequent urinary excretion. As in the urinary bladder, calcium and oxalic acid in the intestinal lumen form a relatively insoluble complex, thereby preventing the absorption of one another. This provides a plausible explanation as to why an epidemiologic study evaluating risk factors for calcium oxalate urolith formation in people unexpectedly discovered that foods with higher calcium levels were associated with reduced risk for urolith formation (Curhan et al, 1993, 1997; Curhan, 2007). Therefore, in hypercalciuric patients, reduction in dietary calcium should be accompanied by an appropriate reduction in dietary oxalic acid (**Tables 40-3** and **40-6**) (Lulich et al, 2001). The increase in the urine concentration of oxalic acid can be prevented by concomitantly reducing calcium and oxalic acid in the food. Caution: severe calcium restriction should be avoided to prevent negative calcium balance. The minimum requirement for calcium in foods for healthy dogs is 0.2% DM and the minimum recommended allowance is 0.4% DM (NRC, 2006). For prevention of recurrence of calcium oxalate uroliths, reduce dietary calcium to 0.4 to 0.7% DM.

People with calcium oxalate uroliths are often cautioned to avoid milk and milk products because the carbohydrate component (lactose) of these products may augment intestinal absorption of calcium from any dietary source (Leman et al, 1969). Likewise, they are often discouraged from consuming foods containing relatively high quantities of oxalic acid (**Table 40-3**). Although there is agreement that excessive consumption of calcium and oxalic acid should be avoided, the consensus of urologists is that it is inadvisable to restrict dietary calcium unless persistent absorptive hypercalciuria has been documented. Even then, only moderate restriction is advocated to minimize development of negative calcium balance.

Phosphorus

Studies of laboratory animals, dogs and people suggest that dietary phosphorus should not be overly restricted in patients with calcium oxalate urolithiasis because reduction in dietary phosphorus is often associated with augmentation of intestinal calcium absorption and hypercalciuria (Brautbar et al, 1979). If calcium oxalate urolithiasis is associated with hypophosphatemia and normal serum calcium concentration, oral phosphorus supplementation should be considered. However, caution must be used because excessive dietary phosphorus may predispose hypercalciuric patients to formation of calcium phosphate uroliths.

Based on a recommended range for calcium (0.4 to 0.7% DM) in foods for calcium oxalate urolith prevention in canine patients, dietary phosphorus levels should be in the range of 0.3 to 0.6% DM with a calcium-phosphorus ratio range of 1.1:1 to 2:1. The minimum recommended allowance for phosphorus in foods for healthy adult dogs is 0.3% DM (NRC, 2006).

Sodium

Sodium chloride can be added to food to increase thirst and urine volume. However, excess sodium increases urine calcium excretion and therefore is a risk factor for calcium oxalate and calcium phosphate urolithiasis, particularly if the urinary pH is high. For the same reason, if oral urinary alkalinizing agents are used, potassium citrate may be a better choice than sodium bicarbonate. Supplemental sodium sources may also contribute to hypertension in salt-sensitive dogs.

In people, high dietary sodium consumption also reduces urine citrate concentration via sodium-induced bicarbonate loss. Daily urine calcium excretion of normal dogs consuming foods with 0.8% DM sodium was comparable to calcium excretion observed in dogs with calcium oxalate uroliths (Lulich, 1991). Based on this evidence, we recommend mod-

erate dietary restriction of sodium (<0.3% DM sodium) for active calcium oxalate urolith formers (Lulich et al, 2001). Typically, commercial dog foods contain two to three times this amount. The minimum recommended allowance for sodium in foods for healthy adult dogs is 0.08% DM (NRC, 2006).

Magnesium

Although supplemental dietary magnesium contributes to formation of magnesium ammonium phosphate uroliths in some species (cats and ruminants), urine magnesium apparently impairs formation of calcium oxalate crystals (Finco et al, 1985; Kallfez et al, 1986; Meyer and Smith, 1969). Therefore, supplemental magnesium has been used in human patients in an attempt to minimize recurrence of calcium oxalate uroliths (Melnick et al, 1971). However, increased urine excretion of calcium by normal dogs given supplemental magnesium has been observed. Urine calcium excretion was 0.5 ± 0.2 mg/kg body weight/day in six normal dogs consuming a food containing 0.03% DM magnesium vs. 2.65 ± 1.7 mg/kg body weight/day when the same dogs consumed a food containing 0.38% DM magnesium (Lulich, 1991a). Pending further studies, dietary magnesium restriction or supplementation is not recommended for treatment of canine calcium oxalate uroliths. A range of 0.04 to 0.15% DM is recommended. The minimum recommended allowance for magnesium content of foods for healthy adult dogs is 0.06% DM (NRC, 2006).

Ascorbic Acid (Vitamin C)

Supplemental ascorbic acid (a precursor of oxalate) should be avoided.

Urinary pH

Urinary pH in healthy subjects reflects the acid load (acidifying effects) of a food. Although formation of acidic urine is desirable for management of struvite uroliths, foods that promote acidic urine promote hypercalciuria and hypocitraturia. Therefore, consumption of foods that result in formation of acidic urine enhances the risk of calcium oxalate urolithiasis in susceptible dogs. Thus, for prevention of calcium oxalate uroliths, the urinary pH should not be less than 7.0.

A recent study of a high-protein, low-carbohydrate food typified by the so-called Atkins diet revealed a significant reduction in urinary pH and citrate during the induction and maintenance phases of the diet (Reddy et al, 2002).

Urine Alkalinizing Agents

Dosage of urine alkalinizing agents should be individualized for each patient, depending on the status of the patient and pretreatment urinary pH values. Although sodium bicarbonate is a readily available urine alkalinizer, at recommended doses, (25 to 50 mg/kg body weight q12h), it provides a significant increase in sodium intake. Also, sodium may combine with uric acid to form sodium urate. In people, urate salts may serve as a nidus for calcium oxalate urolith formation. For these reasons, we prefer potassium citrate. Potassium citrate in wax matrix tablets (Urocit-K[b]), as a liquid (Polycitra-K[c]) or as chewable tablets (K-CIT-V[d]) may be given. An initial dose of 40 to 75 mg/kg body weight q12h is recommended. The final dose should be individualized based on patient response. Potassium citrate should be administered with meals to reduce gastric irritation. Divided doses should be administered to maintain a consistently nonacidic environment in the urinary tract. Additional supplementation is usually unnecessary when feeding foods (e.g., Prescription Diet u/d Canine canned) containing adequate quantities of potassium citrate.

The goal of treatment with urine alkalinizing agents is to maintain a urinary pH between 7.1 to 7.5. Higher values (>7.5) should be avoided until it is determined whether or not high urinary pH is a significant risk factor for formation of calcium phosphate uroliths. Owners may monitor urinary pH with pH paper or handheld "pocket" pH meters.

OTHER NUTRITIONAL FACTORS

Pyridoxine (Vitamin B_6)

A deficiency of pyridoxine should be avoided because vitamin B_6 promotes endogenous production of oxalic acid (Smith, 1992). Pyridoxine increases the transamination of glyoxylate, an important precursor of oxalic acid, to glycine. Experimentally induced pyridoxine deficiency resulted in renal precipitation of calcium oxalate and hyperoxaluria in kittens (Bai et al, 1989). Commercial foods routinely fortified with vitamin supplements would not be deficient in pyridoxine or other vitamins. However, a homemade food might be deficient in pyridoxine if a multivitamin supplement is not added. Because the ability of supplemental pyridoxine (above nutritional requirements) to reduce urine oxalic acid excretion in dogs is unknown, there is insufficient evidence to recommend or abandon this practice. The minimum recommended allowance for pyridoxine in foods for healthy dogs is 1.5 mg/kg DM (NRC, 2006).

Vitamin D

Excessive levels of vitamin D (which promote intestinal absorption of calcium) in foods for patients at risk for calcium oxalate urolithiasis should be avoided. Commercial foods are typically replete with vitamin D and should not be further supplemented. Excessive supplementation of homemade foods with vitamin D could also pose a risk. For prevention of calcium oxalate urolithiasis, restrict vitamin D in foods to between 500 to 1,500 IU/kg DM. The recommended minimum allowance for foods for healthy adult dogs is 552 IU/kg DM (NRC, 2006).

FEEDING PLAN

Although struvite, urate and cystine uroliths dissolve when urine is no longer supersaturated with lithogenic substances, dissolution of calcium oxalate uroliths in dogs has not been

Table 40-7. Recommendations for the management of calcium oxalate urolithiasis in dogs.

1. Obtain data (postsurgical radiography, complete urinalysis, serum concentrations of calcium, urea nitrogen and creatinine) to evaluate effectiveness of renal function, calcium homeostasis, surgery, voiding urohydropropulsion or lithotripsy.
2. If the dog is hypercalcemic, correct underlying cause.
3. If the dog is normocalcemic, consider foods with reduced calcium, oxalate, sodium and protein that do not promote formation of acidic urine. Ideally foods should contain additional water and citrate and have adequate phosphorus and magnesium. Avoid excess and/or supplemental vitamins C and D. Prescription Diet u/d Canine or w/d Canine* is often recommended.
4. Reevaluate patient in two to four weeks to verify dietary compliance (urine specific gravity and pH and serum urea nitrogen concentration) and amelioration of crystalluria (urine sediment examination).
5. Consider additional potassium citrate if calcium oxalate crystals and aciduria persist.
6. Reevaluate patient in two to four weeks to verify dietary compliance (urine specific gravity and pH and serum urea nitrogen concentration) and amelioration of crystalluria (urine sediment examination). Consider vitamin B_6 supplementation (2 to 4 mg/kg body weight q24 to 48 hours) if calcium oxalate crystalluria persists.
7. Again, reevaluate patient in two to four weeks to verify dietary compliance and amelioration of crystalluria. Consider administration of hydrochlorothiazide (2 mg/kg body weight q24 to 48 hours) if calcium oxalate crystalluria persists. Adverse effects of hydrochlorothiazide administration include dehydration, hypokalemia and hypercalcemia.
8. After three to six months, reevaluate patient to verify dietary compliance and amelioration of crystalluria. Check for urolith recurrence by abdominal radiography. If no uroliths are present, continue current therapy and reevaluate in three to six months. If uroliths have recurred, consider voiding urohydropropulsion (Figure 38-5 and Table 38-7), or lithotripsy. If unsuccessful and clinical signs referable to urocystoliths are persistent, consider surgery. Continue therapy to minimize urolith growth if clinical signs are not present.

*Hill's Pet Nutrition, Inc., Topeka, KS, USA.

reported. Therefore, only physical methods are currently available for removing clinically active calcium oxalate uroliths. Surgery is the time-honored method to remove calcium oxalate uroliths from the urinary tract; however, complete surgical removal of all visible uroliths may be difficult because of their small size and irregular contour. Small urocystoliths may be aspirated through a transurethral catheter (Figure 38-6) (Lulich and Osborne, 1992) or removed by voiding urohydropropulsion (Figure 38-5 and Table 38-7) (Lulich et al, 1993). Extracorporeal lithotripsy also provides a nonsurgical means of treating some dogs with calcium oxalate nephroliths and/or ureteroliths (Adams and Senior, 1999). We have had success fragmenting calcium oxalate urocystoliths and urethroliths with intracorporeal laser lithotripsy.

In some patients, calcium oxalate uroliths are clinically silent, obviating the need for intervention. For patients in which intervention is not warranted, the status of uroliths should be periodically assessed by urinalyses, renal function tests and radiography or ultrasonography. (See Reassessment below.)

Dietary and medical dissolution of calcium oxalate uroliths in dogs has not been reported. However, there is a role for dietary management in prevention of calcium oxalate urolith recurrence. In general, dietary and medical therapy should be implemented in stepwise fashion, with the initial goal of reducing the urine concentration of lithogenic substances (**Table 40-7**). Medications that have the potential to induce unwanted, sustained, detrimental alterations in the composition of metabolites should be reserved for patients with active or frequently recurring calcium oxalate uroliths. Caution should be used to ensure that side effects of treatment are not more detrimental than the effects of uroliths. The cause of hypercalcemia (e.g., primary hyperparathyroidism) should be corrected in patients with hypercalcemia and resorptive hypercalciuria. An attempt should be made to identify risk factors for urolith formation in patients with normal serum calcium concentrations (**Table 40-2**). Amelioration or control of the consequences of risk factors (e.g., urine oversaturation with lithogenic minerals) should minimize urolith growth and recurrence.

The feeding plan includes assessing and selecting the best food and assessing and determining the feeding method.

Assess and Select the Food

Table 40-8 compares the recommended levels of key nutritional factors to the key nutritional factor content of selected commercial veterinary therapeutic foods for calcium oxalate urolith prevention. Select the food that most closely matches the recommended levels of key nutritional factors for preventing the recurrence of calcium oxalate uroliths. Because these foods are intended for long-term feeding, they should also be approved by the Association of American Feed Control Officials (AAFCO), or some other credible regulatory agency. Dogs consuming dry commercial foods may be at greater risk for urolithiasis than those consuming moist foods because dry foods are often associated with higher urine concentrations of calcium and oxalic acid and more concentrated urine. When possible, moist foods should be selected.

Dogs with calcium oxalate urolithiasis frequently consume human food. Calcium oxalate is the most common urolith type recognized in people living in developed countries. As people feed their dogs the same dietary proportions and ingredients they feed themselves, it is logical to assume that dogs would be exposed to the same nutritional risk factors for urolith formation (**Tables 40-2** and **40-3**). Therefore, feeding human foods with high levels of calcium and oxalic acid should be avoided.

In addition to consumption of human food, an association between calcium oxalate urolithiasis and consumption of commercially available treats has been noted. The high sodium content of some commercial dog treats may help explain this association because sodium consumption promotes hypercalciuria (Lulich et al, 1992). Like foods, treats should not contain more than 0.3% DM sodium and they should be limited to less than 10% of the total food regimen (volume or weight basis).

Feeding foods designed to dissolve struvite uroliths provides

*Manufacturers' published values. Nutrients expressed as % dry matter, unless otherwise stated; moist foods are best; avoid foods with added vitamin C (ascorbic acid); avoid foods with high oxalate ingredients (**Table 40-3**).
**Calcium-phosphorus ratio should be in the range of 1.1:1 to 2:1.
***Protocols for measuring urinary pH may vary.

some benefits, but also presents several risks to patients with calcium oxalate uroliths (**Table 40-2**). The lower protein content and potential to enhance formation of less concentrated urine promote reduction of calcium and oxalic acid concentrations in urine. Although formation of acidic urine is desirable for management of struvite uroliths, foods that promote acidic urine promote hypercalciuria and hypocitraturia. Therefore, consumption of struvite litholytic foods that result in formation of acidic urine enhances the risk of calcium oxalate urolithiasis in susceptible dogs. Likewise, aggressive reduction of dietary phosphorus may also promote hypercalciuria. If struvite uroliths occur in breeds of dogs commonly affected with calcium oxalate uroliths, patients should be evaluated for calcium oxalate crystalluria after initiating dietary therapy designed to prevent struvite urolith formation. If calcium oxalate crystalluria persists, alternate methods of preventing struvite uroliths should be considered.

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Assess and Determine the Feeding Method

Transitioning the patient from its current food to a calcium oxalate urolith preventive food should be done gradually over several days. Begin the transition by feeding 75% of the current food and 25% of the new food on Day 1. On Day 2 feed half of each food. On Day 3 feed 75% as the new food. By Day 4 or 5, feed only the new food.

Because moist foods are recommended to increase water intake and production of less concentrated urine, specific amounts (meal fed) should be fed two to three times per day rather than free-choice feeding. Moist foods can spoil if left uneaten at room temperature for several hours (Chapter 11). Opened containers of moist foods should be refrigerated and the feeding bowl should be kept clean.

Table 40-9. Expected changes associated with dietary and medical therapy to minimize recurrence of calcium oxalate uroliths.

Factors	Pre-therapy	Prevention therapy
Polyuria	±	Variable
Pollakiuria	0 to 4+	0
Hematuria	0 to 4+	0
Urine specific gravity	Variable	1.004-1.015
Urinary pH	<7.0	>7.0
Pyuria	0 to 4+	0
Calcium oxalate crystals	0 to 4+	0
Bacteriuria	0 to 4+	0
Bacterial culture of urine	0 to 4+	0
Urea nitrogen (mg/dl)	>15	<15
Urolith size and number	Small to large	0

Besides offering moist foods, several additional approaches may facilitate increased water intake. First, ensure multiple bowls are available in prominent locations in the dog's environment; this may mean providing several bowls outside in a large enclosure or a bowl on each level of the house. Second, bowls should be clean and always be filled with fresh water. Third, small amounts of flavoring substances (e.g., salt-free bouillon) can be added to water sources. Fourth, ice cubes can be offered. Fifth, if a dry food is selected, add liberal quantities of water; however, as with moist foods, be aware that potential food safety issues might arise if moistened dry foods are left uneaten for prolonged intervals at room temperature (Chapter 11).

If the patient has a normal body condition score (2.5/5 to 3.5/5), the amount of the previous food being fed was probably appropriate. On an energy basis, a similar amount of the new food would be a good starting place.

Table 40-10. Managing highly recurrent calcium oxalate uroliths.

Causes	Identification	Therapeutic goal
Client and patient causes		
Inadequate dietary compliance	Question owner Persistent calcium oxalate crystalluria Urea nitrogen >10-15 mg/dl Urine specific gravity >1.010-1.020 Urinary pH <7.0-7.5 during treatment with Prescription Diet u/d Canine* (use lower values for the canned food)	Emphasize need to feed dissolution food exclusively
Administration of vitamin-mineral supplements	Question owner	Discontinue vitamin-mineral supplements containing calcium and vitamins C and D
Clinician factors		
Incomplete surgical removal of uroliths	Postsurgical radiography revealing uroliths Persistence of clinical signs after cystotomy or recurrence of clinical signs soon after cystotomy (within one to three months)	Uroliths not causing clinical signs should be monitored for potentially adverse consequences (obstruction, urinary tract infection, etc.) Clinically active uroliths may require surgical removal Remove small uroliths by voiding urohydropropulsion or lithotripsy
Inappropriate food choice	Persistent calcium oxalate crystalluria	Choose foods with reduced levels of calcium, oxalic acid, protein and sodium that do not promote formation of acidic urine Consider adding potassium citrate if aciduria persists
Inadequate monitoring	Postsurgical radiography to verify complete urolith removal was not performed Urinalysis or urine sediment examinations were not performed within three to six months of initiation of therapy	Perform postsurgical radiography to evaluate success of surgery Perform complete urinalysis within one to three months of initiation of therapy Once stable, urinalysis should be performed every four to six months Perform survey lateral abdominal radiography every four to six months to assess recurrence
Corticosteroid administration	Corticosteroids were prescribed to manage other disease conditions	If possible, discontinue corticosteroid administration
Disease factors		
Hypercalcemia	Elevated serum calcium concentration	Identify and, if possible, eliminate underlying cause for hypercalcemia (hyperparathyroidism, neoplasia, hypervitaminosis D, etc.)
Recurrence of uroliths despite appropriate management	Lateral radiograph of abdomen	Uroliths not causing clinical signs should be monitored for potentially adverse consequences (obstruction, urinary tract infection, etc.) Clinically active uroliths may require surgical removal Remove small uroliths by voiding urohydropropulsion or lithotripsy

*Hill's Pet Nutrition, Inc., Topeka, KS, USA.

ADJUNCTIVE MEDICAL MANAGEMENT

Citric Acid

Citric acid forms soluble salts with calcium thereby minimizing calcium oxalate crystal formation (Nicar et al, 1987). Citric acid is also beneficial because it is metabolized to bicarbonate and promotes formation of alkaline urine (Baruch et al, 1975). In dogs, chronic metabolic acidosis inhibits renal tubular reabsorption of calcium, whereas metabolic alkalosis enhances tubular reabsorption of calcium (Sutton et al, 1979). Potassium citrate is preferred to sodium bicarbonate as an alkalinizing agent because oral administration of sodium enhances urine calcium excretion. If persistent aciduria or hypocitraturia is recognized (mean urine citrate excretion of 33 normal beagles was 2.57 ± 2.31 mg/kg body weight/day), therapy with wax matrix tablets of potassium citrate (Urocit-K) should be considered. Alternatively, a liquid product (Polycitra-K) may be given to small dogs. Chewable treats containing potassium citrate (K-CIT-V) are also available. An initial dose of 40 to 75 mg/kg body weight q12h is recommended. The final dose should be based on patient response. Potassium citrate should be administered with meals to reduce gastric irritation. When feeding foods with adequate quantities of potassium citrate, additional supplementation is often not needed.

Thiazide Diuretics

Thiazide diuretics have been recommended to reduce recurrence of calcium-containing uroliths in people because of their

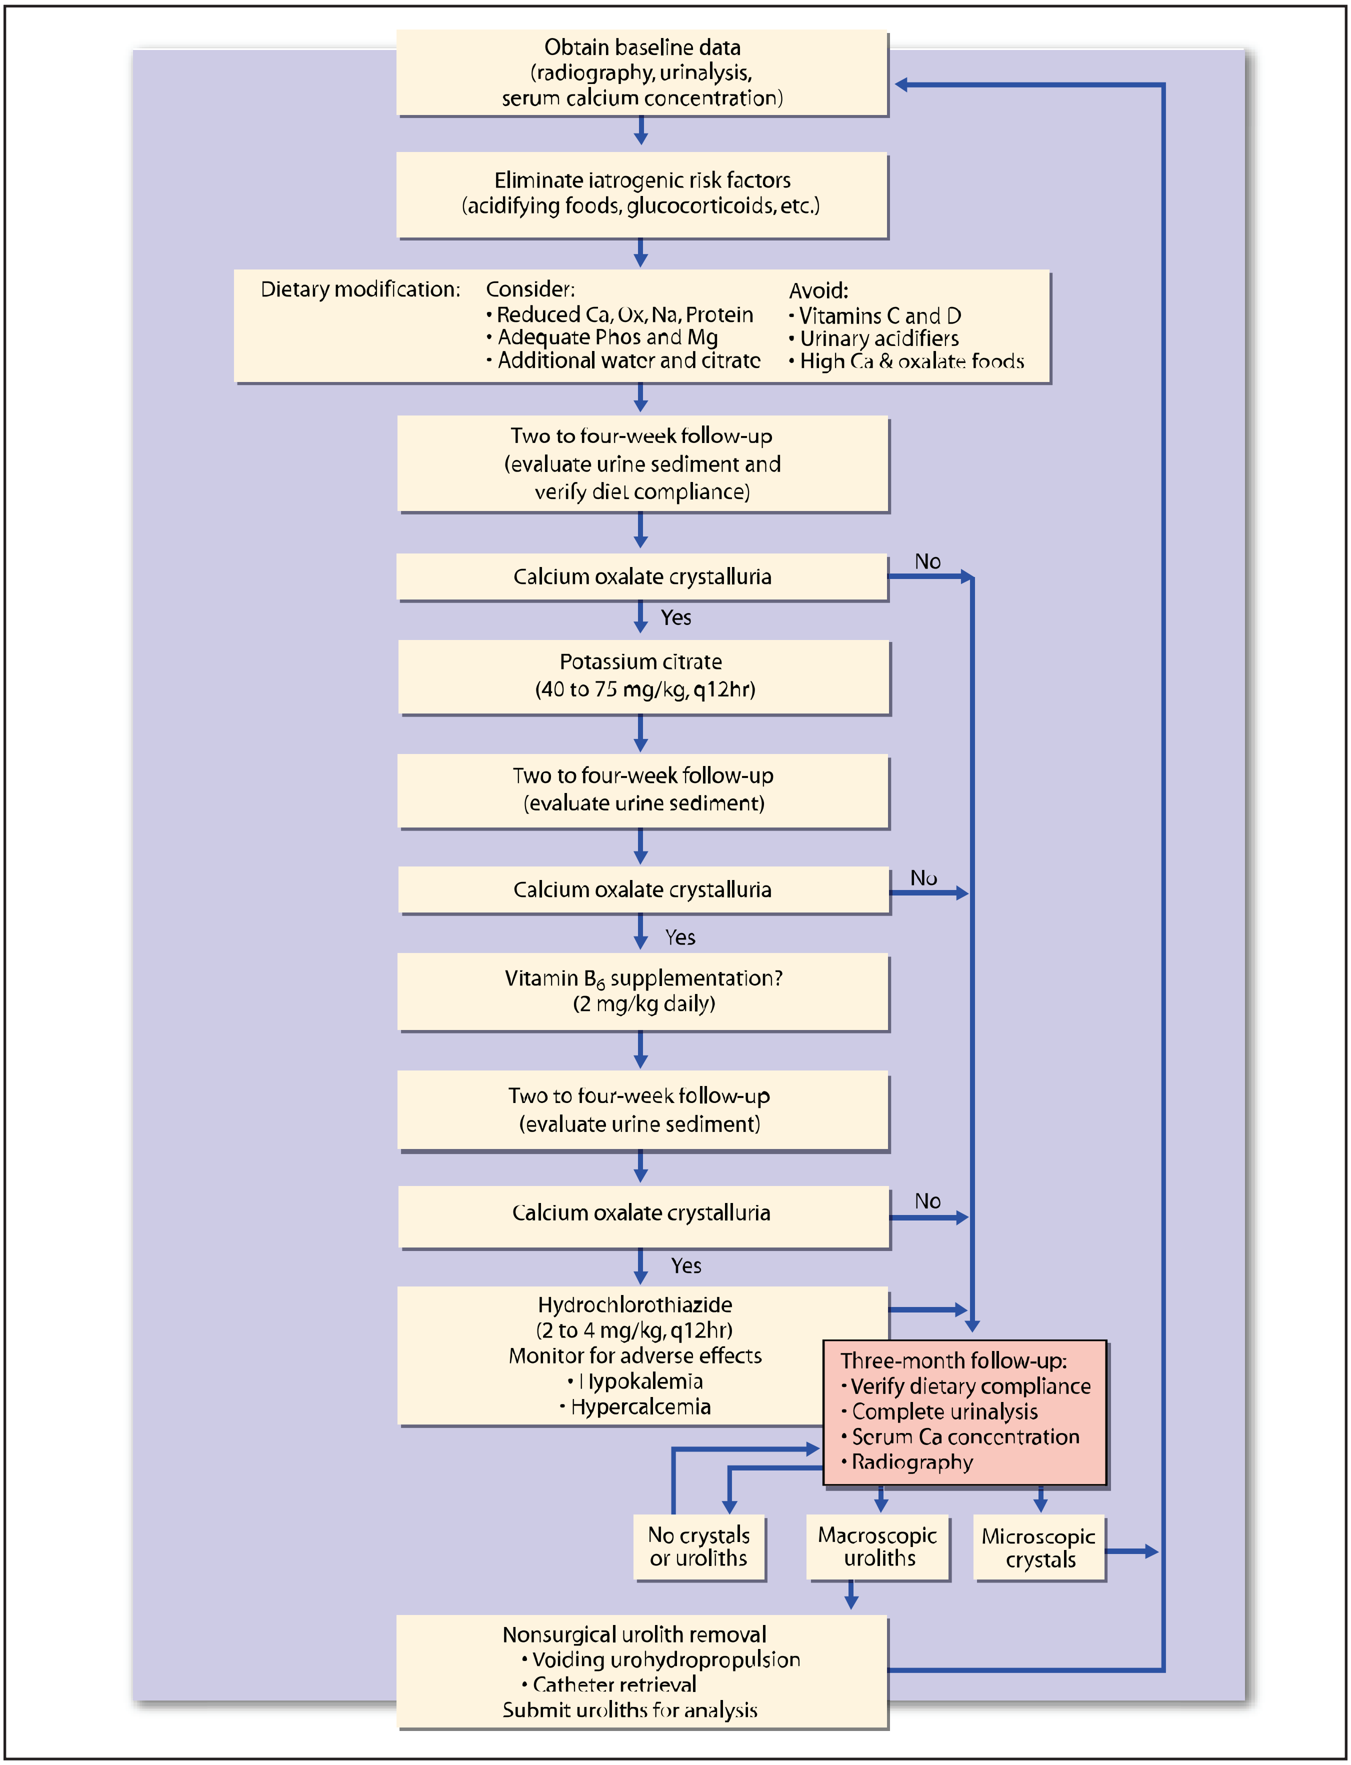

Figure 40-2. Algorithm for dietary and medical management of calcium oxalate uroliths in dogs.

ability to reduce urine calcium excretion (Churchill and Taylor, 1985). However, they should only be considered for patients with severe hypercalciuria. A beneficial reduction in urine calcium excretion in dogs with calcium oxalate urolithiasis has been observed following administration of hydrochlorothiazide (2 to 4 mg/kg body weight q12h) for two weeks. However, a reduction in urine calcium excretion was not detected following hydrochlorothiazide administration (20 to 65 mg/kg body weight q12h) to clinically healthy beagles (Lulich, 1991b). Results of a short-term study of the effects of hydrochlorothiazide on calcium excretion in the urine of adult dogs with naturally occurring calcium oxalate urolithiasis revealed that hydrochlorothiazide significantly reduced urine calcium concentration (Lulich et al, 2001). The greatest reduction in urine calcium concentration and excretion was achieved when dogs received hydrochlorothiazide and a urolith prevention diet. Thiazide diuretic administration is not recommended as first-line therapy at this time. The decision to use thiazides should be accompanied by owner informed consent and appropriate clinical and laboratory monitoring for early detection of adverse effects (dehydration, hypokalemia, hypercalcemia).

Allopurinol

Some people who form calcium oxalate uroliths associated with marked hyperuricosuria have benefited from allopurinol-induced reductions in the magnitude of hyperuricosuria. We are unaware of any counterpart of this phenomenon in dogs. In context of this discussion, it is relevant that the end product of purine metabolism in people is uric acid. However in dogs, the end product of purine metabolism is the highly soluble allantoin. Therefore, we do not recommend that allopurinol be considered for dogs that form calcium oxalate uroliths.

REASSESSMENT

The goal of therapy is to minimize calcium oxalate urolith recurrence (**Figure 40-2**). However, this expectation may be unrealistic because the primary causes responsible for urolith formation are multifactorial and incompletely understood. With the information and techniques currently available, however, veterinarians can minimize urolith recurrence and prevent the need for additional surgical removal of uroliths by appropriate monitoring and intervention.

Therapy should be initiated in a stepwise fashion (**Table 40-7**). If therapy is effective and clients remain compliant, dietary and pharmacologic management should result in formation of less concentrated urine without calcium oxalate crystalluria (**Table 40-9**). Strive to achieve urine specific gravity values less than 1.020. After this is achieved, a urinalysis and survey lateral abdominal radiographs should be performed every two to four months. Dietary and pharmacologic changes should be considered if crystalluria or concentrated urine persist (**Table 40-10**). These recommendations should facilitate detection of recurrent urocystoliths by radiography when they are small enough to remove by voiding urohydropropulsion (Figure 38-5 and Table 38-7). Likewise, urethroliths may be fragmented by intracorporeal laser lithotripsy. Nephroliths may be fragmented by extracorporeal shockwave lithotripsy. After the frequency of urolith recurrence has been established, the frequency of evaluation can be modified such that predicted recurrences can be diagnosed and managed accordingly.

CASE 40-1

Urine Dribbling in a Yorkshire Terrier

Jody P. Lulich, DVM, PhD, Dipl. ACVIM (Internal Medicine)

Carl A. Osborne, DVM, PhD, Dipl. ACVIM (Internal Medicine)
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota, USA

Patient Assessment

A nine-year-old, neutered male Yorkshire terrier was examined for urine dribbling and depression of two days' duration. Physical examination revealed that the dog was 8 to 10% dehydrated; capillary refill time was slightly delayed. The dog voided small spurts of reddish-brown urine onto the examination table when its abdomen was palpated. The physical examination was otherwise nor-

mal. Body weight was 5 kg; the dog had a normal body condition score (3/5). Survey radiographs revealed a large urinary bladder and a radiodense urolith in the urethra at the proximal end of the os penis and several uroliths in the urinary bladder (**Figure 1**).

The diagnosis was urolithiasis of the lower urinary tract associated with urethral obstruction. The depression was probably a consequence of postrenal azotemia.

Assess the Food and Feeding Method

The dog was fed a commercial moist adult maintenance food twice daily and various table foods.

Questions

1. What additional assessments should be performed?
2. What should be the patient's initial treatment plan?

Answers and Discussion

1. A blood sample should be submitted for biochemical analysis to evaluate the degree of azotemia and detect concurrent electrolyte abnormalities. A urinalysis and aerobic bacterial culture of the urine will help predict the mineral composition of the uroliths.
2. Replacement of the patient's fluid deficits with an appropriate fluid given intravenously is important. The urinary bladder can be evacuated by decompressive cystocentesis to enhance renal elimination of waste products. Reducing pressure in the urinary bladder also would facilitate retrograde urohydropropulsion of the urethrolith.

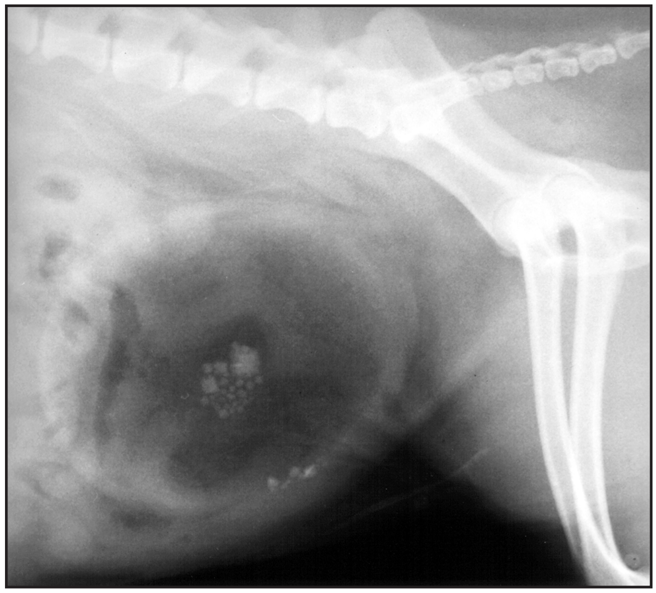

Figure 1. Survey lateral radiograph of a nine-year-old male Yorkshire terrier revealing multiple radiodense uroliths in the urinary bladder and a radiodense urolith at the proximal end of the os penis.

Further Assessment

Results of laboratory tests revealed azotemia, hyperphosphatemia and hypobicarbonatemia (**Table 1**). Serum alkaline phosphatase activity was also increased. Crystals were not observed by urine sediment examination and the urine culture was negative (**Table 2**). The urethrolith was successfully flushed into the urinary bladder by retrograde urohydropropulsion. Prophylactic antimicrobials were administered (amoxicillin-clavulanic acid, 14 mg/kg, q12h) to prevent iatrogenic bacterial urinary tract infection associated with transurethral catheterization.

Table 1. Serum biochemistry values of a nine-year-old male Yorkshire terrier with radiodense urocystoliths.*

Factors	Reference values	Day 1	Day 2	Day 3
SUN (mg/dl)	7-28	186	141	16
Creatinine (mg/dl)	0.5-1.5	6.5	1.2	0.9

Key: SUN = serum urea nitrogen, ALT = alanine aminotransferase, Alk phos = alkaline phosphatase, ND = not done.
*Dietary therapy was initiated on Day 14.

Additional Question

What is the most likely mineral composition of these radiodense uroliths?

Answer and Discussion

The advantages and disadvantages of medical urolith dissolution and surgical urolith removal can be more accurately assessed by predicting the mineral composition of uroliths. Magnesium ammonium phosphate (struvite), calcium oxalate, calcium phosphate, silica and cystine uroliths can all be radiodense (**Table 3**). It was surmised that this patient's uroliths were probably not composed of magnesium ammonium phosphate because of the breed and gender of the dog along with findings of aciduria and a negative bacterial culture. These findings suggested that the uroliths were not composed of struvite and therefore were not amenable to medical dissolution.

Treatment and Further Assessment

The uroliths were surgically removed following resolution of azotemia on the third day of hospitalization (**Table 1**). Postsurgical radiographs verified that all uroliths were removed. Quantitative analysis revealed that the uroliths were composed of 100% calcium oxalate monohydrate.

Further Questions

1. Outline an appropriate feeding plan (food and feeding method) for this dog.

Table 2. Urinalyses of a nine-year-old male Yorkshire terrier with radiodense urocystoliths.*

Factors**	Day 1	Day 14***	Day 28	Day 60
Specific gravity	1.015	1.025	1.008	1.015
pH	6.0	6.5	7.5	7.5
Protein†	1+	1+	Trace	Trace
RBC††	100-150	8-12	0	1-3
WBC††	12-16	2-4	1-2	0
Crystals†††	None	None	None	None

Key: RBC = red blood cells, WBC = white blood cells, Neg = negative.
*Samples collected by cystocentesis.
**Glucose, bilirubin and acetone were not detected in any specimen.
***Dietary therapy was initiated on Day 14.
†Values represent semiquantitative evaluations based on a scale of 0 to 4; urine volume was not considered.
††Per high power field (x450).
†††Per low power field (x100).

Table 3. The advantages and disadvantages of medical urolith dissolution and surgical urolith removal can be accurately assessed after the mineral composition of the urolith is known or predicted. This table lists factors used to predict mineral composition of radiodense uroliths when no uroliths are available for quantitative analysis vs. clinical findings in the patient described in this case.*

Factors	MAP	CaOx	CaP	Silica	Cystine
Typical urinary pH	No	Yes	Possible	Yes	Yes
Typical crystalluria	Possible	Possible	Possible	Possible	Possible
Typical urine culture	No	Yes	Yes	Yes	Yes
Typical radiographic density	Yes	Yes	Yes	Yes	Yes
Typical radiographic contour	Yes	Yes	Yes	No	No
Typical serum biochemistry values	Yes	Yes	Possible	Yes	Yes
Typical breed	No	Yes	Yes	No	No
Typical gender	No	Yes	Yes	Yes	Yes
Typical age	No	Yes	Yes	Yes	No

Key: MAP = magnesium ammonium phosphate, CaOx = calcium oxalate, CaP = calcium phosphate.
*Characteristics of urate uroliths were not considered because they are typically radiolucent.

2. Is reassessment important for this patient?

Answers and Discussion

1. Dietary therapy to prevent urolith recurrence was initiated at the time of suture removal. Dietary recommendations included reducing calcium, oxalic acid, protein and sodium, providing additional water and citrate and maintaining adequate phosphorus and magnesium. A moist veterinary therapeutic food (Prescription Diet u/d Canine[a]) was chosen because its nutrient content matches this nutrient profile. This food avoids excess dietary protein, oxalic acid and calcium, and promotes formation of less concentrated, alkaline urine. These dietary characteristics are helpful in preventing recurrence of calcium oxalate uroliths. The food was offered in two separate meals each day (one-fourth can twice daily, total 375 kcal [1.57 MJ]). The owners were also instructed to avoid feeding the dog any human foods, commercial dog treats and vitamin-mineral supplements (especially those containing vitamins C and D and calcium).
2. Regular reassessment is important because calcium oxalate uroliths commonly recur. Results of a retrospective study on the recurrence rate of calcium oxalate uroliths in dogs indicated that the rate of recurrence increased with the length of time that dogs were evaluated: 3% recurred after three months, 9% after six months, 35% after one year, 42% after two years and 48% after three years. This dog should be examined (i.e., urinalysis, survey abdominal radiography) at regular intervals to evaluate efficacy of medical therapy and to detect uroliths while they are small enough to remove with nonsurgical techniques. This patient should also be evaluated for hyperadrenocorticism because of the increased serum alkaline phosphatase activity. Glucocorticoid administration and hyperadrenocorticism are associated with hypercalciuria and increase the risk for calcium oxalate urolith formation.

Progress Notes

Table 2 summarizes the urinalysis results following six weeks of dietary management. Prescription Diet u/d Canine was successful in promoting less concentrated, alkaline urine in this dog. Reassessment every three to six months was recommended to the owner.

PREVALENCE AND MINERAL COMPOSITION

Uroliths composed predominantly of calcium phosphate have been infrequently identified in dogs and cats. However, calcium phosphate is commonly found as a minor component in naturally occurring struvite and calcium oxalate uroliths. Occasionally a shell of calcium phosphate will form around a urolith composed primarily of struvite.

At least four mineral types have been identified in calcium phosphate uroliths **(Table 41-1)**. The most common form identified in calcium phosphate uroliths from dogs and cats is hydroxyapatite, followed by brushite. Calcium carbonate uncommonly exists as a pure compound in canine and feline uroliths. Calcium carbonate often occurs in equine, rabbit, guinea pig and caprine uroliths (Osborne et al, 1989). In the presence of conditions associated with urinary tract infections (UTIs) caused by urease-positive bacteria, carbonate radicals may be generated that associate with the complex apatite structure to form a carbonate apatite lattice (Osborne et al, 1985). Uncommonly identified crystalline forms of calcium phosphate in uroliths include whitlockite and octacalcium phosphate.

More than one crystalline form of calcium phosphate may be present in a single urolith. In alkaline urine, brushite is readily transformed to apatite; it is possible that some apatite identified in uroliths originated from brushite (Pak et al, 1971). In addition, mixtures of calcium phosphate and calcium oxalate often occur. With the exception of brushite, canine calcium phosphate uroliths do not appear to have a characteristic shape.

Calcium phosphate accounted for 0.51% (1,801) of all (350,803) canine uroliths submitted to the Minnesota Urolith Center from 1981 to 2007 (Table 38-8), and 0.67% (273 of 40,612) of the uroliths submitted in the year 2007. Calcium phosphate accounted for 1.6% of canine upper tract uroliths analyzed at the Minnesota Urolith Center from 2000 to 2006 (Table 38-9). Calcium phosphate accounted for 2.8% of uroliths retrieved from dogs less than 12 months old. Of 1,801 canine

Table 41-1. Common characteristics of canine calcium phosphate uroliths.

Variations in mineral composition
Calcium apatite only
Brushite only
Calcium apatite mixed with calcium oxalate
Brushite mixed with calcium oxalate
In dogs, the carbonate apatite form of calcium phosphate is most commonly detected as a minor component of infection-induced struvite
Physical characteristics
Color: Calcium phosphate uroliths are usually cream or tan. Blood clots mineralized with calcium phosphate are typically black.
Shape: Variable. With the exception of brushite, calcium phosphate uroliths do not have a characteristic shape. The external surface of brushite uroliths is typically round and smooth.
Nuclei: Brushite uroliths are often laminated.
Density: Generally dense and brittle, sometimes chalk-like. Mineralized blood clots may be softer. All forms of calcium phosphate are radiodense compared to soft tissue.
Number: Single or multiple
Location: Kidneys, ureters, urinary bladder (most common) and/or urethra
Size: Variable, with smaller sizes more common
Prevalence
Approximately 0.5% of all canine uroliths. Approximately 1.6% of canine upper tract uroliths.
Characteristics of affected canine patients
No gender prevalence for calcium apatite. Brushite is more common in males. Mean age at diagnosis is seven years (range <1 to >16 years).

hydroxyapatite and carbonate apatite uroliths, 473 were composed entirely (100%) of calcium phosphate, and 694 were composed of at least 70% of these minerals. Of 693 canine brushite uroliths, 233 were composed entirely (100%) of calcium phosphate, and 460 were composed of at least 70% of this mineral. The mean age of dogs at the time of urolith retrieval was approximately nine years (range one month to 19 years). Calcium phosphate accounted for less than 2.3% of calcium phosphate uroliths formed by dogs less than 12 months old. Males were affected (57%) more commonly than females (43%). Forty different breeds were affected including cocker spaniels (10%), mixed breeds (20%), miniature schnauzers (10%), Yorkshire terriers (7%), Shih Tzus (6%) and springer spaniels (5%). Hydroxyapatite uroliths were more commonly removed from the lower urinary tract (81%) than the upper urinary tract (8%). The location of 11% of the hydroxyapatite uroliths was not specified.

ETIOPATHOGENESIS AND RISK FACTORS

Solubility of Calcium Phosphates in Urine

Overview

The solubility of calcium phosphates in urine depends on: 1) urinary pH, 2) urine calcium ion concentration, 3) total urine inorganic phosphate concentration, 4) urine concentration of inhibitors of calcium crystallization and 5) urine concentration of potentiators of crystallization. Factors that decrease calcium phosphate solubility predispose patients to urolith formation.

Urinary pH

Urinary pH has a profound effect on the solubility of some forms of calcium phosphate (Elliot, 1957). With the exception of brushite, calcium phosphate solubility markedly decreases in alkaline urine and increases in acidic urine. Increased urinary pH increases the availability of ionic PO_4^{3-} and HPO_4^{2-}, which are available for incorporation into calcium phosphates (Asplin et al, 1996). Apatite will not crystallize from human urine unless the pH is 6.6 or greater (Elliot, 1968). Approximately 400 mg of calcium phosphate/l can be held in solution at a pH of 5.5, whereas only 32 mg of calcium phosphate/l will be held in solution at a pH of 7.8 (Elliot, 1965). Therefore, people with disorders associated with persistent elevation of urinary pH (e.g., distal renal tubular acidosis [RTA]) are predisposed to calcium phosphate urolith formation. In contrast to carbonate apatite and hydroxyapatite, the solubility of brushite decreases in acidic urine.

Hypercalciuria

Hypercalciuria decreases calcium phosphate solubility and may result in oversaturation with calcium phosphate (Pak, 1978). Hypercalciuria may result from: 1) excessive resorption of calcium from bone, 2) enhanced intestinal absorption of calcium, 3) impaired renal tubular reabsorption of calcium and/or 4) combinations of these factors. Urine specimens obtained from human patients with hypercalciuria and calcium uroliths are usually supersaturated with brushite.

Controversy exists as to the relative importance of urinary pH and hypercalciuria as determinants of calcium phosphate solubility in vivo. Some investigators believe that calcium phosphate crystallization is primarily governed by changes in urinary pH; they minimize the importance of hypercalciuria (Elliot, 1968). However, other investigators suggest that persistent hypercalciuria tends to increase the calcium phosphate saturation of urine so that small increases in urinary pH will result in calcium phosphate crystalluria. Apparently, there have been no studies reported on the relative effect of hypercalciuria and urinary pH on the solubility of different types of calcium phosphate in canine urine.

Crystallization Inhibitors

Normally, urine contains calcium phosphate crystal inhibitors. One mechanism by which inhibitors prevent urolith formation is by chelating urolith constituents, making them unavailable for nidus formation or crystal growth. In addition, crystallization inhibitors may alter crystalline structure in such a way that crystal growth and aggregation are prevented. Inhibitors of calcium phosphate crystallization include inorganic pyrophosphates, citric acid ions, magnesium ions and nephrocalcin (Bisaz et al, 1978; Ito and Coe, 1977). In healthy human urine, these inhibitors provide 70 to 80% of the inhibitory capacity to calcium phosphate crystallization (Asplin et al, 1996). As yet unidentified low-molecular-weight inhibitors provide the remaining 20 to 30%.

Pyrophosphates increase the upper limit of urine calcium phosphate saturation at which spontaneous precipitation

occurs. Pyrophosphates also retard growth of hydroxyapatite crystals by adsorbing to their surfaces and blocking active growth sites. In addition, pyrophosphates inhibit transformation of amorphous calcium phosphate into a crystalline form (Fleisch, 1978). Citrate forms soluble complexes with calcium, thereby decreasing the availability of calcium for incorporation into crystals. Magnesium may replace calcium on the surface of growing crystals and thus block epitaxial growth.

Crystallization Promoters

Formation of calcium phosphate uroliths may be promoted by epitaxy. Epitaxy is the process by which crystals of one salt induce the formation of crystals of another salt. Epitaxic induction occurs between crystals having similar lattice dimensions. Calcium phosphate precipitation has been reported to be stimulated by calcium oxalate and monosodium urate crystals (Fleisch, 1978).

Disorders Associated with Formation of Calcium Phosphate Uroliths

Overview

Calcium phosphate uroliths may occur in patients with: 1) primary hyperparathyroidism, 2) other hypercalcemic disorders, 3) distal RTA and 4) idiopathic hypercalciuria (**Table 41-2**) (Asplin et al, 1996; Curhan et al, 1997; Menon et al, 1998). Because the prevalence of calcium phosphate uroliths in dogs is low, and because appropriate metabolic studies have rarely been performed in affected cases, the association of calcium phosphate uroliths with other canine metabolic disorders has not been as well established.

Primary Hyperparathyroidism

Between 18 to 20% of human patients with primary hyperparathyroidism have uroliths at the time of diagnosis (Nikkila et al, 1989). In one series of 72 dogs with primary hyperparathyroidism, 22 (31%) had uroliths (Feldman and Nelson, 1996). Uroliths from patients with primary hyperparathyroidism are typically composed of calcium phosphate, calcium oxalate or a mixture of the two. Uroliths composed predominantly of calcium phosphate are more commonly identified in people and dogs with primary hyperparathyroidism; uroliths composed primarily of calcium oxalate are more commonly identified in people and dogs with normocalcemic hypercalciuria (Klausner and Osborne, 1986). Bladder uroliths composed primarily of calcium phosphate have been experimentally induced in dogs following injections of parathyroid hormone (PTH) (Leberman, 1940).

Factors that predispose patients with primary hyperparathyroidism to calcium phosphate urolith formation include: hypercalciuria, increased urinary pH and increased renal excretion of metabolites that promote spontaneous precipitation of calcium salts (**Table 41-3**). Hypercalcemia results from PTH-induced bone resorption and renal tubular reabsorption of calcium. In addition, increased intestinal absorption of calcium results from PTH-stimulated conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol (1,25-vitamin D) (Pak, 1978).

Table 41-2. Comparison of disorders that may predispose dogs, people and cats to formation of calcium phosphate uroliths.

Disorders	Dogs	People	Cats

†Adapted from Caruana RJ, Buckalew VM. The syndrome of distal (type 1) renal tubular acidosis: Clinical and laboratory findings in 58 cases. Medicine 1988; 67: 84.

Hypercalcemia results in increased glomerular filtration of calcium and hypercalciuria, which in turn enhances the likelihood of urolith formation by increasing urine saturation with brushite and calcium oxalate (Pak, 1978). The urine of most hypercalciuric people with primary hyperparathyroidism is supersaturated with brushite and calcium oxalate. Hypercalciuria and hyperphosphaturia have been documented to occur in dogs with primary hyperparathyroidism and calcium uroliths (Klausner and Osborne, 1986; Klausner et al, 1987).

Persistent elevation in urinary pH may predispose some patients with primary hyperparathyroidism to calcium phosphate urolithiasis. Urinary pH is elevated in these patients because of impaired renal tubular reabsorption of bicarbonate (Broadus, 1980). This abnormality may explain, at least in part, the increased occurrence of calcium phosphate uroliths in patients with primary hyperparathyroidism compared with patients with other hypercalciuric diseases.

It has been suggested that some human patients with pri-

Table 41-3. Some potential risk factors for canine calcium phosphate uroliths.

Food	Urine	Metabolic	Drugs
Alkalinizing potential	Alkaline pH	Hypercalcemia	Urine alkalinizing drugs

Key: PTH = parathyroid hormone.

mary hyperparathyroidism excrete a substance in their urine that facilitates calcium phosphate and calcium oxalate precipitation (Pak, 1978). The specific nature of this urolithiasis-promoting factor has not been determined.

Other Hypercalcemic Disorders

In addition to primary hyperparathyroidism, other hypercalcemic disorders may predispose patients to formation of calcium phosphate uroliths. Uroliths have been identified in human patients with hypervitaminosis D, neoplastic disorders, Cushing's syndrome and in some patients who are immobilized for long periods (**Table 41-2**) (Menon et al, 1998). Although calcium phosphate is the most frequently identified mineral in uroliths obtained from these patients, calcium oxalate may also be present. Because the frequency of occurrence of uroliths in patients with these hypercalcemic disorders is low, it is likely that factors in addition to hypercalcemia are involved.

Distal Renal Tubular Acidosis

Nephrolithiasis is a common manifestation of hereditary, acquired and idiopathic forms of RTA (Type I) in people (Caruana and Buckalew, 1988). Uroliths are typically composed entirely of calcium phosphate, calcium oxalate and struvite (Backman et al, 1980). Urolith formation has also been observed occasionally in patients with proximal RTA (Type II) (Menon et al, 1998). To the best of our knowledge, struvite uroliths are the only urolith type observed in canine patients with RTA (Bovee et al, 1979; Polzin et al, 1986).

Distal RTA results from functional inability of the distal nephron to establish a hydrogen ion gradient between blood and tubular fluid, regardless of the severity of acidemia. The disorder in people is characterized by the inability to decrease urinary pH below 5.4, hypokalemia, hyperchloremia, hypophosphatemia, hypocalcemia, metabolic acidosis, osteomalacia, nephrocalcinosis and urolithiasis (Caruana and Buckalew, 1988; Menon et al, 1998).

Hypercalciuria, alkaline urine, low urine citrate concentration and excessive urine phosphate excretion contribute to formation of calcium phosphate uroliths observed in patients with distal RTA (**Table 41-4**) (Caruana and Buckalew, 1988; Menon et al, 1998). Hypercalciuria and hyperphosphaturia tend to increase urine saturation with calcium phosphate. Acidosis increases calcium mobilization from bone, causing an increase in the quantity of calcium excreted in urine (Klausner and Osborne, 1986). In addition, acidosis decreases renal tubular reabsorption of calcium, further increasing calcium excretion. Acidosis may alter renal tubular calcium transport, the response of the tubules to PTH or both.

Elevated urinary pH increases the availability of PO_4^{3-} and HPO_4^{2-}, which may be incorporated into ionic octacalcium phosphate and brushite, respectively (Asplin et al, 1996). Increased urinary pH is considered more important than hypercalciuria in predisposing patients with distal RTA to calcium phosphate urolith formation (Asplin et al, 1996).

Patients with distal RTA consistently excrete decreased amounts of citrate in their urine (Caruana and Buckalew, 1988). Hypocitratemia in patients with distal RTA has been attributed to: 1) increased proximal tubule reabsorption of citrate as a consequence of intracellular acidosis, 2) a primary

defect in tubular function and 3) the effects of hypokalemia (Caruana and Buckalew, 1988). Because citrate is a major chelator of calcium, hypocitraturia decreases calcium solubility and may represent an important risk factor in the pathogenesis of calcium phosphate and calcium oxalate uroliths associated with RTA (Menon et al, 1998).

In human patients, distal RTA sometimes occurs as an incomplete form in which urolith formation occurs without systemic acidosis. Urolithiasis may be the only clinical manifestation of this disorder (Konnak et al, 1982). The tubular defect can be recognized by an abnormal response to an ammonium chloride loading test.

Normocalcemic Hypercalciuria

Normocalcemic hypercalciuria is a syndrome characterized by normal serum calcium concentration, increased urinary excretion of calcium, absence of systemic disease and increased tendency for formation of calcium phosphate or calcium oxalate uroliths (Curhan et al, 2007). Approximately 33% of human calcium urolith formers have normocalcemic hypercalciuria (Menon et al, 1998). Normocalcemic hypercalciuria has also been recognized in dogs (Lulich et al, 1991). It has not been documented to occur in cats, likely due to little effort to detect it.

Two types of normocalcemic hypercalciuria have been recognized in dogs (Lulich et al, 1991). One type, called absorptive hypercalciuria, is associated with increased intestinal absorption of calcium. The subsequent increase in serum calcium concentration suppresses PTH secretion, resulting in decreased tubular reabsorption of calcium and hypercalciuria. Hyperabsorption of calcium from the intestinal tract may result from a primary intestinal disturbance in calcium transport. It is also possible that increased calcium absorption results from increased synthesis of 1,25-vitamin D. Absorptive hypercalciuria has been divided into subtypes based on urinary calcium excretion following consumption of different levels of dietary calcium (Menon et al, 1998).

The second type of normocalcemic hypercalciuria, termed renal-leak hypercalciuria, is thought to result from impaired ability of the proximal tubules to reabsorb filtered calcium (Lulich et al, 1991a; Menon et al, 1998). A defect in reabsorption of magnesium may also be present. Renal calcium loss stimulates 1,25-vitamin D and PTH synthesis, resulting in an increase in intestinal absorption of calcium.

Hypercalciuria is probably not the only factor involved in urolith formation in patients with normocalcemic hypercalciuria because many hypercalciuric patients do not form uroliths. Crystallization inhibitor and promoter interaction are also important contributing factors.

The diagnosis of idiopathic hypercalciuria is established by demonstrating an increase in 24-hour urinary calcium excretion and by eliminating other nonhypercalcemic, hypercalciuric disorders such as RTA (**Table 41-4**) (Lulich et al, 1991a, 1991; Menon et al, 1998). Unlike absorptive hypercalciuria, renal-leak hypercalciuria is not affected by withholding food. **Table 41-5** presents a problem-specific database for dogs suspected of having calcium phosphate uroliths, and is a useful clinical tool.

Mineralization of Blood Clots

Nephroliths, urocystoliths and urethroliths composed of blood clots mineralized with calcium phosphate have been observed on numerous occasions in dogs (and cats). Formation of highly concentrated urine in patients with gross hematuria may favor formation of mineralized blood clots. Contrary to one theory, these black-colored uroliths are not composed of bile metabolites.

BIOLOGIC BEHAVIOR

Calcium phosphate uroliths may increase in size and number if underlying causes persist. In our experience, blood clots within the urinary tract that have become mineralized with calcium phosphate often remain inactive for years.

KEY NUTRITIONAL FACTORS

The determination of key nutritional factors for prevention of calcium phosphate uroliths is complicated because these uroliths occur relatively infrequently and there are several different potentially underlying causes. Dietary dissolution of calcium phosphate uroliths has not been successful. Depending on the size, calcium phosphate uroliths are readily removed by surgery, lithotripsy, voiding urohydropropulsion (Figure 38-5 and Table 38-7) (Lulich et al, 1993) or aspiration through a urinary catheter (Figure 38-6) (Lulich and Osborne, 1992). Thus, dietary therapy of patients with recurring calcium phosphate uroliths is limited to removing or minimizing risk factors that contribute to supersaturation of urine with calcium phosphate.

The solubility of calcium phosphates in urine depends on: 1) urinary pH, 2) urine calcium ion concentration, 3) total urine inorganic phosphate concentration, 4) urine concentration of inhibitors of calcium crystallization and 5) urine concentration of potentiators of crystallization. The key nutritional factors that are thought to increase calcium phosphate solubility to help prevent recurrence of uroliths are summarized in **Table 41-6** and are discussed in more detail below.

Water

Dogs eating dry commercial foods are probably at greater risk for urolith formation than dogs consuming moist foods because dry foods tend to be associated with production of a reduced volume of more concentrated urine. Low urine volume is a risk factor for all types of uroliths because it increases the relative urine saturation of lithogenic constituents. However, it is highly improbable that low urine volume alone would create an environment conducive to calcium phosphate urolith formation.

Although understandably difficult in some patients, encouraging fluid consumption throughout the day with the goal of promoting a consistently large volume of urine is likely to be of benefit. Enhancing urine volume by feeding a moist food may

*Nutrients expressed on a dry matter basis.
**Alkaline urine is recommended for patients with distal renal tubular acidosis.

be helpful. Water intake should be encouraged to achieve a urine specific gravity <1.020.

Protein

Foods with a high protein content tend to contribute to hypocitraturia. Citric acid ions inhibit calcium phosphate crystallization. Citrate forms soluble complexes with calcium, thereby decreasing the availability of calcium for incorporation into crystals.

High-protein foods also contribute to hypercalciuria and hyperphosphaturia. Some of the consequences of eating high-protein foods result from obligatory acid excretion associated with protein metabolism. Hypercalciuria occurs in normal dogs fed high-protein foods (40% dry matter [DM]). Therefore, excessive dietary protein consumption should be avoided in dogs at risk for recurrence of calcium phosphate urolithiasis. The recommended range for dietary protein is 10 to 25% DM; the lower end of this range is probably better. The minimum recommended allowance for protein in foods for healthy adult dogs is 10% DM (NRC, 2006).

Calcium and Phosphorus

Hypercalciuria decreases calcium phosphate solubility and may result in oversaturation with calcium phosphate (Pak, 1978). Reduction of dietary calcium appears to be a logical goal for prevention of calcium phosphate urolithiasis because intestinal hyperabsorption of calcium has been identified as one mechanism promoting hypercalciuria in dogs with calcium oxalate uroliths.

Foods with higher levels of phosphorus tend to augment hyperphosphaturia and may predispose hypercalciuric patients to form calcium phosphate uroliths. However, excessive restriction of dietary phosphorus may enhance the availability of dietary calcium for intestinal absorption. It may also enhance production of 1,25-vitamin D by the kidneys, thereby promoting hypercalciuria.

The optimal levels of dietary calcium and phosphorus for dogs with calcium phosphate urolithiasis have not been determined. The following recommendations are the same as for prevention of recurrence of calcium oxalate uroliths (Chapter 40): foods for prevention of calcium phosphate urolith recurrence should contain 0.4 to 0.7% DM calcium and 0.3 to 0.6% DM phosphorus with a calcium-phosphorus ratio range of 1.1:1 to 2:1. The minimum recommended allowances for calcium and phosphorus in foods for healthy adult dogs are 0.4 and 0.3% DM, respectively (NRC, 2006). One survey of the average calcium content of numerous dry grocery brand dog foods was shown to be 1.36% DM and for moist foods 1.73% DM (Debraekeleer, 2000).

In people, some high-fiber foods have been shown to reduce intestinal absorption and urinary excretion of calcium (Menon et al, 1998).

Sodium

Foods with higher quantities of sodium and/or oral administration of sodium chloride are often empirically recommended for prevention of all forms of urolithiasis. However, such excess sodium intake may promote hypercalciuria and enhance the risk of calcium phosphate urolith formation. Therefore, oral sodium chloride therapy is not recommended to promote diuresis in dogs with uroliths containing calcium salts.

Sodium content of foods for canine patients at risk for recurrence of calcium phosphate uroliths should be moderately restricted (<0.3% DM sodium). Typically, commercial dog foods contain two to three times this amount. The minimum recommended allowance for sodium in foods for healthy adult dogs is 0.08% DM (NRC, 2006).

Magnesium

Normally, urine contains calcium phosphate crystal inhibitors. One mechanism by which inhibitors prevent urolith formation is by chelating urolith constituents, making them unavailable

for nidus formation or crystal growth. In addition, crystallization inhibitors may alter crystalline structure in such a way that crystal growth and aggregation are prevented. Magnesium ions are inhibitors of calcium phosphate crystallization (Bisaz et al, 1978; Ito and Coe, 1977).

However, increased urinary excretion of calcium by normal dogs given supplemental magnesium has been observed. Urinary calcium excretion was 0.5 ± 0.2 mg/kg body weight/day in six normal dogs consuming a food containing 0.03% DM magnesium vs. 2.65 ± 1.7 mg/kg body weight/day when the same dogs consumed a food containing 0.38% DM magnesium (Lulich, 1991b). Pending further studies, dietary magnesium restriction or supplementation is not recommended for treatment of canine calcium phosphate uroliths. A moderate range of 0.06 to 0.15% DM is recommended. The minimum recommended allowance for magnesium content of foods for healthy adult dogs is 0.06% DM (NRC, 2006).

Vitamin D

Foods with higher quantities of vitamin D or excessive supplementation with vitamin D may promote hypercalciuria (**Table 41-4**). Vitamin D promotes intestinal absorption of calcium. Commercial foods typically have adequate vitamin D content and should not be further supplemented. Excessive supplementation of homemade foods with vitamin D could also pose a risk. For prevention of calcium phosphate urolithiasis, restrict vitamin D in foods to between 500 to 1,500 IU/kg DM. The recommended minimum allowance for foods for healthy adult dogs is 552 IU/kg DM (NRC, 2006).

Urinary pH

Urinary pH profoundly affects the solubility of some forms of calcium phosphate (Elliot, 1957). With the exception of brushite, calcium phosphate solubility markedly decreases in alkaline urine and increases in acidic urine. Increased urinary pH increases the availability of ionic PO_4^{3-} and HPO_4^{2-}, which are available for incorporation into calcium phosphates (Asplin et al, 1996). Apatite will not crystallize from human urine unless the pH is 6.6 or greater (Elliot, 1968). As mentioned above, approximately 400 mg of calcium phosphate/l can be held in solution at a pH of 5.5, whereas only 32 mg of calcium phosphate/l will be held in solution at a pH of 7.8 (Elliot, 1965). Therefore, people with disorders associated with persistent elevation of urinary pH (e.g., distal RTA) are predisposed to calcium phosphate urolith formation. In contrast to carbonate apatite and hydroxyapatite, the solubility of brushite decreases in acidic urine. Acidification to the degree that induces acidosis should be avoided because it promotes hypercalciuria and hypocitraturia.

For prevention of recurrence of calcium phosphate uroliths in most patients (non-distal RTA patients and non-brushite urolith patients), the food should produce a urinary pH of 6.2 to 6.6.

Long-term alkalinization therapy appears to be beneficial in preventing calcium phosphate urolith formation in people with distal RTA (Caruana and Buckalew, 1988; Menon et al, 1998). Such therapy has been advocated for patients with complete or incomplete forms of distal RTA because it decreases urolith formation and nephrocalcinosis, and it increases urine citrate concentration.

FEEDING PLAN

Patients with primary hyperparathyroidism usually require surgery (Feldman and Nelson, 1996). Parathyroidectomy may result in dissolution of uroliths and generally prevents their recurrence. Parathyroidectomy in a dog with primary hyperparathyroidism and recurrent calcium phosphate uroliths resulted in decreased urinary calcium excretion and prevention of new urolith formation (Klausner et al, 1987).

Surgery and/or lithotripsy are the most reliable ways to remove active calcium phosphate uroliths from the urinary tract. However, surgery may be unnecessary for clinically inactive calcium phosphate uroliths. Voiding urohydropropulsion may be used to remove small urocystoliths (Figure 38-5 and Table 38-7) (Lulich et al, 1993). Although calcium-chelating agents have been reported to be of value in dissolving calcium phosphate uroliths in people, the feasibility of this type of therapy has not yet been reported in dogs and cats.

The frequency of recurrence of calcium phosphate uroliths following removal is not well established. However, unless the underlying cause(s) have been eliminated or controlled, recurrence is likely. Therefore, patients should be periodically monitored by urinalysis, radiographic procedures, and, if indicated, blood and urine tests (**Table 41-7**). If recurrent urocystoliths are detected when they are small, they may be removed by nonsurgical means as described above. Dietary or combined dietary and medical therapy of patients with recurring calcium phosphate uroliths should then be directed at removing or minimizing risk factors that contribute to supersaturation of urine with calcium phosphate.

Assess and Select the Food

Formulation of an optimal food remains a goal for the future. Until such a food becomes available, it is reasonable to recommend trial therapy with foods that most nearly match the key nutritional factor recommendations. **Table 41-8** lists selected veterinary therapeutic foods that can be considered for prevention of calcium phosphate urolith recurrence and compares their key nutritional factor content to the recommended levels. Select the food that most closely matches the key nutritional factor levels described above for preventing the recurrence of calcium phosphate uroliths. Because these foods are intended for long-term feeding, they should also be approved by the Association of American Feed Control Officials (AAFCO), or some other credible regulatory agency. Dogs consuming dry foods may be at greater risk for urolithiasis than dogs consuming moist foods. Dry foods are often associated with higher urine concentrations of urolith constituents and more concentrated urine. Therefore, when possible, moist foods should be selected.

The sodium content of treats should be checked. Treats should not contain more than 0.3% DM sodium and they should be limited to less than 10% of the total food regimen

Table 41-7. Summary of recommendations for managing canine calcium phosphate uroliths.

1. Surgery remains the most reliable way to remove active calcium phosphate uroliths from the urinary tract. However, surgery may be unnecessary for clinically inactive calcium phosphate uroliths. Small urocystoliths may be nonsurgically removed by lithotripsy, voiding urohydropropulsion (Figure 38-5 and Table 38-7) or by aspiration through a urinary catheter (Figure 38-6). Medical therapy of patients with recurrent calcium phosphate uroliths should then be directed at removing or minimizing risk factors that contribute to supersaturation of urine with calcium phosphate.
2. Patients with hypercalcemia and primary hyperparathyroidism usually require surgery. Parathyroidectomy may result in dissolution of uroliths and prevent recurrence in cases that have been properly managed.
3. Several different medical protocols have been reported to be of value in people with normocalcemic hypercalciuria. Ideally, the choice of therapy should be based on the cause of idiopathic hypercalciuria.
   a. There has been little clinical experience with the use of drugs in dogs and cats with calcium phosphate uroliths. However, medications that can enhance urine calcium excretion such as glucocorticoids, furosemide and those containing large quantities of sodium should be avoided (if possible).
   b. Foods designed to avoid excessive protein, sodium, calcium and vitamin D may be of benefit. Excessive restriction or supplementation of dietary phosphorus should probably be avoided. Enhancing urine volume by feeding a moist food (and/or a protein-restricted food to dogs to reduce renal medullary urea concentrations) and encouraging water consumption may be of benefit. Although understandably difficult to accomplish in some patients, fluid intake should be encouraged throughout the day to promote a constantly high urine volume. In people, some high-fiber diets reduce intestinal absorption and urinary excretion of calcium.
   c. With the exception of brushite, calcium phosphates tend to be less soluble in alkaline urine. Whether or not patients with such mineral types would benefit from appropriate dosages of urine acidifiers is unknown. Acidification tends to enhance urine calcium excretion and is a risk factor for calcium oxalate urolith formation. Pending further studies, routine use of urine acidifiers for patients with calcium phosphate urolithiasis is not recommended.
4. Medical dissolution of calcium phosphate uroliths has not been attempted in dogs with distal renal tubular acidosis (RTA). Foods designed to dissolve struvite uroliths would generally not be expected to promote dissolution of calcium phosphate uroliths, in part because they may tend to promote acidemia and aciduria, thus potentially enhancing hypercalciuria and hypocitraturia. However, correction of hypercalciuria, hyperphosphaturia and hypocitraturia by alkalinization therapy with potassium citrate might promote dissolution of these uroliths in patients with complete or incomplete distal RTA. Long-term alkalinization therapy appears to be beneficial in preventing calcium phosphate urolith formation in people with distal RTA. Alkalinization of urine has been advocated for human patients with complete or incomplete forms of distal RTA because it decreases urolith formation and nephrocalcinosis and increases urine citrate concentration. Oral administration of sodium chloride, long recommended for all forms of urolithiasis, may promote hypercalciuria and calcium phosphate urolith formation. Therefore, oral salt therapy is not recommended to promote diuresis in dogs with uroliths containing calcium salts.

(volume or weight basis).

Moderate urinary acidification is recommended for prevention of recurrent calcium phosphate uroliths in most patients. However, for distal RTA patients, long-term alkalinization therapy appears to be beneficial.

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Assess and Determine the Feeding Method

Transitioning a patient from the current food to a new food to help prevent recurrence of calcium phosphate uroliths should be done gradually. Begin the transition by feeding 75% of the current food and 25% of the new food on Day 1. On Day 2, feed half of each food. On Day 3, feed 75% of the new food and 25% of the old food. Feed only the new food beginning on Day 4.

Because moist foods increase water intake and produce a more dilute urine, feeding specific amounts (meal fed) of food two to three times per day is preferred to free-choice feeding. Moist foods can spoil if left at room temperature for several hours (Chapter 11). Opened containers of moist foods should be refrigerated and the feeding bowl should be kept clean.

Besides offering moist foods, several additional ways can facilitate increased water intake. These include: 1) Ensuring multiple bowls are available in prominent locations in the dog's environment; this may mean providing several bowls outside in a large enclosure or a bowl on each level of the house. 2) Bowls should be clean and always be filled with fresh water. 3) Small amounts of flavoring substances (e.g., salt-free bouillon) can be added to water sources. 4) Ice cubes can be offered as treats or snacks. 5) If a dry food is selected, add liberal quantities of water; however, potential food safety issues might arise from leaving moistened dry foods out for prolonged intervals (Chapter 11).

If the patient has a normal body condition score (BCS 2.5/5 to 3.5/5), the amount fed previously was probably appropriate. On an energy basis, a similar amount of the new food would be a good starting place.

ADJUNCTIVE MEDICAL AND SURGICAL MANAGEMENT

Urine Acidifying and Alkalinizing Agents

With the exception of brushite, calcium phosphates tend to be less soluble in alkaline urine. Acidification reduces urine concentrations of ionic phosphate (PO_4^{3-}) and hydroxyl ions (OH^-). However, whether or not patients with calcium phos-

phate uroliths would benefit from appropriate dosages of urine acidifiers is unknown. Overacidification tends to enhance urine calcium excretion and is a risk factor for calcium oxalate urolith formation. Pending further studies, we do not recommend routine use of urine acidifiers with urine acidifying foods for patients with calcium phosphate urolithiasis.

Because calcium hydrogen phosphate dihydrate (brushite) is less soluble in acidic urine, it might seem logical to promote formation of alkaline urine in patients with brushite uroliths. However, brushite may be converted to other insoluble forms of calcium phosphate in alkaline urine (Pak et al, 1971). Use of potassium citrate, an alkalinizing agent, might be rationalized on the basis of minimizing acidosis-induced hypercalciuria, and formation of soluble calcium citrate rather than insoluble calcium phosphate in urine. The benefits or detrimental effects of orally administered potassium citrate to dogs and cats with calcium phosphate urolithiasis, however, have not been carefully evaluated. Consult Chapter 40 (canine calcium oxalate urolithiasis) for additional therapeutic information about potassium citrate.

Thiazide Diuretics

Because thiazide diuretics decrease renal calcium excretion, they may be considered to minimize renal-leak hypercalciuria (Pak, 1982). However, because the long-term effects of thiazide diuretics have not been reported, appropriate caution should be used when giving them to prevent recurrence of calcium-containing uroliths. Patients should be monitored for dehydration, hypercalcemia, hypokalemia and magnesium depletion. Hydrochlorothiazide may be given on a trial basis at a dosage of 2 to 4 mg/kg body weight q12h. Thiazide diuretic therapy is not recommended to treat absorptive hypercalciuria because it does not correct the hyperabsorptive state and may promote positive systemic calcium balance that in turn would predispose the patient to soft-tissue calcification.

Other Drugs

Other drugs have been used in an attempt to minimize hypercalciuria in people (Asplin et al, 1996). Sodium cellulose phosphate, the sodium salt of the phosphoric ester of cellulose, is an ion-exchange cellulose with special affinity for divalent ions. In the gastrointestinal tract it exchanges sodium for dietary calcium, which is then eliminated in the feces. It also binds calcium secreted into the gastrointestinal tract, minimizing its reabsorption. Oral administration of orthophosphates to people with normocalcemic hypercalciuria reduces urine excretion of calcium and increases urine crystal inhibitory activity by increasing the urine concentration of pyrophosphates (Pak, 1982). We have had minimal experience with the use of sodium cellulose phosphate.

REASSESSMENT

Therapy should be initiated in a stepwise fashion (**Table 41-7**). The likelihood of recurrence of calcium phosphate uroliths following removal is not well established. Therefore, patients should be periodically monitored by urinalysis, radiographic or ultrasonographic procedures and other hematologic and urologic laboratory tests, as indicated (**Table 41-7**). Small, recurrent urocystoliths may be removed by voiding urohydropropulsion (Figure 38-5 and Table 38-7) (Lulich et al, 1993), by aspi-

ration through a urinary catheter (Figure 38-6) (Lulich and Osborne, 1992) or by lithotripsy. Dietary and combined dietary and medical therapy of patients with recurring calcium phosphate uroliths should be directed at removing or minimizing risk factors that contribute to supersaturation of urine with calcium phosphate.

Amy Cokley

"If misinterpreted observations are accepted as facts, the result may be misdiagnosis leading to ineffective or even contraindicated treatment."
Carl A. Osborne

PREVALENCE AND MINERAL COMPOSITION

Uroliths composed predominantly of calcium phosphate have been infrequently identified in dogs and cats. However, calcium phosphate is commonly found as a minor component in naturally occurring struvite and calcium oxalate uroliths. Occasionally a shell of calcium phosphate will form around a urolith composed primarily of struvite.

At least four mineral types have been identified in calcium phosphate uroliths **(Table 41-1)**. The most common form identified in calcium phosphate uroliths from dogs and cats is hydroxyapatite, followed by brushite. Calcium carbonate uncommonly exists as a pure compound in canine and feline uroliths. Calcium carbonate often occurs in equine, rabbit, guinea pig and caprine uroliths (Osborne et al, 1989). In the presence of conditions associated with urinary tract infections (UTIs) caused by urease-positive bacteria, carbonate radicals may be generated that associate with the complex apatite structure to form a carbonate apatite lattice (Osborne et al, 1985). Uncommonly identified crystalline forms of calcium phosphate in uroliths include whitlockite and octacalcium phosphate.

More than one crystalline form of calcium phosphate may be present in a single urolith. In alkaline urine, brushite is readily transformed to apatite; it is possible that some apatite identified in uroliths originated from brushite (Pak et al, 1971). In addition, mixtures of calcium phosphate and calcium oxalate often occur. With the exception of brushite, canine calcium phosphate uroliths do not appear to have a characteristic shape.

Calcium phosphate accounted for 0.51% (1,801) of all (350,803) canine uroliths submitted to the Minnesota Urolith Center from 1981 to 2007 (Table 38-8), and 0.67% (273 of 40,612) of the uroliths submitted in the year 2007. Calcium phosphate accounted for 1.6% of canine upper tract uroliths analyzed at the Minnesota Urolith Center from 2000 to 2006 (Table 38-9). Calcium phosphate accounted for 2.8% of uroliths retrieved from dogs less than 12 months old. Of 1,801 canine

Table 41-1. Common characteristics of canine calcium phosphate uroliths.

Variations in mineral composition
Calcium apatite only
Brushite only
Calcium apatite mixed with calcium oxalate
Brushite mixed with calcium oxalate
In dogs, the carbonate apatite form of calcium phosphate is most commonly detected as a minor component of infection-induced struvite
Physical characteristics
Color: Calcium phosphate uroliths are usually cream or tan. Blood clots mineralized with calcium phosphate are typically black.
Shape: Variable. With the exception of brushite, calcium phosphate uroliths do not have a characteristic shape. The external surface of brushite uroliths is typically round and smooth.
Nuclei: Brushite uroliths are often laminated.
Density: Generally dense and brittle, sometimes chalk-like. Mineralized blood clots may be softer. All forms of calcium phosphate are radiodense compared to soft tissue.
Number: Single or multiple
Location: Kidneys, ureters, urinary bladder (most common) and/or urethra
Size: Variable, with smaller sizes more common
Prevalence
Approximately 0.5% of all canine uroliths. Approximately 1.6% of canine upper tract uroliths.
Characteristics of affected canine patients
No gender prevalence for calcium apatite. Brushite is more common in males. Mean age at diagnosis is seven years (range <1 to >16 years).

hydroxyapatite and carbonate apatite uroliths, 473 were composed entirely (100%) of calcium phosphate, and 694 were composed of at least 70% of these minerals. Of 693 canine brushite uroliths, 233 were composed entirely (100%) of calcium phosphate, and 460 were composed of at least 70% of this mineral. The mean age of dogs at the time of urolith retrieval was approximately nine years (range one month to 19 years). Calcium phosphate accounted for less than 2.3% of calcium phosphate uroliths formed by dogs less than 12 months old. Males were affected (57%) more commonly than females (43%). Forty different breeds were affected including cocker spaniels (10%), mixed breeds (20%), miniature schnauzers (10%), Yorkshire terriers (7%), Shih Tzus (6%) and springer spaniels (5%). Hydroxyapatite uroliths were more commonly removed from the lower urinary tract (81%) than the upper urinary tract (8%). The location of 11% of the hydroxyapatite uroliths was not specified.

ETIOPATHOGENESIS AND RISK FACTORS

Solubility of Calcium Phosphates in Urine

Overview

The solubility of calcium phosphates in urine depends on: 1) urinary pH, 2) urine calcium ion concentration, 3) total urine inorganic phosphate concentration, 4) urine concentration of inhibitors of calcium crystallization and 5) urine concentration of potentiators of crystallization. Factors that decrease calcium phosphate solubility predispose patients to urolith formation.

Urinary pH

Urinary pH has a profound effect on the solubility of some forms of calcium phosphate (Elliot, 1957). With the exception of brushite, calcium phosphate solubility markedly decreases in alkaline urine and increases in acidic urine. Increased urinary pH increases the availability of ionic PO_4^{3-} and HPO_4^{2-}, which are available for incorporation into calcium phosphates (Asplin et al, 1996). Apatite will not crystallize from human urine unless the pH is 6.6 or greater (Elliot, 1968). Approximately 400 mg of calcium phosphate/l can be held in solution at a pH of 5.5, whereas only 32 mg of calcium phosphate/l will be held in solution at a pH of 7.8 (Elliot, 1965). Therefore, people with disorders associated with persistent elevation of urinary pH (e.g., distal renal tubular acidosis [RTA]) are predisposed to calcium phosphate urolith formation. In contrast to carbonate apatite and hydroxyapatite, the solubility of brushite decreases in acidic urine.

Hypercalciuria

Hypercalciuria decreases calcium phosphate solubility and may result in oversaturation with calcium phosphate (Pak, 1978). Hypercalciuria may result from: 1) excessive resorption of calcium from bone, 2) enhanced intestinal absorption of calcium, 3) impaired renal tubular reabsorption of calcium and/or 4) combinations of these factors. Urine specimens obtained from human patients with hypercalciuria and calcium uroliths are usually supersaturated with brushite.

Controversy exists as to the relative importance of urinary pH and hypercalciuria as determinants of calcium phosphate solubility in vivo. Some investigators believe that calcium phosphate crystallization is primarily governed by changes in urinary pH; they minimize the importance of hypercalciuria (Elliot, 1968). However, other investigators suggest that persistent hypercalciuria tends to increase the calcium phosphate saturation of urine so that small increases in urinary pH will result in calcium phosphate crystalluria. Apparently, there have been no studies reported on the relative effect of hypercalciuria and urinary pH on the solubility of different types of calcium phosphate in canine urine.

Crystallization Inhibitors

Normally, urine contains calcium phosphate crystal inhibitors. One mechanism by which inhibitors prevent urolith formation is by chelating urolith constituents, making them unavailable for nidus formation or crystal growth. In addition, crystallization inhibitors may alter crystalline structure in such a way that crystal growth and aggregation are prevented. Inhibitors of calcium phosphate crystallization include inorganic pyrophosphates, citric acid ions, magnesium ions and nephrocalcin (Bisaz et al, 1978; Ito and Coe, 1977). In healthy human urine, these inhibitors provide 70 to 80% of the inhibitory capacity to calcium phosphate crystallization (Asplin et al, 1996). As yet unidentified low-molecular-weight inhibitors provide the remaining 20 to 30%.

Pyrophosphates increase the upper limit of urine calcium phosphate saturation at which spontaneous precipitation

occurs. Pyrophosphates also retard growth of hydroxyapatite crystals by adsorbing to their surfaces and blocking active growth sites. In addition, pyrophosphates inhibit transformation of amorphous calcium phosphate into a crystalline form (Fleisch, 1978). Citrate forms soluble complexes with calcium, thereby decreasing the availability of calcium for incorporation into crystals. Magnesium may replace calcium on the surface of growing crystals and thus block epitaxial growth.

Crystallization Promoters

Formation of calcium phosphate uroliths may be promoted by epitaxy. Epitaxy is the process by which crystals of one salt induce the formation of crystals of another salt. Epitaxic induction occurs between crystals having similar lattice dimensions. Calcium phosphate precipitation has been reported to be stimulated by calcium oxalate and monosodium urate crystals (Fleisch, 1978).

Disorders Associated with Formation of Calcium Phosphate Uroliths

Overview

Calcium phosphate uroliths may occur in patients with: 1) primary hyperparathyroidism, 2) other hypercalcemic disorders, 3) distal RTA and 4) idiopathic hypercalciuria (**Table 41-2**) (Asplin et al, 1996; Curhan et al, 1997; Menon et al, 1998). Because the prevalence of calcium phosphate uroliths in dogs is low, and because appropriate metabolic studies have rarely been performed in affected cases, the association of calcium phosphate uroliths with other canine metabolic disorders has not been as well established.

Primary Hyperparathyroidism

Between 18 to 20% of human patients with primary hyperparathyroidism have uroliths at the time of diagnosis (Nikkila et al, 1989). In one series of 72 dogs with primary hyperparathyroidism, 22 (31%) had uroliths (Feldman and Nelson, 1996). Uroliths from patients with primary hyperparathyroidism are typically composed of calcium phosphate, calcium oxalate or a mixture of the two. Uroliths composed predominantly of calcium phosphate are more commonly identified in people and dogs with primary hyperparathyroidism; uroliths composed primarily of calcium oxalate are more commonly identified in people and dogs with normocalcemic hypercalciuria (Klausner and Osborne, 1986). Bladder uroliths composed primarily of calcium phosphate have been experimentally induced in dogs following injections of parathyroid hormone (PTH) (Leberman, 1940).

Factors that predispose patients with primary hyperparathyroidism to calcium phosphate urolith formation include: hypercalciuria, increased urinary pH and increased renal excretion of metabolites that promote spontaneous precipitation of calcium salts (**Table 41-3**). Hypercalcemia results from PTH-induced bone resorption and renal tubular reabsorption of calcium. In addition, increased intestinal absorption of calcium results from PTH-stimulated conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol (1,25-vitamin D) (Pak, 1978).

†Adapted from Caruana RJ, Buckalew VM. The syndrome of distal (type 1) renal tubular acidosis: Clinical and laboratory findings in 58 cases. Medicine 1988; 67: 84.

Hypercalcemia results in increased glomerular filtration of calcium and hypercalciuria, which in turn enhances the likelihood of urolith formation by increasing urine saturation with brushite and calcium oxalate (Pak, 1978). The urine of most hypercalciuric people with primary hyperparathyroidism is supersaturated with brushite and calcium oxalate. Hypercalciuria and hyperphosphaturia have been documented to occur in dogs with primary hyperparathyroidism and calcium uroliths (Klausner and Osborne, 1986; Klausner et al, 1987).

Persistent elevation in urinary pH may predispose some patients with primary hyperparathyroidism to calcium phosphate urolithiasis. Urinary pH is elevated in these patients because of impaired renal tubular reabsorption of bicarbonate (Broadus, 1980). This abnormality may explain, at least in part, the increased occurrence of calcium phosphate uroliths in patients with primary hyperparathyroidism compared with patients with other hypercalciuric diseases.

It has been suggested that some human patients with pri-

Table 41-3. Some potential risk factors for canine calcium phosphate uroliths.

Food	Urine	Metabolic	Drugs
Alkalinizing potential	Alkaline pH	Hypercalcemia	Urine alkalinizing drugs
High calcium content	Hypercalciuria	Distal renal tubular acidosis	Furosemide
High sodium content	High phosphate ion concentration		Glucocorticoids
High phosphorus content?	Increased concentration of promoters		Sodium chloride
Low-moisture content	Decreased concentration of inhibitors		Vitamin D
Excessive vitamin D content	Hypocitraturia		
High protein content	Hypomagnesuria		
Low magnesium content	Blood clots in renal pelvis or bladder lumen		
	Urine concentration

mary hyperparathyroidism excrete a substance in their urine that facilitates calcium phosphate and calcium oxalate precipitation (Pak, 1978). The specific nature of this urolithiasis-promoting factor has not been determined.

Other Hypercalcemic Disorders
In addition to primary hyperparathyroidism, other hypercalcemic disorders may predispose patients to formation of calcium phosphate uroliths. Uroliths have been identified in human patients with hypervitaminosis D, neoplastic disorders, Cushing's syndrome and in some patients who are immobilized for long periods (**Table 41-2**) (Menon et al, 1998). Although calcium phosphate is the most frequently identified mineral in uroliths obtained from these patients, calcium oxalate may also be present. Because the frequency of occurrence of uroliths in patients with these hypercalcemic disorders is low, it is likely that factors in addition to hypercalcemia are involved.

Distal Renal Tubular Acidosis
Nephrolithiasis is a common manifestation of hereditary, acquired and idiopathic forms of RTA (Type I) in people (Caruana and Buckalew, 1988). Uroliths are typically composed entirely of calcium phosphate, calcium oxalate and struvite (Backman et al, 1980). Urolith formation has also been observed occasionally in patients with proximal RTA (Type II) (Menon et al, 1998). To the best of our knowledge, struvite uroliths are the only urolith type observed in canine patients with RTA (Bovee et al, 1979; Polzin et al, 1986).

Distal RTA results from functional inability of the distal nephron to establish a hydrogen ion gradient between blood and tubular fluid, regardless of the severity of acidemia. The disorder in people is characterized by the inability to decrease urinary pH below 5.4, hypokalemia, hyperchloremia, hypophosphatemia, hypocalcemia, metabolic acidosis, osteomalacia, nephrocalcinosis and urolithiasis (Caruana and Buckalew, 1988; Menon et al, 1998).

Hypercalciuria, alkaline urine, low urine citrate concentration and excessive urine phosphate excretion contribute to formation of calcium phosphate uroliths observed in patients with distal RTA (**Table 41-4**) (Caruana and Buckalew, 1988; Menon et al, 1998). Hypercalciuria and hyperphosphaturia tend to increase urine saturation with calcium phosphate. Acidosis increases calcium mobilization from bone, causing an increase in the quantity of calcium excreted in urine (Klausner and Osborne, 1986). In addition, acidosis decreases renal tubular reabsorption of calcium, further increasing calcium excretion. Acidosis may alter renal tubular calcium transport, the response of the tubules to PTH or both.

Elevated urinary pH increases the availability of PO_4^{3-} and HPO_4^{2-}, which may be incorporated into ionic octacalcium phosphate and brushite, respectively (Asplin et al, 1996). Increased urinary pH is considered more important than hypercalciuria in predisposing patients with distal RTA to calcium phosphate urolith formation (Asplin et al, 1996).

Patients with distal RTA consistently excrete decreased amounts of citrate in their urine (Caruana and Buckalew, 1988). Hypocitratemia in patients with distal RTA has been attributed to: 1) increased proximal tubule reabsorption of citrate as a consequence of intracellular acidosis, 2) a primary

defect in tubular function and 3) the effects of hypokalemia (Caruana and Buckalew, 1988). Because citrate is a major chelator of calcium, hypocitraturia decreases calcium solubility and may represent an important risk factor in the pathogenesis of calcium phosphate and calcium oxalate uroliths associated with RTA (Menon et al, 1998).

In human patients, distal RTA sometimes occurs as an incomplete form in which urolith formation occurs without systemic acidosis. Urolithiasis may be the only clinical manifestation of this disorder (Konnak et al, 1982). The tubular defect can be recognized by an abnormal response to an ammonium chloride loading test.

Normocalcemic Hypercalciuria

Normocalcemic hypercalciuria is a syndrome characterized by normal serum calcium concentration, increased urinary excretion of calcium, absence of systemic disease and increased tendency for formation of calcium phosphate or calcium oxalate uroliths (Curhan et al, 2007). Approximately 33% of human calcium urolith formers have normocalcemic hypercalciuria (Menon et al, 1998). Normocalcemic hypercalciuria has also been recognized in dogs (Lulich et al, 1991). It has not been documented to occur in cats, likely due to little effort to detect it.

Two types of normocalcemic hypercalciuria have been recognized in dogs (Lulich et al, 1991). One type, called absorptive hypercalciuria, is associated with increased intestinal absorption of calcium. The subsequent increase in serum calcium concentration suppresses PTH secretion, resulting in decreased tubular reabsorption of calcium and hypercalciuria. Hyperabsorption of calcium from the intestinal tract may result from a primary intestinal disturbance in calcium transport. It is also possible that increased calcium absorption results from increased synthesis of 1,25-vitamin D. Absorptive hypercalciuria has been divided into subtypes based on urinary calcium excretion following consumption of different levels of dietary calcium (Menon et al, 1998).

The second type of normocalcemic hypercalciuria, termed renal-leak hypercalciuria, is thought to result from impaired ability of the proximal tubules to reabsorb filtered calcium (Lulich et al, 1991a; Menon et al, 1998). A defect in reabsorption of magnesium may also be present. Renal calcium loss stimulates 1,25-vitamin D and PTH synthesis, resulting in an increase in intestinal absorption of calcium.

Hypercalciuria is probably not the only factor involved in urolith formation in patients with normocalcemic hypercalciuria because many hypercalciuric patients do not form uroliths. Crystallization inhibitor and promoter interaction are also important contributing factors.

The diagnosis of idiopathic hypercalciuria is established by demonstrating an increase in 24-hour urinary calcium excretion and by eliminating other nonhypercalcemic, hypercalciuric disorders such as RTA (**Table 41-4**) (Lulich et al, 1991a, 1991; Menon et al, 1998). Unlike absorptive hypercalciuria, renal-leak hypercalciuria is not affected by withholding food. **Table 41-5** presents a problem-specific database for dogs suspected of having calcium phosphate uroliths, and is a useful clinical tool.

Mineralization of Blood Clots

Nephroliths, urocystoliths and urethroliths composed of blood clots mineralized with calcium phosphate have been observed on numerous occasions in dogs (and cats). Formation of highly concentrated urine in patients with gross hematuria may favor formation of mineralized blood clots. Contrary to one theory, these black-colored uroliths are not composed of bile metabolites.

BIOLOGIC BEHAVIOR

Calcium phosphate uroliths may increase in size and number if underlying causes persist. In our experience, blood clots within the urinary tract that have become mineralized with calcium phosphate often remain inactive for years.

KEY NUTRITIONAL FACTORS

The determination of key nutritional factors for prevention of calcium phosphate uroliths is complicated because these uroliths occur relatively infrequently and there are several different potentially underlying causes. Dietary dissolution of calcium phosphate uroliths has not been successful. Depending on the size, calcium phosphate uroliths are readily removed by surgery, lithotripsy, voiding urohydropropulsion (Figure 38-5 and Table 38-7) (Lulich et al, 1993) or aspiration through a urinary catheter (Figure 38-6) (Lulich and Osborne, 1992). Thus, dietary therapy of patients with recurring calcium phosphate uroliths is limited to removing or minimizing risk factors that contribute to supersaturation of urine with calcium phosphate.

The solubility of calcium phosphates in urine depends on: 1) urinary pH, 2) urine calcium ion concentration, 3) total urine inorganic phosphate concentration, 4) urine concentration of inhibitors of calcium crystallization and 5) urine concentration of potentiators of crystallization. The key nutritional factors that are thought to increase calcium phosphate solubility to help prevent recurrence of uroliths are summarized in **Table 41-6** and are discussed in more detail below.

Water

Dogs eating dry commercial foods are probably at greater risk for urolith formation than dogs consuming moist foods because dry foods tend to be associated with production of a reduced volume of more concentrated urine. Low urine volume is a risk factor for all types of uroliths because it increases the relative urine saturation of lithogenic constituents. However, it is highly improbable that low urine volume alone would create an environment conducive to calcium phosphate urolith formation.

Although understandably difficult in some patients, encouraging fluid consumption throughout the day with the goal of promoting a consistently large volume of urine is likely to be of benefit. Enhancing urine volume by feeding a moist food may

Oxalic acid	

Table 41-6. Key nutritional factors for foods for the prevention of recurrence of calcium phosphate urolithiasis in dogs.*

Factors	Recommended levels
Water	Water intake should be encouraged to achieve a urine specific gravity <1.020 Moist food will increase water consumption and formation of less concentrated urine
Protein	10 to 25%
Calcium	0.4 to 0.7%
Phosphorus	0.3 to 0.6%
Ca:P ratio	1.1:1 to 2:1
Sodium	<0.3%
Magnesium	0.06 to 0.15%
Vitamin D	500 to 1,500 IU/kg
Urinary pH	6.2 to 6.6**

Key: Ca:P ratio = calcium-phosphorus ratio.
*Nutrients expressed on a dry matter basis.
**Alkaline urine is recommended for patients with distal renal tubular acidosis.

be helpful. Water intake should be encouraged to achieve a urine specific gravity <1.020.

Protein

Foods with a high protein content tend to contribute to hypocitraturia. Citric acid ions inhibit calcium phosphate crystallization. Citrate forms soluble complexes with calcium, thereby decreasing the availability of calcium for incorporation into crystals.

High-protein foods also contribute to hypercalciuria and hyperphosphaturia. Some of the consequences of eating high-protein foods result from obligatory acid excretion associated with protein metabolism. Hypercalciuria occurs in normal dogs fed high-protein foods (40% dry matter [DM]). Therefore, excessive dietary protein consumption should be avoided in dogs at risk for recurrence of calcium phosphate urolithiasis. The recommended range for dietary protein is 10 to 25% DM; the lower end of this range is probably better. The minimum recommended allowance for protein in foods for healthy adult dogs is 10% DM (NRC, 2006).

Calcium and Phosphorus

Hypercalciuria decreases calcium phosphate solubility and may result in oversaturation with calcium phosphate (Pak, 1978). Reduction of dietary calcium appears to be a logical goal for prevention of calcium phosphate urolithiasis because intestinal hyperabsorption of calcium has been identified as one mechanism promoting hypercalciuria in dogs with calcium oxalate uroliths.

Foods with higher levels of phosphorus tend to augment hyperphosphaturia and may predispose hypercalciuric patients to form calcium phosphate uroliths. However, excessive restriction of dietary phosphorus may enhance the availability of dietary calcium for intestinal absorption. It may also enhance production of 1,25-vitamin D by the kidneys, thereby promoting hypercalciuria.

The optimal levels of dietary calcium and phosphorus for dogs with calcium phosphate urolithiasis have not been determined. The following recommendations are the same as for prevention of recurrence of calcium oxalate uroliths (Chapter 40): foods for prevention of calcium phosphate urolith recurrence should contain 0.4 to 0.7% DM calcium and 0.3 to 0.6% DM phosphorus with a calcium-phosphorus ratio range of 1.1:1 to 2:1. The minimum recommended allowances for calcium and phosphorus in foods for healthy adult dogs are 0.4 and 0.3% DM, respectively (NRC, 2006). One survey of the average calcium content of numerous dry grocery brand dog foods was shown to be 1.36% DM and for moist foods 1.73% DM (Debraekeleer, 2000).

In people, some high-fiber foods have been shown to reduce intestinal absorption and urinary excretion of calcium (Menon et al, 1998).

Sodium

Foods with higher quantities of sodium and/or oral administration of sodium chloride are often empirically recommended for prevention of all forms of urolithiasis. However, such excess sodium intake may promote hypercalciuria and enhance the risk of calcium phosphate urolith formation. Therefore, oral sodium chloride therapy is not recommended to promote diuresis in dogs with uroliths containing calcium salts.

Sodium content of foods for canine patients at risk for recurrence of calcium phosphate uroliths should be moderately restricted (<0.3% DM sodium). Typically, commercial dog foods contain two to three times this amount. The minimum recommended allowance for sodium in foods for healthy adult dogs is 0.08% DM (NRC, 2006).

Magnesium

Normally, urine contains calcium phosphate crystal inhibitors. One mechanism by which inhibitors prevent urolith formation is by chelating urolith constituents, making them unavailable

for nidus formation or crystal growth. In addition, crystallization inhibitors may alter crystalline structure in such a way that crystal growth and aggregation are prevented. Magnesium ions are inhibitors of calcium phosphate crystallization (Bisaz et al, 1978; Ito and Coe, 1977).

However, increased urinary excretion of calcium by normal dogs given supplemental magnesium has been observed. Urinary calcium excretion was 0.5 ± 0.2 mg/kg body weight/day in six normal dogs consuming a food containing 0.03% DM magnesium vs. 2.65 ± 1.7 mg/kg body weight/day when the same dogs consumed a food containing 0.38% DM magnesium (Lulich, 1991b). Pending further studies, dietary magnesium restriction or supplementation is not recommended for treatment of canine calcium phosphate uroliths. A moderate range of 0.06 to 0.15% DM is recommended. The minimum recommended allowance for magnesium content of foods for healthy adult dogs is 0.06% DM (NRC, 2006).

Vitamin D

Foods with higher quantities of vitamin D or excessive supplementation with vitamin D may promote hypercalciuria (**Table 41-4**). Vitamin D promotes intestinal absorption of calcium. Commercial foods typically have adequate vitamin D content and should not be further supplemented. Excessive supplementation of homemade foods with vitamin D could also pose a risk. For prevention of calcium phosphate urolithiasis, restrict vitamin D in foods to between 500 to 1,500 IU/kg DM. The recommended minimum allowance for foods for healthy adult dogs is 552 IU/kg DM (NRC, 2006).

Urinary pH

Urinary pH profoundly affects the solubility of some forms of calcium phosphate (Elliot, 1957). With the exception of brushite, calcium phosphate solubility markedly decreases in alkaline urine and increases in acidic urine. Increased urinary pH increases the availability of ionic PO_4^{3-} and HPO_4^{2-}, which are available for incorporation into calcium phosphates (Asplin et al, 1996). Apatite will not crystallize from human urine unless the pH is 6.6 or greater (Elliot, 1968). As mentioned above, approximately 400 mg of calcium phosphate/l can be held in solution at a pH of 5.5, whereas only 32 mg of calcium phosphate/l will be held in solution at a pH of 7.8 (Elliot, 1965). Therefore, people with disorders associated with persistent elevation of urinary pH (e.g., distal RTA) are predisposed to calcium phosphate urolith formation. In contrast to carbonate apatite and hydroxyapatite, the solubility of brushite decreases in acidic urine. Acidification to the degree that induces acidosis should be avoided because it promotes hypercalciuria and hypocitraturia.

For prevention of recurrence of calcium phosphate uroliths in most patients (non-distal RTA patients and non-brushite urolith patients), the food should produce a urinary pH of 6.2 to 6.6.

Long-term alkalinization therapy appears to be beneficial in preventing calcium phosphate urolith formation in people with distal RTA (Caruana and Buckalew, 1988; Menon et al, 1998). Such therapy has been advocated for patients with complete or incomplete forms of distal RTA because it decreases urolith formation and nephrocalcinosis, and it increases urine citrate concentration.

FEEDING PLAN

Patients with primary hyperparathyroidism usually require surgery (Feldman and Nelson, 1996). Parathyroidectomy may result in dissolution of uroliths and generally prevents their recurrence. Parathyroidectomy in a dog with primary hyperparathyroidism and recurrent calcium phosphate uroliths resulted in decreased urinary calcium excretion and prevention of new urolith formation (Klausner et al, 1987).

Surgery and/or lithotripsy are the most reliable ways to remove active calcium phosphate uroliths from the urinary tract. However, surgery may be unnecessary for clinically inactive calcium phosphate uroliths. Voiding urohydropropulsion may be used to remove small urocystoliths (Figure 38-5 and Table 38-7) (Lulich et al, 1993). Although calcium-chelating agents have been reported to be of value in dissolving calcium phosphate uroliths in people, the feasibility of this type of therapy has not yet been reported in dogs and cats.

The frequency of recurrence of calcium phosphate uroliths following removal is not well established. However, unless the underlying cause(s) have been eliminated or controlled, recurrence is likely. Therefore, patients should be periodically monitored by urinalysis, radiographic procedures, and, if indicated, blood and urine tests (**Table 41-7**). If recurrent urocystoliths are detected when they are small, they may be removed by nonsurgical means as described above. Dietary or combined dietary and medical therapy of patients with recurring calcium phosphate uroliths should then be directed at removing or minimizing risk factors that contribute to supersaturation of urine with calcium phosphate.

Assess and Select the Food

Formulation of an optimal food remains a goal for the future. Until such a food becomes available, it is reasonable to recommend trial therapy with foods that most nearly match the key nutritional factor recommendations. **Table 41-8** lists selected veterinary therapeutic foods that can be considered for prevention of calcium phosphate urolith recurrence and compares their key nutritional factor content to the recommended levels. Select the food that most closely matches the key nutritional factor levels described above for preventing the recurrence of calcium phosphate uroliths. Because these foods are intended for long-term feeding, they should also be approved by the Association of American Feed Control Officials (AAFCO), or some other credible regulatory agency. Dogs consuming dry foods may be at greater risk for urolithiasis than dogs consuming moist foods. Dry foods are often associated with higher urine concentrations of urolith constituents and more concentrated urine. Therefore, when possible, moist foods should be selected.

The sodium content of treats should be checked. Treats should not contain more than 0.3% DM sodium and they should be limited to less than 10% of the total food regimen

Table 41-7. Summary of recommendations for managing canine calcium phosphate uroliths.

1. Surgery remains the most reliable way to remove active calcium phosphate uroliths from the urinary tract. However, surgery may be unnecessary for clinically inactive calcium phosphate uroliths. Small urocystoliths may be nonsurgically removed by lithotripsy, voiding urohydropropulsion (Figure 38-5 and Table 38-7) or by aspiration through a urinary catheter (Figure 38-6). Medical therapy of patients with recurrent calcium phosphate uroliths should then be directed at removing or minimizing risk factors that contribute to supersaturation of urine with calcium phosphate.
2. Patients with hypercalcemia and primary hyperparathyroidism usually require surgery. Parathyroidectomy may result in dissolution of uroliths and prevent recurrence in cases that have been properly managed.
3. Several different medical protocols have been reported to be of value in people with normocalcemic hypercalciuria. Ideally, the choice of therapy should be based on the cause of idiopathic hypercalciuria.
   a. There has been little clinical experience with the use of drugs in dogs and cats with calcium phosphate uroliths. However, medications that can enhance urine calcium excretion such as glucocorticoids, furosemide and those containing large quantities of sodium should be avoided (if possible).
   b. Foods designed to avoid excessive protein, sodium, calcium and vitamin D may be of benefit. Excessive restriction or supplementation of dietary phosphorus should probably be avoided. Enhancing urine volume by feeding a moist food (and/or a protein-restricted food to dogs to reduce renal medullary urea concentrations) and encouraging water consumption may be of benefit. Although understandably difficult to accomplish in some patients, fluid intake should be encouraged throughout the day to promote a constantly high urine volume. In people, some high-fiber diets reduce intestinal absorption and urinary excretion of calcium.
   c. With the exception of brushite, calcium phosphates tend to be less soluble in alkaline urine. Whether or not patients with such mineral types would benefit from appropriate dosages of urine acidifiers is unknown. Acidification tends to enhance urine calcium excretion and is a risk factor for calcium oxalate urolith formation. Pending further studies, routine use of urine acidifiers for patients with calcium phosphate urolithiasis is not recommended.
4. Medical dissolution of calcium phosphate uroliths has not been attempted in dogs with distal renal tubular acidosis (RTA). Foods designed to dissolve struvite uroliths would generally not be expected to promote dissolution of calcium phosphate uroliths, in part because they may tend to promote acidemia and aciduria, thus potentially enhancing hypercalciuria and hypocitraturia. However, correction of hypercalciuria, hyperphosphaturia and hypocitraturia by alkalinization therapy with potassium citrate might promote dissolution of these uroliths in patients with complete or incomplete distal RTA. Long-term alkalinization therapy appears to be beneficial in preventing calcium phosphate urolith formation in people with distal RTA. Alkalinization of urine has been advocated for human patients with complete or incomplete forms of distal RTA because it decreases urolith formation and nephrocalcinosis and increases urine citrate concentration. Oral administration of sodium chloride, long recommended for all forms of urolithiasis, may promote hypercalciuria and calcium phosphate urolith formation. Therefore, oral salt therapy is not recommended to promote diuresis in dogs with uroliths containing calcium salts.

(volume or weight basis).

Moderate urinary acidification is recommended for prevention of recurrent calcium phosphate uroliths in most patients. However, for distal RTA patients, long-term alkalinization therapy appears to be beneficial.

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Assess and Determine the Feeding Method

Transitioning a patient from the current food to a new food to help prevent recurrence of calcium phosphate uroliths should be done gradually. Begin the transition by feeding 75% of the current food and 25% of the new food on Day 1. On Day 2, feed half of each food. On Day 3, feed 75% of the new food and 25% of the old food. Feed only the new food beginning on Day 4.

Because moist foods increase water intake and produce a more dilute urine, feeding specific amounts (meal fed) of food two to three times per day is preferred to free-choice feeding. Moist foods can spoil if left at room temperature for several hours (Chapter 11). Opened containers of moist foods should be refrigerated and the feeding bowl should be kept clean.

Besides offering moist foods, several additional ways can facilitate increased water intake. These include: 1) Ensuring multiple bowls are available in prominent locations in the dog's environment; this may mean providing several bowls outside in a large enclosure or a bowl on each level of the house. 2) Bowls should be clean and always be filled with fresh water. 3) Small amounts of flavoring substances (e.g., salt-free bouillon) can be added to water sources. 4) Ice cubes can be offered as treats or snacks. 5) If a dry food is selected, add liberal quantities of water; however, potential food safety issues might arise from leaving moistened dry foods out for prolonged intervals (Chapter 11).

If the patient has a normal body condition score (BCS 2.5/5 to 3.5/5), the amount fed previously was probably appropriate. On an energy basis, a similar amount of the new food would be a good starting place.

ADJUNCTIVE MEDICAL AND SURGICAL MANAGEMENT

Urine Acidifying and Alkalinizing Agents

With the exception of brushite, calcium phosphates tend to be less soluble in alkaline urine. Acidification reduces urine concentrations of ionic phosphate (PO_4^{3-}) and hydroxyl ions (OH^-). However, whether or not patients with calcium phos-

**Alkaline urine recommended for patients with distal renal tubular acidosis.

phate uroliths would benefit from appropriate dosages of urine acidifiers is unknown. Overacidification tends to enhance urine calcium excretion and is a risk factor for calcium oxalate urolith formation. Pending further studies, we do not recommend routine use of urine acidifiers with urine acidifying foods for patients with calcium phosphate urolithiasis.

Because calcium hydrogen phosphate dihydrate (brushite) is less soluble in acidic urine, it might seem logical to promote formation of alkaline urine in patients with brushite uroliths. However, brushite may be converted to other insoluble forms of calcium phosphate in alkaline urine (Pak et al, 1971). Use of potassium citrate, an alkalinizing agent, might be rationalized on the basis of minimizing acidosis-induced hypercalciuria, and formation of soluble calcium citrate rather than insoluble calcium phosphate in urine. The benefits or detrimental effects of orally administered potassium citrate to dogs and cats with calcium phosphate urolithiasis, however, have not been carefully evaluated. Consult Chapter 40 (canine calcium oxalate urolithiasis) for additional therapeutic information about potassium citrate.

Thiazide Diuretics

Because thiazide diuretics decrease renal calcium excretion, they may be considered to minimize renal-leak hypercalciuria (Pak, 1982). However, because the long-term effects of thiazide diuretics have not been reported, appropriate caution should be used when giving them to prevent recurrence of calcium-containing uroliths. Patients should be monitored for dehydration, hypercalcemia, hypokalemia and magnesium depletion. Hydrochlorothiazide may be given on a trial basis at a dosage of 2 to 4 mg/kg body weight q12h. Thiazide diuretic therapy is not recommended to treat absorptive hypercalciuria because it does not correct the hyperabsorptive state and may promote positive systemic calcium balance that in turn would predispose the patient to soft-tissue calcification.

Other Drugs

Other drugs have been used in an attempt to minimize hypercalciuria in people (Asplin et al, 1996). Sodium cellulose phosphate, the sodium salt of the phosphoric ester of cellulose, is an ion-exchange cellulose with special affinity for divalent ions. In the gastrointestinal tract it exchanges sodium for dietary calcium, which is then eliminated in the feces. It also binds calcium secreted into the gastrointestinal tract, minimizing its reabsorption. Oral administration of orthophosphates to people with normocalcemic hypercalciuria reduces urine excretion of calcium and increases urine crystal inhibitory activity by increasing the urine concentration of pyrophosphates (Pak, 1982). We have had minimal experience with the use of sodium cellulose phosphate.

REASSESSMENT

Therapy should be initiated in a stepwise fashion (**Table 41-7**). The likelihood of recurrence of calcium phosphate uroliths following removal is not well established. Therefore, patients should be periodically monitored by urinalysis, radiographic or ultrasonographic procedures and other hematologic and urologic laboratory tests, as indicated (**Table 41-7**). Small, recurrent urocystoliths may be removed by voiding urohydropropulsion (Figure 38-5 and Table 38-7) (Lulich et al, 1993), by aspi-

ration through a urinary catheter (Figure 38-6) (Lulich and Osborne, 1992) or by lithotripsy. Dietary and combined dietary and medical therapy of patients with recurring calcium phosphate uroliths should be directed at removing or minimizing risk factors that contribute to supersaturation of urine with calcium phosphate.

"If in doubt whether or not to give a drug, DON'T."
D.R. Lawrence

INTRODUCTION

Cystine (also called dicysteine) is a nonessential sulfur-containing amino acid composed of two molecules of the amino acid cysteine. What is the etymology of the name cystine? A report published in 1810 described some unusual bladder stones in people as "cystic oxide" (Wollenstan). The etymology of the name cystic oxide was based on the location of the stones in the urinary bladder ("kystis," the Greek term for bladder, is spelled "cystic" in English) and "oxide" for what was thought to be these unique stone's chemical nature. A few decades later, the fact that these stones were not an "oxide" was recognized; however, they were still considered to be composed of material that originated from the urinary bladder (or urocyst). The authors renamed the stones "cystine" (Berzelius, 1833). Subsequently, it was discovered that the stones were composed of a nonessential sulfur-containing amino acid, some of which is eliminated from the body by the urinary system (Segal and Thier, 1989). However, this amino acid is still called cystine (Rogers et al, 2007).

PREVALENCE

The prevalence of cystine uroliths in dogs varies geographically. The prevalence is 1 to 3% of the uroliths removed from dogs in the United States (Bovee and McGuire, 1984; Ling and Ruby, 1986; Osborne et al, 1986, 1999) and as high as 39% in some European centers (Hicking et al, 1981). Cystine accounted for 0.97% (3,402 of 350,803) of all canine uroliths submitted to the Minnesota Urolith Center from 1981 to 2007 (Table 38-8) and 1.1% (447 of 40,612) of canine uroliths submitted in 2007. Cystine accounted for 0.4 to 1.5% (77 of 5,050) of upper tract canine uroliths analyzed at the Minnesota Urolith Center from 1981 to 2006 (Table 38-9). The mean age of dogs at the time of cystine urolith retrieval was approximately 6.0 years (range three months to 16 years). Only 1.4% of uroliths retrieved from dogs less than 12 months of age were cystine. Our epidemiologic data indicate that Newfoundlands appear to be an exception to this generality inasmuch as cystine uroliths were commonly detected before one year of age.

Males (98%) were affected more often than females (2%). With

Table 42-1. Key nutritional factors for foods for canine cystine urolith dissolution and prevention.

Factors	Dietary recommendations
Water	Water intake should be encouraged to achieve a urine specific gravity <1.020 Moist food will increase water consumption and formation of less concentrated urine
Protein	Avoid excess dietary protein Restrict high quality dietary protein to 10 to 18% dry matter
Sodium	Restrict sodium to less than 0.3% dry matter
Urinary pH	Feed a food that maintains an alkaline urine (urinary pH = 7.1 to 7.7)

few exceptions, notably Newfoundlands, other investigators have reported the predominance of cystine uroliths in male dogs. From 2000 to 2006, 146 different breeds were affected including English bulldogs (18%), mixed breeds (16%), dachshunds (6%), mastiffs (6%), basset hounds (3%) and Newfoundlands (2%). At the University of Minnesota Veterinary Medical Center, English bulldogs have surpassed dachshunds in frequency of admissions for evaluation of cystine urolithiasis.

MINERAL COMPOSITION AND ARCHITECTURE

Quantitative analysis of canine cystine uroliths submitted to our center has revealed that most (3,275 of 3,402) are pure; however, a few contain ammonium urate, calcium oxalate and/or silica. Like cystine uroliths, ammonium urate and calcium oxalate uroliths tend to form in acidic urine. It is also of interest that in vitro studies have demonstrated that cystine is a promoter of calcium oxalate crystal growth and aggregation (Martins et al, 2002). Secondary urinary tract infections (UTIs) with urease-producing microbes may result in a nucleus of cystine surrounded by layers of struvite. However, this scenario is uncommon in our experience.

Pure cystine uroliths are usually multiple, ovoid and smooth. They are light yellow and vary from 0.5 mm to several cm in diameter. Some have a rough exterior, but this feature is unusual.

LOCATION

As mentioned above, cystine uroliths were more commonly removed from the lower urinary tract of dogs (98%) than the upper urinary tract (2%). The number of uroliths in each patient varied from one to more than 100. It is noteworthy that, compared to other affected breeds, a relatively high incidence of cystine nephroliths have been observed in Newfoundlands (Casal et al, 1995). Some of them may fill the renal pelvis, although this finding is uncommon. Whereas, cystine uroliths primarily affect the lower urinary tract of other breeds, the upper and lower urinary tracts of Newfoundlands may contain cystine uroliths.

ETIOPATHOGENESIS AND RISK FACTORS

Overview

Cystine is absorbed through the wall of the small intestine. It is normally present in low concentrations in plasma, and is freely filtered by glomeruli. Most filtered cystine is actively reabsorbed in the proximal tubules. The solubility of cystine in urine is pH dependent. It is relatively insoluble in acidic urine, but becomes more soluble in alkaline urine (Rogers et al, 2007). In dogs, the solubility of cystine at a urinary pH of 7.8 has been reported to be approximately double that at a urinary pH of 5.0 (Treacher, 1966).

Genetics

Cystinuria is an inborn error of metabolism characterized by impaired absorption of dibasic amino acids including cystine, ornithine, lysine and arginine by both the intestine and the proximal tubules of the kidneys. The amino acids other than cystine are soluble at the normal physiologic range of urinary pH, and therefore are not lithogenic. The intestinal defect in amino acid absorption is apparently harmless inasmuch as these amino acids are classified as nonessential, and their dipeptide forms are still absorbed. The precise genetic mode of inheritance of canine cystinuria in most breeds is unknown. Although in past years this genetic disorder was thought to be sex-linked in all affected breeds, cystinuria in Newfoundlands (and probably Labrador retrievers) has been recently confirmed to be a mutation in the rBAT gene (renal Basic Amino Acid Transporter) transmitted in a simple autosomal recessive pattern (Calonge et al, 1995; Henthorn, 2007; Segal et al, 1989). In Newfoundlands, the parents of cystinuric dogs are either cystinuric or are carriers, whereas littermates may be: 1) cystinuric, 2) cystinuric carriers or 3) normal. Evaluation of DNA and nitroprusside test results indicates that equal proportions of males and females are affected. However, as will be discussed, male Newfoundlands develop clinical signs referable to uroliths much more frequently than females.

Evaluation of the rBAT gene in several other breeds with cystinuria and with and without cystine uroliths (mastiffs, English bulldogs and Scottish deerhounds) has revealed no mutations.

Aminoaciduria

Cystinuria is characterized by abnormal transport of cystine and other dibasic amino acids by the renal tubules and intestines. Unlike normal dogs, some cystinuric dogs reabsorb a much smaller proportion of the amino acid from the glomerular filtrate (Bovee, 1984). Some may even have net cystine secretion.

The exact mechanism of abnormal renal tubular transport of cystine in most dogs is unknown. When measured, plasma concentrations of cystine in affected dogs were normal, indicating faulty tubular reabsorption and/or tubular secretion rather than hyperexcretion through glomeruli (Bovee, 1984, 1984a; Bovee and McGuire, 1984). Levels of plasma methionine, a precursor of cystine, have been found to be elevated in some cystinuric

**Protocols for measuring urinary pH may vary.

dogs. Results of some studies in people suggest that tubular reabsorption of cysteine, the immediate precursor of cystine, may be abnormal (Segal and Thier, 1989). In this situation, the increase in urinary cystine concentration may result from dimerization of two cysteine molecules in tubular urine.

In dogs with cystinuria, the pattern of dibasic aminoaciduria reported by various investigators has been variable (Bovee, 1984; Clark and Cuddeford, 1971; Cornelius et al, 1967; Crane and Turner, 1956). Apparently there are several different populations of cystinuric dogs (Bovee, 1984; Casal et al, 1995). One group had cystinuria without significant loss of other amino acids. Another group had cystinuria and a lesser degree of lysinuria. Our studies indicate that cystine urolith-forming English bulldogs have cystinuria and lysinuria. Another group had cystinuria, glutaminuria, threoninuria and citrullinuria (Hoppe et al, 1993). A fourth group had cystinuria, ornithinuria, lysinuria and arginuria, a pattern commonly encountered in people with this disorder (Bovee, 1984; Sanderson et al, 1995). This pattern of aminoaciduria may be remembered with the acronym COLA (cystine, ornithine, lysine, arginine).

Unless protein intake is severely restricted, abnormalities associated with loss of amino acids have not resulted in recognizable disorders, with the exception of formation of cystine uroliths. One general exception to this is cystinuric dogs with concomitant carnitinuria. Carnituric dogs consuming foods with reduced quantities of carnitine are predisposed to dilated cardiomyopathy (Sanderson et al, 1995). We have observed a cystinuric dachshund with carnitinuria.

The magnitude of cystinuria varies widely between cystinuric dogs, between serial measurements of the same dog and may decline in older dogs. In one study, four of 14 dogs with a history of cystine urolith formation had urine cystine concentrations that fell within the normal range of those found in control dogs (Bovee, 1984). One explanation that may be related, at least in part, to these differences is diurnal variations in urinary cystine excretion. Some variability may also be related to differences in diets consumed by cystinuric dogs, and differences related to urine collections during fasting and postprandial states. In a study of human cystinuric patients, analysis of six-hour urine samples revealed transient episodes of cystine saturation that were not observed in corresponding 24-hour urine samples.

The major causes of morbidity and mortality recognized in association with this disorder are sequelae of urolith formation. Unfortunately, the exact mechanisms of cystine urolith formation are unknown. Because not all cystinuric dogs form uroliths, and because not all dogs with cystine crystalluria form uroliths, cystinuria is a predisposing rather than the sole cause of cystine urolith formation.

Cystine is sparingly soluble at the usual urinary pH range of 5.5 to 7.5. However, a substantial increase in cystine solubility occurs at urinary pHs above 7.5.

On the basis of observations to date, it is possible to formulate the following working hypothesis. Newfoundlands and possibly other breeds of dogs (excluding mastiffs and English bulldogs) that form cystine uroliths before the age of one year have a severe form of cystinuria caused by homozygous mutation of the rBAT gene. To date, breeds in which cystine uroliths are recognized after the first year of life do not have a mutation in the rBAT gene. The quantity of cystine and other amino acids excreted in the urine of these dogs is highly variable, but is not as severe as the magnitude observed in Newfoundlands. It appears that the genetic abnormality in these dogs can be explained as an x-linked recessive inheritance with incomplete penetrance.

BIOLOGIC BEHAVIOR

Cystine uroliths are not recognized in most affected dogs until after they reach maturity. The average age at detection in many breeds is approximately two to five years. This is surprising inasmuch as one might expect an earlier onset of clinical manifestations of an inherited disorder. It is notable that cystinuria

Table 42-3. Summary of recommendations for combined dietary and medical/surgical treatment and prevention of canine cystine uroliths.

1. Perform appropriate diagnostic studies including complete urinalysis, quantitative urine culture and diagnostic radiography and/or ultrasonography. Determine precise location, size and number of uroliths. The size and number of uroliths are not a reliable index of probable therapeutic efficacy.
2. If uroliths are available, determine their mineral composition. If they are unavailable, determine their composition by evaluation of appropriate clinical data.
3. Consider surgical correction if uroliths obstruct urine outflow and/or if correctable abnormalities predisposing the patient to recurrent urinary tract infection are identified by radiography or other means. Small urocystoliths may be removed by voiding urohydropropulsion (Figure 38-5 and Table 38-7). Urethroliths may be removed by lithotripsy.
4. Initiate therapy with an appropriate litholytic food (**Table 42-2**). For optimal results, no other food or mineral supplements should be fed to the patient. Compliance with dietary recommendation is suggested by a reduction in urea nitrogen concentration (usually <10 mg/dl).
5. Initiate therapy with N-(2-mercaptopropionyl)-glycine (2-MPG)* at a daily dosage of approximately 30 mg/kg body weight, divided into two equal subdoses.
6. If necessary, administer potassium citrate orally to eliminate aciduria. Strive for a urinary pH of approximately 7.5 (range = 7.1 to 7.7).
7. If necessary, eradicate or control urinary tract infections with appropriate antimicrobial agents.
8. Devise a protocol for followup therapy.
   a. Try to avoid diagnostic followup studies that require urinary catheterization. If they are required, give appropriate peri-catheterization antimicrobial agents to prevent iatrogenic urinary tract infection.
   b. Perform serial urinalyses. Urinary pH, specific gravity and microscopic examination of sediment for crystals are especially important. Remember, crystals formed in urine stored at room or refrigeration temperatures may represent in vitro artifacts.
   c. Perform serial radiography monthly to evaluate urolith location(s), number, size, density and shape. Intravenous urography may be used to identify radiolucent uroliths in the kidneys, ureters and urinary bladder. Antegrade contrast cystourethrography may be required for radiolucent uroliths located in the bladder and urethra.
9. Continue litholytic food, 2-MPG and alkalinizing therapy for approximately one month after disappearance of uroliths as detected by radiography.
10. Prevention. Feeding a low-protein food that promotes alkaline urine (**Table 42-2**) has been effective in minimizing cystine urolith recurrence. If necessary, low doses of 2-MPG may also be given.

*Thiola, Mission Pharmacal, San Antonio, TX, USA.

and cystine uroliths have been detected in male and female Newfoundlands less than one year of age (Casal et al, 1995).

Compared to other breeds, the magnitude of the tubular transport defect for cystine in Newfoundlands is more severe. This provides a plausible explanation for the earlier onset of detectable cystine urolith formation in this breed and for the involvement of the kidneys in addition to the urinary bladder in female as well as male dogs (Casal et al, 1995). Because cystinuria is an inherited defect, uroliths commonly recur in two to 12 months unless prophylactic therapy has been initiated. Recurrence in Newfoundlands appears to be more rapid than in other breeds. In some older dogs, the rate of recurrence declines as a consequence of a reduction in magnitude of cystinuria. Spontaneous partial dissolution of cystine uroliths occurred in a 10-year-old neutered male dachshund (adopted by and evaluated for years by CAO). This dachshund was eating a moist maintenance food because it would not eat foods designed to minimize some risk factors for cystine urolithiasis. The patient was not given N-(2-mercaptopropionyl)-glycine (2-MPG[a]) to manage its cystine uroliths because on a previous occasion it developed protein-losing glomerulonephropathy while being treated with this drug.

DIAGNOSIS

Urinalysis

Detection of flat colorless hexagonal cystine crystals provides strong support for a diagnosis of cystinuria. The six sides of cystine crystals may or may not be equal, and the crystals tend to aggregate and may appear layered. Caution: cystine crystals are not constantly present in dogs with cystinuria or cystine uroliths. However, acidification of urine with glacial acetic acid, refrigeration and centrifugation may foster cystine crystal formation. Cystine crystals are insoluble in acetic acid, alcohol, acetone, ether and boiling water. They are soluble in ammonia and hydrochloric acid (pH <2).

We have observed crystals from a cystinuric, leucinuric female Scottish terrier that appeared similar to leucine crystals. Leucine crystals are highly refractile yellow to brown spheres with concentric circles or radial striations.

Assessment of Aminoaciduria

If a sufficient quantity of cystine is present in urine (75 to 125 mg/g of creatinine; 10 mmol/mol creatinine), the colorimetric cyanide-nitroprusside test result will be positive. Sodium cyanide reduces cystine to cysteine, and the free sulfhydryl groups subsequently react with nitroprusside to form a characteristic purple color. Ampicillin and sulfur-containing drugs have been reported to cause false positive reactions to this test.

Screening patients for cystinuria with the nitroprusside test may be aided by submitting fresh urine samples, or urine allowed to dry on 3-mm filter paper, to the Metabolic Screening Laboratory, Section of Medical Genetics, Veterinary Hospital, University of Pennsylvania, Philadelphia 19104-6010 (fax number 215-573-2162). Contact this center for specific instructions about DNA testing, urine and blood sample preservation and sample submission. Their website address is www.vet.upenn.edu./penngen/research/ (Henthorn and Giger, 2007).

Evaluation of urine amino acid excretion rates may provide additional definitive information about cystinuria and associated aminoacidurias. The most commonly used techniques are high-pressure liquid chromatography, and automated amino acid analyzers.

In breeds, such as Newfoundlands, in which the mode of inheritance is simple autosomal recessive, cystinuria may occur in the offspring of phenotypically normal parents. Unfortunately from a diagnostic standpoint, obligate carriers of the disease have no clinical signs, normal cystine urine concentrations and normal renal absorption of amino acids. Ongoing studies at the University of Pennsylvania to identify the gene(s) responsible for cystinuria will likely result in development of diagnostic molecular markers that can be used to identify these genetic carriers.

Radiography and Ultrasonography

The size of cystine uroliths varies from that just detectable by the unaided eye to more than three centimeters. The number present in each patient may vary from one to more than 100. Most canine cystine uroliths are smooth and spherical.

The radiodensity of cystine uroliths compared to soft tissue is similar to struvite and silica, less than calcium oxalate and calcium phosphate and greater than ammonium and sodium urate. Thus, when of sufficient size, cystine uroliths can be detected by survey radiography.

In our experience, double-contrast cystography is more sensitive in detecting small cystine urocystoliths than survey radiography and most techniques of ultrasonography. Cystine uroliths appear radiolucent when surrounded by, but not completely submerged in, radiopaque contrast medium.

Survey radiography may be insensitive for detecting cystine urethroliths. Positive-contrast urethrography may be required to detect and localize cystine uroliths that have passed into the urethral lumen.

Although uroliths can be detected by ultrasonography, this method does not provide information about the degree of their radiodensity or shape. Evaluation of the density and shape of uroliths often provides useful information in predicting their mineral type.

Urolith Analysis

Quantitative analysis of uroliths provides a definitive diagnosis of cystinuria. Uroliths may be collected with a tropical fishnet during the voiding phase of micturition, by catheter-assisted retrieval (Figure 38-6) (Lulich and Osborne, 1992) or by voiding urohydropropulsion (Figure 38-5 and Table 38-7) (Lulich et al, 1993). Samples may be submitted to the Minnesota Urolith Center for quantitative analysis (fax number 612-624-0751).

KEY NUTRITIONAL FACTORS

The key nutritional factors for foods intended for dissolution and prevention of cystine uroliths in dogs are discussed below and summarized in **Table 42-1**.

Table 42-4. Expected changes associated with combined dietary and medical therapy of cystine uroliths.

Factors	Pre-therapy	During therapy	Prevention therapy
Polyuria	±	1+ to 3+	1+ to 3+
Pollakiuria	0 to 4+	↑ then ↓	0
Hematuria	0 to 4+	↓	0
Urine specific gravity	Variable	1.004-1.020	1.004-1.020
Urinary pH	<7.0	>7.0	>7.0
Pyuria	0 to 4+	↓	0
Cystine crystals	0 to 4+	0	Variable
Bacteriuria	0 to 4+	0	0
Bacterial culture of urine	0 to 4+	0	0
Urea nitrogen (mg/dl)	Variable	<15	≤15
Urolith size and number	Small to large	↓	0

Water

Increasing urine volume to reduce urine cystine concentration is likely to be of benefit. Feeding moist rather than dry foods is recommended. Strive to obtain a urine specific gravity value less than 1.020.

Protein

High-protein foods should be avoided in dogs at risk for cystine urolithiasis. These include high-protein dry diets, especially those rich in methionine (a precursor of cysteine). Besides most meats, other food ingredients high in methionine include eggs, wheat and peanuts.

Reduction of dietary protein has the potential of minimizing formation of cystine uroliths. Pilot studies performed on cystinuric dogs at the University of Minnesota revealed a 20 to 25% reduction in 24-hour urine cystine excretion when subjects consumed a low-protein, moist veterinary therapeutic food[b] vs. when they received a moist, canine adult maintenance food. Reducing the concentration of urea in the renal medulla associated with reduced consumption of protein, and the associated reduction in urine concentration is an important indirect effect (Osborne et al, 1985). Protein levels in foods for dogs with cystine urolithiasis should be between 10 to 18% dry matter (DM). The minimum recommended allowance for protein in foods for healthy adult dogs is 10% DM (NRC, 2006).

Sodium

Data derived from studies in cystinuric people suggest that dietary sodium may enhance cystinuria (Jaeger et al, 1986). In one study of cystinuric people, dietary restriction of sodium reduced the urinary excretion of cystine. Further studies are required to evaluate the effect of dietary sodium on urinary excretion of cystine in dogs. Until data indicate otherwise, dietary sodium should be limited to less than 0.3% DM in cystine litholytic and prevention foods. Typically, commercial dog foods contain two to three times this amount. The minimum recommended allowance for sodium in foods for healthy adult dogs is 0.08% DM (NRC, 2006).

Table 42-5. Managing cystine uroliths refractory to complete dissolution.

Causes	Identification	Therapeutic goal
Client and patient factors		
Inadequate dietary compliance	Question owner Persistent cystine crystalluria Urea nitrogen >10-17 mg/dl Urine specific gravity >1.010-1.020 Urinary pH <7.0-7.5 during treatment with Prescription Diet u/d Canine* (use lower values for the moist food)	Emphasize value of feeding dissolution food
Inadequate 2-MPG** administration	Question owner Count remaining pills	Emphasize value of giving the full dose of medication Determine if owner is capable and willing to administer medication If necessary, demonstrate a variety of methods to administer medication
Clinician factors		
Incorrect prediction of mineral type	Analysis of retrieved urolith	Adjust therapy based on correct identification of mineral type
Inadequate 2-MPG dose for degree of diuresis	No change in urolith size after two months of appropriate therapy	Increase 2-MPG dose to 20 mg/kg body weight q12h
Disease factors		
Compound urolith	Radiographic density of nucleus and outer layer(s) of urolith are different Analysis of retrieved urolith	Adjust therapy based on identification of new mineral type Uroliths not causing clinical signs should be monitored for potentially adverse consequences(obstruction, urinary tract infection, etc.) Clinically active uroliths may require surgical removal Remove small uroliths by voiding urohydropropulsion (Figure 38-5 and Table 38-7); consider removing urethroliths by lithotripsy

*Hill's Pet Nutrition, Inc., Topeka, KS, USA.
**2-MPG = N-(2-mercaptopropionyl)-glycine. Thiola. Mission Pharmacal, San Antonio, TX, USA.

Urinary pH

The solubility of cystine in urine is pH dependent. Foods that promote formation of acidic urine are risk factors for cystine urolithiasis in susceptible dogs. Cystine is relatively insoluble in acidic urine, but becomes more soluble in alkaline urine (Rogers et al, 2007). In dogs, the solubility of cystine at a urinary pH of 7.8 has been reported to be approximately double that at a urinary pH of 5.0 (Treacher, 1966). Changes in urinary pH that remain in the acidic range have minimal effect on cystine solubility. A protein-restricted alkalinizing food without other therapy,[b] was observed to have a beneficial effect in promoting reduction in cystine urocystolith size in a three-year-old male dachshund (Osborne et al, 1989). Urinary pH values greater than 7.7 should be avoided until it is determined whether or not they provide a significant risk factor for formation of calcium phosphate uroliths. Thus, a food that produces a urinary pH range of 7.1 to 7.7 is recommended for dogs with cystine urolithiasis.

FEEDING PLAN

Current recommendations for dissolution of cystine uroliths encompass reducing urine concentration of cystine and increasing the solubility of cystine in urine. This may be accomplished by various combinations of: 1) dietary modification, 2) administration of thiol-containing drugs and 3) alkalinization of urine, if necessary. Small cystine urocystoliths may be removed by voiding urohydropropulsion (Figure 38-5 and Table 38-7) (Lulich et al, 1993) or retrieval with a urinary catheter (Figure 38-6) (Lulich and Osborne, 1992). Urethroliths may be removed by lithotripsy.

Assess and Select the Food

Table 42-2 lists selected veterinary therapeutic foods that can be considered for dissolution and prevention of cystine uroliths and compares their key nutritional factor content to the recommended levels. Select the food that is most similar to the key nutritional factor targets. Because these foods are intended for long-term feeding, they should also be approved by the Association of American Feed Control Officials (AAFCO), or some other credible regulatory agency. Dogs consuming dry foods may be at greater risk for urolithiasis than dogs consuming moist foods. Dry foods are often associated with higher urine concentrations of urolith constituents and more concentrated urine. Therefore, when possible, moist foods should be selected.

If treats are fed, their sodium content should be checked.

Treats should contain no more than 0.3% DM sodium (the same as the food recommendation) and they should be limited to less than 10% of the daily total food regimen (volume or weight basis).

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Assess and Determine the Feeding Method

Transitioning a patient from its current food to a new food selected for the management of cystine uroliths should be done gradually over a period of a few days. Begin the transition by feeding 75% of the current food and 25% of the new food on Day 1. On Day 2, feed half of each food. On Day 3, feed 75% of the new food and 25% of the old. By Day 4 or 5, feed only the new food.

Moist foods increase water intake and produce less concentrated urine; therefore, encourage clients to feed specific amounts (meal fed) of moist food two to three times per day rather than free-choice feeding. Moist foods can spoil if left at room temperature for several hours (Chapter 11). Opened containers of moist foods should be refrigerated and the feeding bowl should be kept clean.

Besides offering moist foods, increased water intake can be facilitated by: 1) Ensuring multiple bowls are available in prominent locations in the dog's environment; this may mean providing several bowls outside in a large enclosure or a bowl on each level of the house. 2) Bowls should be clean and kept filled with fresh water. 3) Small amounts of flavoring substances (e.g., salt-free bouillon) can be added to water sources to encourage consumption. 4) Ice cubes can be offered as treats or snacks. 5) If a dry food is selected, ask the client to add liberal quantities of water; however, as with moist foods left at room temperature for prolonged intervals, potential food safety issues might arise (Chapter 11).

If the patient has a normal body condition score (BCS 2.5/5 to 3.5/5), the amount of the previous food being fed was appropriate. On an energy basis, a similar amount of the new food would probably be a good starting place.

ADJUNCTIVE MEDICAL MANAGEMENT

Thiol-Containing Drugs

2-MPG

Drugs that increase the solubility of cystine in urine contain a thiol group that can dissociate and then bind with the sulfide moiety of cysteine. The resulting complexes are more soluble in urine than cystine (dicysteine).

2-MPG is commonly called tiopronin.[a] Tiopronin is a second-generation cysteine chelating agent that decreases the concentration of cystine by a thiol-disulfide exchange reaction. Studies in people and dogs indicate that the drug is highly effective in reducing urine cystine concentration and has less toxicity than D-penicillamine[c] (Hoppe et al, 1988, 1993; Osborne et al, 1989).

Oral administration of 2-MPG at a daily dosage of approximately 30 to 40 mg/kg of body weight (divided in two equal doses) was effective in inducing dissolution of multiple cystine urocystoliths in nine of 17 dogs evaluated (Hoppe et al, 1993; Osborne et al, 1989). Dissolution required two to four months of therapy. One dog developed nonpruritic vesicular skin lesions following three months of therapy. One month following reduction of the daily dosage of 2-MPG from 30 to 25 mg/kg of body weight, the skin lesions healed. Thrombocytopenia, anemia and elevated hepatic enzyme activities have also occurred in a few cystinuric dogs treated with 2-MPG (Osborne et al, 1989). During therapy with 2-MPG, we encountered protein-losing glomerular disease in a cystinuric dachshund.

Unfortunately, dogs that become hypersensitive to D-penicillamine may also simultaneously become hypersensitive to 2-MPG. The beneficial action of both drugs is dose dependent as are the associated side effects. To avoid this predicament when thiol-containing drugs are needed, we discourage use of D-penicillamine and encourage use of the less toxic 2-MPG. Appropriate evaluations should be performed, especially if 2-MPG is used in dogs with a history of D-penicillamine hypersensitivity.

In our experience, a combination of a litholytic food and 2-MPG therapy is more effective in promoting dissolution of uroliths than either alone. We induced dissolution of 18 episodes of cystine urocystoliths affecting 14 dogs using this combination of diet and drug therapy (Osborne et al, 1989). The mean time required to dissolve the cystine uroliths was 78 days (range 11 to 211 days).

D-Penicillamine

D-penicillamine,[c] also called dimethylcysteine, is commonly referred to as a first-generation cysteine chelating drug. It is a nonmetabolizable degradation product of penicillin that may combine with cysteine to form cysteine-D-penicillamine disulfide (Bovee, 1984a). This disulfide exchange reaction is facilitated by an alkaline pH. The resulting compound has been reported to be 50 times more soluble than free cystine (Lotz et al, 1966). The cysteine-D-penicillamine complex does not react with nitroprusside as does cystine, providing a marker to aid in titrating dosage of the drug (Pahira, 1987).

Although D-penicillamine is effective in reducing urine cystine concentrations, drug-related adverse events limit its use. With the availability of 2-MPG, we have discontinued use of D-penicillamine.

The most commonly used dosage of D-penicillamine for dogs has been 30 mg/kg body weight/day given in two divided

doses. Higher dosages frequently cause vomiting and may cause other undesirable reactions. If nausea and vomiting occur with the aforementioned dosage, the drug may be mixed with food or given at mealtimes. In some instances, it may be necessary to prevent gastrointestinal disturbances by initiating therapy with a low dose and gradually increasing it until a therapeutic dosage is reached.

D-penicillamine has been associated with a variety of adverse reactions in people, including immune complex glomerulonephropathy, fever, lymphadenopathy and skin hypersensitivity (Pahira, 1987). We observed fever and lymphadenopathy in a dachshund given D-penicillamine at a dosage of 30 mg/kg body weight/day (Osborne et al, 1995). The signs subsided following withdrawal of the drug and administration of a short course of glucocorticoids. To minimize such adverse drug events, we prefer to use 2-MPG rather than D-penicillamine.

Captopril

Captopril is a thiol-containing angiotensin-converting enzyme inhibitor that is primarily used as an antihypertensive agent. Captopril has been reported to form a thiol-cystine disulfide that is markedly more soluble than cystine; the mechanism of action is similar to that of 2-MPG and D-penicillamine.

Results of uncontrolled clinical trials of treatment of cystinuric people with captopril have been interpreted to suggest a beneficial effect. However, the clinical value of thiol-containing angiotensin-converting enzyme inhibitors in the management of cystinuria remains unproved by properly controlled clinical trials. Note: the angiotensin-converting enzyme inhibitor enalapril is not a thiol-containing drug.

Bucillamine

Bucillamine[d] is a third-generation cysteine chelating agent that may have greater affinity for cysteine than 2-MPG. Bucillamine has been used to treat human patients with rheumatoid arthritis and apparently has been well tolerated. We have not critically evaluated the efficacy and safety of this drug.

Urine Alkalinizing Agents

The solubility of cystine is pH dependent. In dogs, the solubility of cystine at a urinary pH of 7.8 has been reported to be approximately double that at a urinary pH of 5.0 (Treacher, 1966). Changes in urinary pH that remain in the acidic range have minimal effect on cystine solubility. Therefore, if lack of cystine urolith dissolution occurs in dogs whose urinary pH does not become sufficiently alkaline following compliant initiation of dietary therapy, a sufficient quantity of potassium citrate should be given orally in divided doses to sustain a urinary pH of approximately 7.5. Caution: recall that alkalinization of urine is a risk factor for calcium phosphate uroliths.

Data derived from studies in cystinuric people suggest that dietary sodium may enhance cystinuria (Jaeger et al, 1986). Therefore, potassium citrate may be preferable to sodium bicarbonate to alkalinize urine.

It is of interest that UTIs caused by urease-producing bacteria in an adult male human patient with cystine nephroliths resulted in extreme urine alkalinity and subsequent urolith dissolution (Gutierrez Millet et al, 1985).

REASSESSMENT

Therapy should be initiated in a stepwise fashion (**Table 42-3**). The goal of therapy is to promote cystine urolith dissolution. To be consistently effective, we have found that this requires careful and planned monitoring (**Tables 42-4** and **42-5**). Dietary management should result in formation of less concentrated urine without cystine crystalluria. Strive to achieve urine specific gravity values less than 1.020 (range of 1.015 to 1.020). If the urinary pH remains acidic despite dietary therapy in patients known to be compliant with dietary recommendations, orally administered potassium citrate may be considered.

We recommend that a urinalysis and survey abdominal radiographs be performed approximately every four weeks. Reduction in serum urea nitrogen concentration and urine specific gravity values provides supportive evidence that the client and patient are complying with recommendations to feed a moist food with reduced quantities of protein.

PREVENTION

Because cystinuria is an inherited metabolic defect, and because cystine uroliths recur in a high percentage of young to middle-aged dogs within two to 12 months after surgical removal, prophylactic therapy should be considered. Dietary therapy and if necessary, urine alkalinization may be initiated with the objective of minimizing cystine crystalluria and promoting a negative cyanide-nitroprusside test result. If necessary, 2-MPG may be added to the regimen in sufficient quantities to maintain a urine concentration of cystine less than approximately 200 mg/liter. If the dosage cannot be titrated by measurement of urine cystine concentration, 2-MPG may be given at a dosage of 15 mg/kg body weight q12h. Continuous therapy of urolith-free cystinuric dogs with 2-MPG has been effective in preventing formation of cystine uroliths in studies performed in Sweden and at the University of Minnesota (Hoppe et al, 1988, 1993a; Osborne et al, 1999a).

CASE 42-1

Dysuria in a Dachshund

Carl A. Osborne, DVM, PhD, Dipl. ACVIM (Internal Medicine)
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota, USA

Patient Assessment

A four-year-old, neutered male dachshund was examined for vomiting, depression, dysuria and anuria of two days' duration. Dysuria and pollakiuria were present for two weeks. Physical examination revealed a depressed, mildly dehydrated dog with a large urinary bladder. The dog weighed 6.5 kg and had a normal body condition score (3/5).

Survey radiographs confirmed obstructive uropathy due to multiple urethroliths with marginal radiodensity (**Figure 1**). Blood and urine were collected for routine diagnostic tests. The urethroliths were flushed back into the bladder lumen by urohydropropulsion after the bladder was decompressed via cystocentesis (**Figure 2**). Lactated Ringer's solution was given subcutaneously to correct the dehydration and oral amoxicillin-clavulanic acid (Clavamox[a]) was given to prevent urinary tract infection.

Results of the complete blood count were normal. The major serum biochemistry abnormalities were azotemia (urea nitrogen = 52 mg/dl, normal 4 to 26 mg/dl; creatinine = 3.1 mg/dl, normal 0.4 to 1.5 mg/dl) and hyperphosphatemia (phosphorus = 8.4 mg/dl, normal 2.9 to 6.4 mg/dl). Urinalysis results included the following: specific gravity = 1.025, pH = 6.5, hematuria, pyuria, proteinuria and numerous cystine crystals.

The diagnosis was obstructive uropathy due to urethroliths and postrenal azotemia.

Assess the Food and Feeding Method

The dog was fed a commercial dry adult maintenance food free choice and received a vitamin-mineral supplement each day.

Questions

1. What is the most likely mineral composition of this dog's uroliths?
2. Outline a treatment and feeding plan for this patient.

Answers and Discussion

1. The key diagnostic findings in this dog include: 1) multiple, smooth uroliths with marginal radiodensity, 2) urinary pH = 6.5, 3) cystine crystalluria, 4) sterile urine, 5) normal serum biochemistry profile results, other than azotemia and hyperphosphatemia and 6) dachshund breed. All these findings are consistent with cystine uroliths.
2. Fluid therapy should be continued if azotemia persists. Urohydropropulsion can be repeated if urethral obstruction occurs again. Combined dietary and medical dissolution of canine cystine uroliths is accomplished by a combination of N-(2-mercaptopropionyl)-glycine (2-MPG[b]) and dietary management with a food that reduces urinary excretion of cystine, promotes formation of alkaline urine and reduces urinary concentration. A veterinary therapeutic food that closely matches the key nutritional factor recommendations for cystine dissolution/prevention was selected (Prescription Diet u/d Canine[c]). 2-MPG reduces the urine concentration of cystine by combining with cysteine to form cysteine-2-MPG, which is more soluble than cystine. In studies conducted at the University of Minnesota, mean dissolution time with this combination of therapy was 10 weeks (range two to 30 weeks). Drug-induced adverse events associated with 2-MPG are uncommon in dogs, but when they occur they include Coombs positive spherocytic anemia, thrombocytopenia and

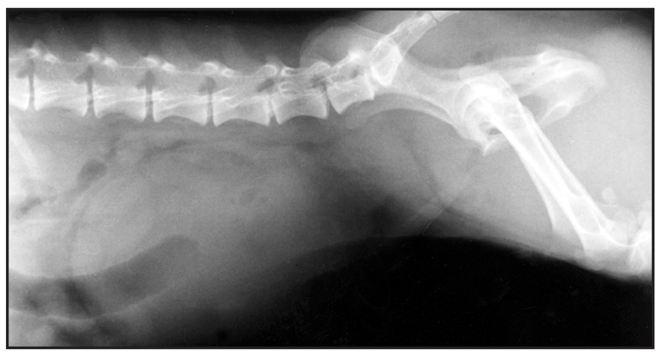

Figure 1. Survey abdominal radiograph of a four-year-old male dachshund illustrating marked distention of the urinary bladder. Two marginally radiodense urethroliths were located behind the os penis.

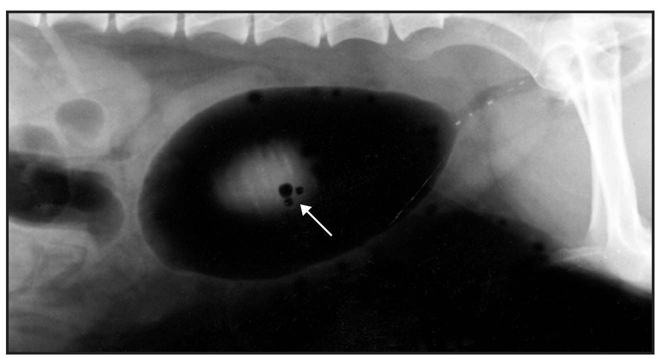

Figure 2. Double-contrast cystogram of the dog described in Figure 1. Three urocystoliths (arrow) can be seen surrounded by contrast media.

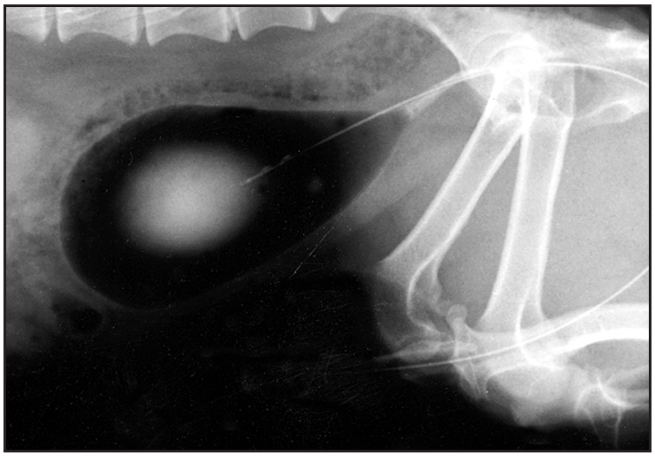

Figure 3. Double-contrast cystogram of the dog described in Figures 1 and 2 taken 40 days after initiation of therapy with 2-MPG and Prescription Diet u/d Canine. There are no uroliths in the bladder lumen. Contrast urethrography confirmed that there were no uroliths in the urethral lumen.

increased hepatic enzyme activity. Antibiotics should also be continued for at least 10 more days. The vitamin-mineral supplement is unnecessary and should be discontinued.

Progress Notes

The azotemia and hyperphosphatemia resolved by the second day of hospitalization, confirming their prerenal origin. The combination of amoxicillin and clavulanic acid was continued. The dog was released from the hospital with instructions for the owner to give 2-MPG at a dosage of 15 mg/kg body weight, per os, twice daily. The food was changed to moist Prescription Diet u/d Canine and the vitamin-mineral supplement was discontinued. Radiographs taken 40 days after initial hospitalization showed no evidence of uroliths (**Figure 3**). Urinalysis results included un-concentrated alkaline urine with amorphous crystals. The serum urea nitrogen concentration was 4 mg/dl, which confirmed that the low-protein food was being fed at home. 2-MPG was discontinued and Prescription Diet u/d Canine was continued. Examination 75 and 232 days after initial hospitalization revealed that the urine continued to be un-concentrated and alkaline with no evidence of crystalluria. The urea nitrogen concentration remained low (5 to 6 mg/dl), which indicated that the owner was compliant with the feeding plan.

"Diagnoses are often a matter of opinion rather than a matter of fact. It is one thing to make a diagnosis, and another thing to substantiate it."
Carl A. Osborne

PREVALENCE AND MINERAL COMPOSITION

Currently, the second most common type of mineral encountered in uroliths from dogs is magnesium ammonium phosphate (MAP) hexahydrate, also known as struvite (Figure 40-1 and Table 38-8). Struvite accounted for 43% of all canine uroliths submitted to the Minnesota Urolith Center from 2000 to 2006 and 39% (16,124 of 40,612) of all canine uroliths submitted during 2007. Struvite accounted for 26% of canine upper urinary tract uroliths analyzed at the Minnesota Urolith Center from 2000 to 2006 (Table 38-9).

Although urolithiasis is most commonly recognized in adult dogs, approximately 1.0% of the total canine uroliths analyzed at the Minnesota Urolith Center were obtained from dogs less than 12 months old. Of 800 uroliths retrieved from dogs less than one year of age, approximately 56% were struvite, 23% were purines (ammonium, sodium and calcium urate, uric acid), 8% were compound uroliths (minerals in the center of uroliths were different from minerals in outer layers), 5% were calcium oxalate, 4% were of mixed mineral composition, 2% were calcium phosphate, 2% were cystine and less than 1% were silica.

The mean age at the time of MAP retrieval from dogs was six years (range one month to 24 years). Females (85%) were affected more often than males (12%; 3% of affected breeds were of unknown gender). A total of 239 different breeds were affected, including mixed breeds (24%), Shih Tzus (11%), miniature schnauzers (9%), Bichon Frises (8%), pugs (4%), dachshunds (4%), Labrador retrievers (3%), miniature poodles (2%), Pekingese (2%), cocker spaniels (3%) and Lhasa apsos (2%). Struvite uroliths were more commonly removed from the lower urinary tract (99%) than the upper urinary tract (1%). They form in a variety of shapes and sizes (**Table 43-1**).

ETIOPATHOGENESIS AND RISK FACTORS

Infection-Induced Struvite Uroliths

Sequential Steps in Urolith Formation

Urine must be supersaturated with MAP hexahydrate for stru-

Table 43-1. Common characteristics of canine struvite uroliths.

Chemical name	Formula	Crystal name
Magnesium ammonium phosphate hexahydrate	$MgNH_4PO_4 \cdot 6H_2O$	Struvite

Variations in mineral composition

Struvite only

Struvite mixed with lesser quantities of calcium apatite and/or ammonium acid urate

Nucleus of a different mineral surrounded by variable layers composed primarily of struvite. Small quantities of calcium apatite and/or ammonium acid urate also may be present.

Physical characteristics

Color: Struvite uroliths are usually white, cream or light brown. The surface of uroliths is commonly red because of concomitant hematuria and may be green due to bile pigments.

Shape: Variable. Solitary urocystoliths are commonly round or elliptic. Multiple urocystoliths may be any shape, but are often pyramidal. Rapidly growing uroliths with a large quantity of matrix may form a cast of the lumen (renal pelvis, ureter, bladder, urethra) in which they are formed.

Nuclei and laminations: Common in infection-induced uroliths

Density: Variable. Soft if they contain a large quantity of matrix. Dense and harder to cut if little matrix is present. A combination of hard and soft internal density may occur within the same urolith. Radiodense compared with non-skeletal tissue on survey radiographs. Degree of radiodensity is related to the quantity of matrix (inversely proportional) and other minerals, especially calcium apatite (more proportional).

Number: Single or multiple

Location: May be located in the kidney, ureter, urinary bladder and/or urethra. Most occur in the urinary bladder.

Size: Subvisual to a size limited by the capacity of the structure (kidney and urinary bladder) in which they form. Very large uroliths are often composed of struvite.

Predisposing factors

Urinary tract infections with urease-producing microbes in patients whose urine contains a large quantity of urea

Alkaline urinary pH

Unidentified factors

Characteristics of affected patients

Mean age: Six years (range = ≤1 to more than 24 years). Especially common in Shih Tzus, pugs, Bichon Frises, miniature schnauzers and dachshunds; however, any breed may be affected. More common in females (~85%) than males (~15%).

$$NH_2\text{-}\overset{\overset{O}{\|}}{C}\text{-}NH_2 + H_2O \xrightarrow{\text{urease}} 2NH_3 + CO_2$$

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^- \leftrightarrow CO_3^=$$

$$NH_3 + H_2O \leftrightarrow NH_4^+ + OH^-$$

Figure 43-1. Illustration of factors leading to formation of struvite, calcium apatite and carbonate apatite as a consequence of degradation of urea by microbial urease. See text below for details.

vite uroliths to form (Osborne et al, 1999). However, acidic urine from people and presumably dogs is normally undersaturated with respect to MAP (Elliot et al, 1958, 1959). Normally, physiologic concentrations of urine ammonium (NH_4^+) increase only when the kidneys excrete high concentrations of acid catabolites. The increase in urine concentration of ammonium in this situation represents a normal compensatory response by the renal tubular cells to secrete ammonia (NH_3) into the tubular lumen to reduce acidity by subsequent formation of ammonium.

Whereas ammonia is lipid soluble and can penetrate tubular cell walls, ammonium is lipid insoluble and cannot penetrate cell walls (so-called ion trapping). Likewise, excretion of alkaline urine under physiologic conditions is associated with reduced renal production of ammonia; thus the quantity of ammonium ions in urine is reduced. However, when urinary tract infections (UTIs) with urease-producing microbes occur in animals forming urine with a sufficient quantity of urea, the unique combination of concomitant elevation in the concentrations of ammonium and carbonate (CO_3^{2-}) in an alkaline environment may develop. These conditions favor formation of uroliths containing struvite [$MgNH_4PO_4 \cdot 6H_2O$], calcium apatite [$Ca_{10}(PO_4)_6(OH)_2$] and carbonate apatite [$Ca_{10}(PO_4CO_3OH_4)_6(OH)_2$] (**Figure 43-1**). The following mechanisms are involved (Osborne et al, 1999). First, urease (a metalloenzyme containing nickel) produced by some types of bacteria or ureaplasmas hydrolyze one molecule of urea to form two molecules of ammonia and one molecule of carbon dioxide. Second, the ammonia molecules react spontaneously with water to form ammonium and hydroxyl ions (pK of NH_3 = 9.03), which alkalinize urine by reducing hydrogen ion concentration. The solubility of struvite and calcium apatite decreases in alkaline urine (Hedelin et al, 1984). In addition to alkalinization of urine, the newly generated ammonium ions are available for formation of MAP crystals. Third, the newly generated molecules of carbon dioxide combine with water to form carbonic acid, which in turn dissociates to form bicarbonate (pK = 6.33) and hydrogen ions. In an extremely alkaline environment, bicarbonate may lose its proton to become carbonate (pK = 10.1). Carbonate anions may displace phosphate anions in calcium apatite crystals to form carbonate apatite crystals. Fourth, in the progressively alkaline environment induced by microbial hydrolysis of urea, dissociation of monobasic hydrogen phosphate (H_2PO^{4-}) results in an increased concentration of dibasic hydrogen phosphate ($H_2PO_4^{2-}$) and anionic phosphate (PO_4^{3-}). Given a constant concentration of total phosphate, a change in pH from 6.8 to 7.4 increases the PO_4^{3-} concentration by a factor of approximately 6 (Burns and Finlayson, 1982). Anionic phosphate is then available in increased quantities to combine with magnesium and ammonium to form struvite or with calcium to form calcium apatite. Fifth, ammonium ions may combine with urates to form ammonium urate (Garcia de la Pena and Cifuentes Delatte, 1981; He et al, 1984).

Both urea (molecular weight = 60 daltons) and urease (molecular weight = 483,000 daltons) are required for ammonia production, alkalinization, supersaturation and subsequent precipitation of struvite, calcium apatite and carbonate apatite crystals. The majority of urea in urine originates from dietary protein (Abdullahi et al, 1984), whereas the urease in vertebrates must be derived from microbes (some bacteria, some yeasts or ureaplasmas) (Delluva et al, 1968; Griffith and Klein, 1983; Kornberg et al, 1954; Levenson et al, 1959). The high

Table 43-2. Some potential risk factors for canine infection-induced struvite uroliths.

Diet	Urine	Patient/metabolic	Drugs
High protein content (source of urea)	Urease-positive UTI	Females	Glucocorticoid-associated bacterial UTI
Urine alkalinizing potential	High urea concentration	Breeds	
High phosphorus content	Hyperammonuria	Miniature schnauzers	
High magnesium content	High-ionic phosphorus concentration	Bichon Frises	
	High magnesium levels	Shih Tzus	
	High pH	Pugs	
	Urine retention	Dachshunds	
	Concentration of urine and thus lithogenic substances	Hyperadrenocorticism associated with bacterial UTI	

Key: UTI = urinary tract infection.

concentration of urea normally present in urine of individuals that consume dietary protein in excess of the daily requirement for protein anabolism makes urine an environment well suited to support the pathogenic effects of urease-producing microbes. Because of the importance of urease in the etiopathogenesis of struvite urolithiasis in people and many other animals, the name "urease stones" has been proposed (Griffith, 1978). Following a parallel line of reasoning in context of pathophysiologic events, the name "urea stones" would also be appropriate (Osborne et al, 1985).

Continued production of ammonia and perhaps other toxic reactants as a consequence of urease-induced ureolysis appears to induce an inflammatory response in the urothelium and adjacent structures (Griffith, 1978a; Krawiec et al, 1984, 1984a). In fact, urease production contributes to the virulence of uropathogens that produce this enzyme (Brande and Siemienski, 1960; MacLaren, 1968; Parsons et al, 1984; Rosenstein and Hamilton-Miller, 1984). The associated increase in urine concentration of proteinaceous inflammatory products acts as a form of matrix and contributes to lithogenesis.

Another mechanism that has been hypothesized to predispose patients with UTIs to urolithiasis is a bacteria-mediated reduction in the urine concentration of citrate (Conway et al, 1949; Robertson and Peacock, 1982; Scott et al, 1943). Citrate is often called a crystallization inhibitor because it can combine with cations such as calcium and magnesium to increase their solubility (Schwille et al, 1979). It has also been suggested that bacteria may produce lithogenic matrix substances (Stegmayr and Stegmayr, 1983).

Bacterial UTIs

Clinical and non-clinical studies involving dogs have repeatedly demonstrated a close relationship between formation of struvite uroliths and UTIs caused by urease-producing bacteria (Osborne et al, 1999). Bacterial UTIs have been such a common finding in dogs with struvite uroliths that they are sometimes called infection stones (Griffith, 1978; Osborne et al, 1981).

Several in vitro observations indicate that bacterial urease-induced supersaturation of urine with MAP is the primary (but not necessarily the only) cause of infection-induced struvite uroliths (Griffith, 1978; Griffith et al, 1976; Griffith and Musher, 1975). First, growth of urease-producing *Proteus* spp. in urea-free urine, or in urine containing a urease inhibitor, did not cause alkalinization, supersaturation or crystallization of struvite and apatite. Second, growth of weak urease-producing bacteria (*Klebsiella* spp. and *Pseudomonas* spp.) and non-urease-producing bacteria (*Escherichia* spp.) was not associated with alkalinization, supersaturation and subsequent precipitation of struvite and apatite crystals.

Staphylococcus and *Proteus* spp. are consistent and potent urease producers and have been commonly isolated from animals and people with infection-induced struvite uroliths (Griffith, 1978, 1978a; Osborne et al, 1981). For unexplained reasons, staphylococci have been more commonly associated with struvite uroliths in dogs than *Proteus* spp., whereas *Proteus* spp. are more commonly associated with struvite uroliths in people (Osborne et al, 1999; Griffith and Klein, 1983; Feit and Fair, 1979; Krajden et al, 1984; Lewis et al, 1984; Stamey, 1980). It appears that some strains of *Proteus mirabilis* have special affinity for the urinary tract of people (Senior, 1979). In pilot studies involving dogs at the University of Minnesota, better success occurred in inducing struvite uroliths with clinical isolates of staphylococci than with *Proteus* spp. Results of studies in rats were interpreted to indicate that different strains of staphylococci had different lithogenic potential (Vermeulen and Goetz, 1954).

Although other organisms such as *Klebsiella* and *Pseudomonas* spp. have potential to produce varying quantities of urease (Griffith, 1978), they have not been as commonly associated with initiation of struvite urolith formation in people or dogs. Likewise, *E. coli* and other non-urease-producing microbes have not been linked to naturally occurring struvite uroliths, presumably because they infrequently produce urease (Griffith, 1978; Lesher and Jones, 1978). However, it has been reported that urease activity may be transferred by bacterial plasmids (Grant et al, 1981).

The bacterial flora of urine may change after formation of struvite uroliths in dogs as a result of staphylococcal UTI. The change in bacterial flora may be associated with damage to local host defense mechanisms by uroliths, iatrogenic infection induced by urinary catheters or administration of antimicrobial agents.

A very small percentage of dogs with struvite uroliths have

Table 43-3. Key nutritional factors for dissolution and prevention of canine struvite uroliths.

Factors	Dietary recommendations
Water	Water intake should be encouraged to achieve urine specific gravity <1.020
	Moist food will increase water consumption and formation of less concentrated urine
Protein	Avoid excess dietary protein
	Dissolution: restrict dietary protein to ≤8%, dry matter (DM)
	Prevention: restrict dietary protein to <25% DM
Phosphorus	Avoid excess dietary phosphorus
	Dissolution: restrict dietary phosphorus to ≤0.1% DM
	Prevention: restrict dietary phosphorus to <0.6% DM
Magnesium	Avoid excess dietary magnesium
	Dissolution: restrict dietary magnesium to <0.02% DM
	Prevention: restrict dietary magnesium to 0.04 to 0.1% DM
Urinary pH	Feed a food that maintains an acidic urine
	Dissolution: urinary pH = 5.9 to 6.1
	Prevention: urinary pH = 6.2 to 6.4

sterile urine. In some of these cases, however, urease-forming bacteria have been isolated from the inside of uroliths even though the urine surrounding the uroliths was sterile. This observation indicates that bacterial infection of the urinary tract may undergo spontaneous remission after initiating urolith formation in some patients. Bacteria that become trapped within struvite uroliths may remain viable for long periods. Several studies have revealed that lithogenic bacteria harbored within uroliths are protected from the destructive effects of antimicrobial agents in urine by biofilms (Nikkila et al, 1989; Fowler, 1984; Nemoy and Stamey, 1971; Rocha and Santos, 1969; Takeuchi et al, 1984).

In contrast to struvite uroliths, bacterial infection of the urinary tract is not a consistent finding in dogs with non-struvite uroliths (ammonium urate, calcium oxalate, cystine, silica, etc.). When infection does occur in association with these so-called metabolic uroliths, it appears to be a sequela rather than a predisposing cause of urolith formation.

Ureaplasma UTIs

Ueaplasmas differ from all other mycoplasmas because they produce urease and, therefore, hydrolyze urea (Ford and MacDonald, 1967; Shepard and Lunceford, 1967). Urea is required for growth of these organisms. Ureaplasmas were recognized as etiologic agents in struvite urolithiasis when struvite uroliths were rapidly produced in male rat urinary bladders by intrarenal or intravesical injection of urease-producing ureaplasmas isolated from people (Friedlander and Braude, 1974; Lamm et al, 1977).

Ureaplasma urealyticum has been isolated from struvite uroliths removed from the renal pelves of people (Hedelin et al, 1984; Pettersson et al, 1983). However, ureaplasmas could not be isolated from nephroliths composed of calcium oxalate, calcium phosphate or uric acid. Large numbers of ureaplasmas were isolated from an adult female basset hound with uroliths presumed to be composed of struvite and located in the renal pelves and urinary bladder.[a] Although the urine from this dog contained urease, urease-producing bacteria could not be isolated from it.

Efforts at the University of Minnesota to isolate ureaplasmas from urine of other dogs with nonbacterial struvite uroliths have been unsuccessful. Further studies are necessary, however, because ureaplasmas are fastidious and cell associated. Factors reported to limit growth of ureaplasmas in broth cultures include pH values greater than 7.5 (Ford and MacDonald, 1967; Shepard and Lunceford, 1967), osmotic activity more than 600 mOsm/kg (Kenney and Cartwright, 1977) and a high ammonia concentration (Rosenstein and Hamilton-Miller, 1984; Ford and MacDonald, 1967).

Food

The quantity of dietary protein catabolized for energy influences formation and dissolution of infection-induced struvite uroliths. Consumption of dietary protein in quantities that exceed daily protein requirements for anabolism results in formation of urea from catabolism of amino acids. Hyperammonuria, hypercarbonaturia and alkaluria mediated by microbial urease are influenced by the quantity of urea (the substrate of urease) in urine (**Table 43-2**).

Abnormal urinary excretion of minerals as a result of enhanced glomerular filtration rate, reduced tubular reabsorption or enhanced tubular secretion is not required for initiation and growth of infection-induced uroliths.

Genetics

The high incidence of struvite urolithiasis in some breeds of dogs such as miniature schnauzers suggests a familial tendency (**Table 43-2**). Susceptible miniature schnauzers apparently inherit some abnormality of local host defenses of the urinary tract that increases their susceptibility to UTIs (Klausner et al, 1980, 1980a). Hereditary factors thought to be associated with inbreeding have been reported to increase the incidence of struvite uroliths in beagles (Kasper et al, 1978). The incidence of struvite uroliths was 10.7% in an inbred line vs. only 2.0% in an outbred line of beagles.

Sterile Struvite Uroliths

Clinical studies indicate that microbial urease is not involved in formation of struvite uroliths in some dogs (Bovee and McGuire, 1984; Osborne et al, 1985, 1999). Several observations suggest that dietary or metabolic factors may be involved

in the genesis of sterile struvite uroliths. Pilot studies involving clinical cases of struvite uroliths in dogs at the University of Minnesota revealed a population of patients (nine of 20) whose urine was frequently alkaline but did not contain identifiable bacteria or detectable quantities of urease. Microscopic examination of demineralized, gram-stained sections of some struvite uroliths removed from dogs with bacteriologically sterile urine did not reveal gram-positive bacteria (Clark, 1974).[a] Whereas infection-induced struvite uroliths from people frequently contain calcium apatite or carbonate apatite, a substantial number of the canine sterile uroliths were 100% struvite.

Recurrent urocystoliths apparently composed of sterile struvite were encountered at the University of Minnesota in three related English cocker spaniels: a sire and two of its male offspring from different dams (Bartges et al, 1992). These dogs were followed for several years and had several episodes of struvite urocystolithiasis associated with alkaluria, but not with bacterial UTI, urinary urease enzyme activity or renal tubular acidosis (RTA). Since that time, other investigators have also observed sterile struvite urocystoliths in English cocker spaniel dogs (Lees et al, 1998).

Although struvite is less soluble in alkaline than acidic urine, the mechanism(s) of sterile struvite urolith formation in dogs is unclear. Under physiologic conditions associated with alkaluria, urine contains low concentrations of ammonia (and thus ammonium ions) (Tannen, 1983). Therefore, alkaline urine formed in the absence of ureolysis would not be expected to favor formation of crystals that contain ammonium ions (e.g., MAP hexahydrate). Clinical studies of naturally occurring urolithiasis in people support this generality (Griffith and Klein, 1983).

Formation of persistently alkaline urine in the absence of urease-mediated ureolysis may predispose patients to formation of uroliths containing hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] but not carbonate apatite. Pathologic conditions that may result in this sequence of events include distal RTA (Coe and Flavus, 1991), incomplete distal RTA (Backman et al, 1981) and perhaps primary hyperparathyroidism (Coe and Flavus, 1991; Klausner et al, 1987). Because alkaline urine favors dissociation of monobasic phosphate ($H_2PO_4^-$) to dibasic phosphate (HPO_4^{2-}) and phosphate ion (PO_4^{3-}), formation of calcium phosphate is enhanced. Patients with distal RTA have impaired ability to acidify urine associated with hypercalciuria and excretion of reduced concentration of urine citrate (Coe and Flavus, 1991; Dedmond and Wrong, 1962; Morrissey et al, 1963; Thornhill, 1977).

BIOLOGIC BEHAVIOR

Struvite uroliths can rapidly form (within two to eight weeks) after infection with urease-producing staphylococci (Klausner et al, 1980, 1980a). Struvite urocystoliths associated with UTI caused by staphylococci or *Proteus* spp. have been detected in puppies as young as five weeks of age (Hardy et al, 1972).

Spontaneous dissolution of uroliths appears to be uncommon. Five cases (two nephroliths and three urocystoliths) of struvite urolithiasis in dogs have been observed in which uroliths underwent spontaneous dissolution (Klausner and Osborne, 1979). Others have also reported spontaneous dissolution of canine nephroliths (Kirby et al, 1980). Bilateral nephroliths were reported to exist for about four years in a miniature schnauzer before causing death from renal failure (Pollack and Wagner, 1976). Urocystoliths frequently pass into the urethra. In male dogs, they commonly lodge behind the os penis, but in female dogs they are frequently voided. Small nephroliths may pass into the ureters. The rapid rates at which struvite uroliths form and the potential they have to migrate to lower portions of the urinary tract are of clinical importance. If several days have elapsed between the date of diagnostic imaging and the date scheduled to remove uroliths, the number and location of uroliths should be reevaluated by radiography or other suitable imaging technique.

Struvite uroliths have a tendency to recur after surgical removal or dietary and medical dissolution (Brown et al, 1977; Kasper et al, 1978; Brodey, 1955). Miniature schnauzers have been observed with at least seven known recurrences following surgery. However, many episodes of multiple recurrences have been associated with lack of removal of all uroliths at the time of surgery (pseudo-recurrence), and poor control of recurrent UTI with urease-producing microbes. With the advent of effective therapeutic and preventive antimicrobial protocols to control recurrent or persistent UTI, the frequency of recurrent infection-induced struvite urolithiasis in dogs has markedly declined. Multiple recurrences of sterile struvite uroliths have been observed in dogs, presumably because the underlying mechanisms causing their formation persisted following dietary and medical dissolution or surgical removal.

The rate of recurrence following dietary and medical dissolution of canine struvite uroliths is less frequent than that associated with surgery. In addition, time elapsed between recurrent episodes is longer following dietary and medical dissolution. The apparent higher rate of recurrence associated with surgical removal of uroliths may be associated with inability to remove all uroliths, especially those located in inaccessible sites or those that are subvisual. The tendency for uroliths to recur after surgery may also be associated with persistence of an environment that favors initiation and growth of struvite at the time of removal.

KEY NUTRITIONAL FACTORS

Urine must be saturated with magnesium, ammonium and phosphate for struvite uroliths to form (Osborne et al, 1999). However, as described above, the process is complex, including multiple interactions. Altering nutrient levels and specific food ingredients can modify several of these interactions, which are reflected in the following key nutritional factors for dissolution and prevention of struvite uroliths. **Table 43-3** summarizes these key nutritional factors.

Water

Increasing urine volume is an effective means of reducing the urinary concentration of urolith constituents. One way to increase urine volume is to increase the water content of the food. Total water intake increases as the moisture content of the food increases. Therefore, consumption of moist foods, which generally contain between 75 to 80% water, effectively increases urine volume. Foods can also be supplemented with sodium chloride to stimulate thirst and induce compensatory polyuria. However, the risks and benefits of adding sodium chloride should be considered in each individual patient, especially those with comorbid diseases that may be aggravated by excessive dietary sodium.

Dietary protein restriction can also increase urine volume by contributing to obligatory polyuria due to a decrease in renal medullary urea concentration resulting from a reduction of hepatic urea production. (See below.)

As a generality, as long as the struvite uroliths are present in the urinary tract, water intake should be encouraged with the goal of promoting a urine specific gravity <1.020.

Protein

The quantity of dietary protein catabolized for energy can influence formation and dissolution of infection-induced struvite uroliths. Consumption of dietary protein in quantities that exceed daily protein requirements results in increased formation of urea due to the deamination of the excess amino acids so that they can be used for energy. The majority of urea in urine originates from dietary protein (Abdullahi et al, 1984). Urease in vertebrates must be derived from microbes (some bacteria, some yeasts or ureaplasmas) (Delluva et al, 1968; Griffith and Klein, 1983; Kornberg et al, 1954; Levenson et al, 1959).

If patients have urinary tract infections caused by urease-producing microbes, and their urine contains a sufficient quantity of urea (the substrate of urease), the result is a unique combination of concomitant high urinary concentrations of ammonium and carbonate in an alkaline environment. These conditions favor formation of struvite (and calcium apatite and carbonate apatite) (**Table 43-2**). One goal of dietary management for patients with infected struvite uroliths is to reduce urinary concentration of urea.

Studies indicate that protein restriction is not essential for dissolution of canine sterile struvite uroliths (Boistelle et al, 1984). High ammonia concentrations were not necessary for formation of struvite crystals provided the concentration of (Mg) x (NH_4) x (PO_4) was of sufficient magnitude at a given pH. Corresponding in vivo studies in dogs have not been performed, but it is probable that similar observations would occur.

Acidification of urine to approximately 6.0 has been effective in promoting sterile struvite urolith dissolution (Osborne et al, 1987). In this respect, canine struvite uroliths are similar to feline sterile struvite uroliths. Dietary protein restriction has the additional advantage of contributing to obligatory polyuria by decreasing renal medullary urea concentration and thus enhancing the rate of sterile struvite urolith dissolution.

The minimum recommended allowance for protein in foods for adult dogs is 10% for foods providing 4 kcal/g dry matter (DM); the minimum requirement is 8% DM (NRC, 2006). For dissolution of struvite uroliths, high quality dietary protein should be restricted to 8% or less DM. For prevention of struvite uroliths, food protein content should be less than 25% DM.

Foods high in protein are generally high in phosphorus unless special ingredients are used in their formulation.

Phosphorus

Abnormal urinary excretion of minerals is not required for initiation and growth of infection-induced struvite uroliths. However, phosphate concentrations in dog urine relate directly to the amount of phosphorus consumed in food (Morris and Doering, 1978).

Although not validated by experimental or clinical studies in dogs, foods high in phosphorus (and magnesium) would be expected to predispose susceptible dogs to sterile struvite urolith formation. In vitro studies in which magnesium (in the form of $MgSO_4$), ammonium (in the form of ammonium of NH_4Cl) or phosphate (as $NH_4H_2PO_4$ or NaH_2PO_4) added to sterile human urine (ranging in pH from 5.0 to 9.6) revealed that struvite crystals could be induced to form in an acidic or an alkaline environment (Boistelle et al, 1984). It is probable that similar observations would occur in dog studies.

The minimum recommended allowance for phosphorus in foods for adult dogs is 0.3% DM (NRC, 2006). The recommended level for phosphorus in foods for dissolution of struvite uroliths should not exceed 0.1% DM. Patients consuming foods with this level of phosphorus could possibly be in negative phosphorus balance for the relatively short period of time they need to be fed a dissolution food. An older study noted that puppies fed a purified food containing 0.11% DM phosphorus from age two months through adulthood (age 34 months) had equivalent performance compared to dogs fed the same food with 0.63% DM phosphorus (Gershoff et al, 1958). Struvite dissolution using a food containing 0.1% DM phosphorus has been safely accomplished in puppies (Osborne et al, 1986; Lulich et al, 1989). For prevention of recurrence of struvite uroliths, phosphorus levels should be less than 0.6% DM.

As discussed above, urinary phosphate can exist in several states. Anionic phosphate is the important form in either the precipitation or dissolution of struvite. Furthermore, as discussed above, urinary concentration of anionic phosphate is reversibly influenced by pH.

Magnesium

Abnormal urinary excretion of minerals as a result of enhanced glomerular filtration rate, reduced tubular reabsorption or enhanced tubular secretion is not required for initiation and growth of infection-induced uroliths. Apparently, however, for sterile struvite precipitates to form, excess dietary magnesium would be required (Boistelle et al, 1984). Avoiding excessive dietary magnesium can reduce the urinary concentration of magnesium (Morris and Doering, 1978).

The minimum requirement for magnesium in foods for healthy adult dogs is 0.018% DM; whereas the minimum rec-

Table 43-4. Summary of recommendations for dietary and medical dissolution of canine struvite uroliths.

1. Adult dogs with urinary tract infection (UTI)
   a. Perform appropriate diagnostic studies including complete urinalysis, quantitative urine culture and diagnostic imaging. Determine precise location, size and number of uroliths. The size and number of uroliths are not a reliable index of probable therapeutic efficacy.
   b. If uroliths are available, determine their mineral composition. If unavailable, determine their composition by evaluation of appropriate clinical data.
   c. Consider lithotripsy or surgical correction if urethroliths obstruct urine outflow. Consider surgery if correctable abnormalities predisposing the patient to recurrent UTIs are identified by diagnostic imaging or other means. Small urocystoliths may be removed by voiding urohydropropulsion (Figure 38-5 and Table 38-7) or lithotripsy.
   d. Eradicate or control UTIs with appropriate antimicrobial agents. Maintain full-dose antimicrobial therapy during and for three to four weeks after urolith dissolution.
   e. Initiate therapy with litholytic foods. Other foods or mineral supplements should not be fed to the patient. Compliance with dietary recommendations is suggested by a reduction in urea nitrogen concentration (usually <10 mg/dl).
   f. Devise a protocol to monitor efficacy of therapy.
      1) Try to avoid diagnostic followup studies that require urinary tract catheterization. If they are required, give appropriate pericatheterization antimicrobial agents to prevent iatrogenic UTIs.
      2) Perform serial urinalyses. Determination of urinary pH and specific gravity and microscopic examination of sediment for crystals are especially important. Remember, crystals formed in urine stored at room or refrigeration temperatures may represent in vitro artifacts.
      3) Perform serial imaging monthly to evaluate urolith location(s), number, size, density and shape.
      4) If necessary, perform quantitative urine cultures. They are especially important in patients infected before therapy and in patients catheterized during therapy.
      5) Feed patients a litholytic food for one month following disappearance of uroliths as detected by survey radiography.
      6) Consider alternative methods if uroliths increase in size during dietary management, or do not begin to decrease in size after four to eight weeks of appropriate dietary and medical management. Difficulty in inducing complete dissolution of uroliths by creating urine that is undersaturated with the suspected lithogenic crystalloids should prompt consideration that: a) the wrong mineral component was identified, b) the nucleus of the uroliths is of different mineral composition than other portions of the urolith (i.e., a compound urolith) and/or c) the client or the patient is not complying with dietary and medical recommendations.
   g. Consider administration of acetohydroxamic acid (25 mg/kg body weight/day divided into two equal doses) to patients with persistent uroliths and persistent urease-producing microburia despite the use of antimicrobial agents and litholytic foods.
2. Adult dogs with persistently sterile urine
   a. Follow the protocol described above, but do not administer antimicrobial agents or acetohydroxamic acid.
   b. Periodically culture urine specimens obtained by cystocentesis to detect secondary UTIs. Initiate antimicrobial therapy if a UTI develops.
   c. Monitor urinary pH with a reliable pH meter. Monitor urine specific gravity with a reliable refractometer. Evaluate urine sediment for evidence of calcium oxalate, calcium phosphate and/or struvite crystalluria.
3. Immature dogs
   a. Use caution when feeding protein-restricted foods to growing dogs.
   b. Short-term therapy with litholytic foods has been effective in dissolving struvite urocystoliths. If initiated, monitor the patient for evidence of nutritional deficiencies (especially protein-calorie malnutrition).
   c. Acetohydroxamic acid has not been evaluated in growing dogs.
   d. Small urocystoliths may be removed by voiding urohydropropulsion (Figure 38-5 and Table 38-7) or lithotripsy. Pending further studies, surgery remains the safest means of removing large uroliths from immature dogs.

ommended allowance is 0.06% DM (NRC, 2006). For dissolution of struvite uroliths, the recommendation for magnesium in food is less than 0.02% DM. The recommendation for prevention of recurrence is 0.04 to 0.1% DM.

Urinary pH

Urinary pH can affect the concentration of important struvite constituents, including anionic phosphate (PO_4^{3-}). As discussed above, as urine becomes more acidic, anionic phosphate is converted to monobasic hydrogen phosphate (H_2PO^{4-}) and dibasic hydrogen phosphate ($H_2PO_4^{2-}$), thereby reducing the concentration of anionic phosphate for incorporation into struvite precipitates. Conversely, as urine becomes more alkaline, the reaction proceeds in the opposite direction and anionic phosphate is then available in increased quantities to combine with magnesium and ammonium to form struvite. Given a constant concentration of total phosphate, a change in pH from 6.8 to 7.4 increases the PO_4^{3-} concentration by a factor of approximately 6 (Burns and Finlayson, 1982).

Urinary tract infections caused by urease-producing microbes can modify urinary pH and anionic phosphate concentration. In the progressively alkaline environment induced by microbial hydrolysis of urea, dissociation of monobasic hydrogen phosphate results in an increased concentration of dibasic hydrogen phosphate and anionic phosphate.

In sterile urine, pH also influences the concentration of ammonium ions (NH_4^+), but in the opposite direction of anionic phosphate. In acidic urine, ammonia (NH_3) combines with hydrogen ions to form ammonium, a struvite constituent. The resolution of this seeming paradox results from the fact that the effect of acidic urine on anionic phosphate concentration is greater than its effect on ammonium; the net effect of urine acidification is a reduction in the likelihood of formation of struvite precipitates. Acidification of urine to approximately 6.0 has been effective in promoting sterile struvite urolith dissolution (Osborne et al, 1987). In this respect, canine sterile struvite uroliths are similar to feline sterile struvite uroliths.

However, if patients have UTIs caused by urease-producing

microbes, and their urine contains a sufficient quantity of urea (See Protein, above.), the result is a unique combination of concomitant high urinary concentrations of ammonium and carbonate in an alkaline environment, further contributing to the likelihood of formation of struvite precipitates.

Urinary pH can be modified by food ingredients and by feeding method. (See Feeding Methods, below.) The target urinary pH range for dissolution of struvite uroliths is 5.9 to 6.1. The target urinary pH range for prevention of recurrence of struvite is 6.2 to 6.4.

FEEDING PLAN

Current recommendations for dietary and medical dissolution of canine struvite uroliths include: 1) eradication or control of UTI (if present), 2) use of litholytic foods and 3) administration of urease inhibitors (acetohydroxamic acid) to patients if struvite uroliths persist because of persistent UTI caused by urease-producing microbes (**Table 43-4**). **Table 43-4** also summarizes the overall dietary/medical/surgical management of struvite urolithiasis in adult dogs with a UTI, adult dogs with sterile urine and immature dogs.

Assess and Select the Food: Struvite Dissolution

Table 43-5 lists commercially available litholytic foods and compares their key nutritional factor content with the recommended levels of key nutritional factors. Select a food that most closely matches the recommended key nutritional factors and/or has the best efficacy evidence. Avoid treats and vitamin-mineral supplements.

Encouraging water consumption is recommended. If possible, feed a moist food. Although understandably difficult to accomplish in some patients, fluid intake should be encouraged throughout the day to help promote a constantly high urine volume. Ensure water is readily available and is neither too cold nor too warm.

Certain nutrients in properly formulated canine litholytic foods are very restricted (See Key Nutritional Factors, above.); nutrient levels are near the minimum requirements for the majority of the dog population. For some patients, these foods may only be marginally adequate. As a result, serum biochemistry profiles of patients undergoing dietary dissolution of struvite uroliths may be altered. Consumption of a struvite litholytic food by dogs with induced staphylococcal UTIs and struvite uroliths was associated with a marked reduction in the serum concentration of urea nitrogen and mild reductions in the serum concentrations of magnesium, phosphorus and albumin (Abdullahi et al, 1984). A mild increase in the serum activity of hepatic alkaline phosphatase was also observed. These alterations in serum chemistry values were of no clinical consequence during six-month experimental studies or during clinical studies. However, they underscore the fact that struvite litholytic foods are designed for short-term (weeks to months) dissolution therapy rather than long-term (months to years) prophylactic therapy.

The anticipated reduction of serum urea nitrogen in such patients can be useful. Appropriate reduction in concentrations of serum urea nitrogen obtained while the patient is eating a properly formulated struvite litholytic food compared to values obtained while the patient was eating a maintenance food may be used as one index of client and patient compliance with dietary management (**Table 43-6**).

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Precautions with Litholytic Foods

There are several points to consider when feeding struvite litholytic foods. These include affected puppies and adult patients with certain medical conditions. Besides the benefits of feeding litholytic foods, there are also risks for certain patients. Not all patients are candidates for dietary dissolution. Included are patients with abnormal fluid retention, azotemic primary renal failure and patients at risk for pancreatitis. Benefits and risks of litholytic foods should be considered and discussed with the client if these health problems coexist in dogs with struvite uroliths, or if risk factors for their development are present. During such discussions with clients, avoid making "all or none" and "always or never" statements because risk factor associations are not synonymous with cause and effect relationships.

IMMATURE DOGS

Struvite urocystoliths can be successfully dissolved in immature dogs (**Table 43-4**). One such case involved a 12-week-old female miniature dachshund with a sterile struvite urocystolith (Osborne et al, 1986[a]). The urocystolith was dissolved within two weeks after feeding was begun with a struvite litholytic food. Another dog was a nine-week-old, male, mixed-breed puppy with a vesicourachal diverticulum, urethral stricture, *Staphylococcus intermedius* UTI and multiple struvite urocystoliths (Lulich et al, 1989). These urocystoliths dissolved within nine days of initiation of therapy with the litholytic food and a combination of amoxicillin and clavulanic acid. The food was discontinued on Day 10. Slight reductions in serum albumin concentration (from approximately 3.2 to 2.7 g/dl) were observed in both dogs during the two weeks of dietary therapy. Serum albumin concentrations returned to reference values soon after the puppies resumed eating a normal growth food.

Based on uncontrolled clinical experience, litholytic foods should not be fed to immature dogs with struvite uroliths for more than two weeks. If circumstances warrant that the food be fed for longer periods, serial monitoring of body weight,

**All forms of therapy withdrawn.

body condition, serum albumin concentration and packed cell volume for evidence of protein-calorie malnutrition should be considered. Adjustments in dietary management should be made if marked reductions in these variables are observed. The urocystoliths may be removed by voiding urohydropropulsion (Figure 38-5 and Table 38-7) or lithotripsy, if their size has been reduced enough to permit their passage pass through a distended urethra (Lulich et al, 1993).

ABNORMAL FLUID RETENTION

Properly formulated struvite litholytic foods are restricted in protein and supplemented with sodium chloride. Both could affect fluid balance. Therefore, the food should not be routinely fed to patients with comorbid diseases associated with positive fluid balance (e.g., heart failure, nephrotic syndrome) or hypertension.

AZOTEMIC PRIMARY RENAL FAILURE

Complete obstruction of urine outflow caused by uroliths in patients with a concomitant UTI should be regarded as an emergency. In this situation, a combination of obstruction and pyelonephritis caused by a rapid spread of infection throughout the kidneys is likely to induce acute renal failure and then septicemia. Dietary dissolution of struvite uroliths located in the upper urinary tract should not be considered until adequate urine flow has been restored, and life-threatening deficits and excesses in fluid, electrolyte, acid-base and endocrine balance have been corrected.

Nonobstructing struvite nephroliths have been dissolved in patients with nonazotemic renal failure caused by ascending pyelonephritis (Osborne et al, 1985, 1986). But, protein-restricted litholytic foods should be used with caution in patients with azotemic primary renal failure. Such foods may induce

protein malnutrition if fed for prolonged periods to dogs with moderate azotemic primary renal failure (Polzin et al, 1983).

To minimize adverse drug reactions/events, adjustments in doses and maintenance intervals of drugs excreted primarily by the kidneys should be considered in patients with azotemic primary renal failure.

PATIENTS AT RISK FOR PANCREATITIS

Approximately one in 250 dogs seen in private veterinary practices is affected by pancreatitis (0.4%). There appears to be no relationship between pancreatitis and gender, but there is a significant relationship between the disease and age. The mean age of dogs with pancreatitis in private veterinary practices is eight years (vs. 5.5 years for the general canine population). Breed is another strong risk factor for pancreatitis. For example, miniature schnauzers have a fivefold increase in risk for pancreatitis (i.e., about one in 50 miniature schnauzers can be expected to have pancreatitis). Other breeds at increased risk include Bichon Frises, Yorkshire terriers, Chihuahuas, Jack Russell terriers, Japanese spaniels, Labrador retrievers, Maltese and Shetland sheepdogs.

Investigators conducting an independent epidemiologic study asked veterinarians to ascertain the health of dogs fed a commercial veterinary therapeutic pet food.[b] This study disclosed an association between feeding a struvite litholytic food and acute pancreatitis. The risk of a dog developing pancreatitis when fed the struvite litholytic food was comparable to that of a miniature schnauzer developing acute pancreatitis, or about one in 40 (i.e., about one in 40 dogs fed the struvite litholytic food might develop pancreatitis).

The litholytic food that was tested is relatively high in fat, which increases the energy density of the food so that restriction of other specified nutrients is more readily accomplished. Because dietary fat is a risk factor for pancreatitis, the serum activity of pancreatic enzymes (amylase, lipase, trypsin-like immunoreactivity) should be monitored before initiating therapy with high-fat struvite litholytic foods in patients known to be at increased risk for pancreatitis. These tests should be repeated if signs of pancreatitis develop during treatment with the litholytic food. Because abnormal increases in activity of these enzymes are not pathognomonic for pancreatitis, other relevant findings should also be considered.

Female miniature schnauzers are at increased risk for infection-induced struvite uroliths and pancreatitis. Likewise, patients with hyperadrenocorticism are at increased risk for UTIs (which could include staphylococci) and pancreatitis. Although risk factors are not synonymous with cause and effect, clients should be informed of these associations and advised of how to respond to adverse events if they occur. They should be informed about adverse events that need medical attention and those that need medical attention only if they continue.

Assess and Determine the Feeding Method: Struvite Dissolution

Transitioning the patient from its current food to a litholytic food should be done gradually over a period of a few days. Begin the transition by feeding 75% of the current food and 25% of the litholytic food on Day 1. On Day 2, feed half of each food. On Day 3, feed 75% as the litholytic food. By Day 4 or 5, feed only the litholytic food.

As discussed above, modification of urinary pH is an important part of overall dietary management of struvite urolithiasis. Free-choice feeding is often associated with more persistent aciduria compared to meal feeding. Because moist foods are recommended to increase water intake and produce less concentrated urine, clients should be advised to feed specific amounts (meal feed) two to three times per day rather than free-choice feeding. More frequent feedings are desirable if the client can feed multiple meals per day. Moist foods often spoil if left uneaten at room temperature for several hours (Chapter 11). Opened containers of moist foods should be refrigerated and the feeding bowl should be kept clean.

Besides offering moist foods, several additional approaches may facilitate increased water intake. First, ensure multiple bowls are available in prominent locations in the dog's environment; this may mean providing several bowls outside in a large enclosure or a bowl on each level of the house. Second, bowls should be clean and always filled with fresh water. Third, small amounts of flavoring substances (e.g., salt-free bouillon) can be added to water sources. Fourth, ice cubes can be offered as treats or snacks. Fifth, if a dry food is selected, add liberal quantities of water; however, as with moist foods, be aware that potential food safety issues might arise if moistened dry foods are left uneaten for prolonged intervals at room temperature (Chapter 11).

If the patient has a normal body condition score (2.5/5 to 3.5/5), the amount of the previous food being fed was appropriate. On an energy basis, a similar amount of the new food would be a good starting place.

ADJUNCTIVE MEDICAL AND SURGICAL MANAGEMENT

Eradication or Control of UTIs

The importance of UTIs with urease-producing bacteria in the formation of many struvite uroliths in dogs emphasizes the need to eliminate or control infection. Because of the quantity of urease produced by bacterial pathogens, it may be impossible to consistently acidify urine with urine acidifiers administered at dosages that do not cause systemic acidosis (Musher et al, 1974). Therefore, sterilization of urine appears to be an important objective in creating a state of struvite undersaturation that would prevent further growth of uroliths or promote their dissolution.

Appropriate antimicrobial agents selected on the basis of susceptibility or minimum inhibitory concentrations should be used at therapeutic dosages. The fact that diuresis reduces the urine concentration of the antimicrobial agent should be considered when formulating antimicrobial dosages (Ling and Hirsch, 1983). Antimicrobial agents should be administered as long as uroliths can be identified by survey radiography. This recommendation is based on the fact that bacterial pathogens

harbored inside uroliths may be protected from antimicrobial agents (Nickel et al, 1985). Although the urine and surface of uroliths may be sterilized following appropriate antimicrobial therapy, the original and secondary infecting microbes may remain viable below the surface of the urolith. Therefore, discontinuation of antimicrobial therapy may result in relapse of bacteriuria and infection.

Although use of antimicrobial agents alone may result in dissolution of struvite uroliths in some patients, studies in rats (Musher et al, 1974a) and dogs[a] and clinical studies in people (Feit and Fair, 1979; Lewis et al, 1983; Senior et al, 1984)[a] indicate that this phenomenon represents the exception rather than the rule. In one controlled study, six dogs with induced struvite uroliths were given therapeutic dosages of oral ampicillin (16 mg/kg body weight/day divided into three equal subdoses) and were fed a maintenance food. Only two uroliths dissolved; the remaining four uroliths increased in size.[a] In addition to the unpredictable response to this form of therapy, the time required to induce urolith dissolution with antimicrobial agents is usually measured in multiples of months rather than in multiples of weeks.

The litholytic effects of various combinations of antibiotics (ampicillin given orally at a dosage of 16 mg/kg body weight/day), acetohydroxamic acid and a struvite litholytic therapeutic food were studied in dogs with staphylococcal-induced struvite uroliths.[a] After five months of therapy, four uroliths increased in size and two dissolved in six dogs given ampicillin and an adult maintenance-type food. Four of six uroliths dissolved and two decreased in size in six dogs given ampicillin and the litholytic food over the same time frame. All uroliths in six dogs dissolved six weeks after initiation of therapy with a combination of the litholytic food, ampicillin and acetohydroxamic acid.

Similar results were obtained when a combination of the litholytic food and antimicrobial agents was given to 11 dogs with naturally occurring urease-positive UTIs and urocystoliths presumed to be composed of struvite (Osborne et al, 1984, 1985). The mean time required to induce urocystolith dissolution in these dogs was approximately three months (range two weeks to seven months).

Urease Inhibitors

Studies in dogs have revealed that administration of microbial urease inhibitors in pharmacologic doses is capable of inhibiting struvite urolith growth and promoting struvite urolith dissolution. Acetohydroxamic acid given orally to dogs at a dosage of 25 mg/kg body weight (divided into two daily subdoses) reduced urease activity, struvite crystalluria and urolith growth (Krawiec et al, 1984). By reducing the pathogenicity of staphylococci, acetohydroxamic acid may also result in less severe dysuria, bacteriuria, pyuria, hematuria and proteinuria.

Although higher dosages of acetohydroxamic acid may result in urolith dissolution, they are not recommended because they may cause a reversible hemolytic anemia and abnormalities in bilirubin metabolism (Krawiec et al, 1984; Kobashi et al, 1971). Likewise, acetohydroxamic acid should not be administered to pregnant dogs because it is teratogenic (Bailie et al, 1986).

Acetohydroxamic acid has not been used routinely in promoting dissolution of infection-induced struvite uroliths in dogs because of the efficacy of the litholytic food and antimicrobial therapy. However, acetohydroxamic acid has been used in combination with litholytic foods and antimicrobial agents in patients that have recalcitrant urease-producing UTIs associated with persistent struvite uroliths. Acetohydroxamic acid may be added to the therapeutic regimen if infection-induced struvite uroliths do not dissolve after an appropriate therapeutic trial with diet modification and antimicrobial agents.

INFECTION-INDUCED STRUVITE NEPHROLITHS

Nephroliths and ureteroliths causing outflow obstruction and marked impairment of renal function should be managed by surgical intervention or, if possible, by percutaneous nephropyelolithotomy, especially if associated with concomitant bacterial infection (Ross et al, 1999). Dietary and medical therapy designed to induce urolith dissolution over several weeks is unlikely to be effective in patients with poorly functioning kidneys because uroliths must be completely surrounded by urine that is undersaturated with struvite for prolonged periods to be dissolved. Intermittent passage of urine through a partially obstructed kidney or ureter would logically preclude dissolution of struvite nephroliths or ureteroliths.

Dissolution of nephroliths presumed to be composed of infection-induced struvite in six dogs has been reported. The mean time required for dissolution was 184 days (range 67 to 300 days). Although the dogs had varying degrees of impaired capacity to concentrate urine as a result of pyelonephritis, none had primary renal azotemia at the time therapy was initiated with the veterinary therapeutic struvite litholytic food and antimicrobial agents. This point is emphasized because dogs with moderate to severe primary renal failure require a greater quantity of protein for anabolism than normal. The litholytic food used could induce or aggravate protein malnutrition if given for prolonged periods to dogs with moderate azotemic primary renal failure, or other comorbid disorders associated with protein malnutrition (Polzin et al, 1983).

REASSESSMENT

Because litholytic foods stimulate thirst and promote diuresis, the magnitude of pollakiuria in dogs with urocystoliths may increase for a variable time following initiation of dietary therapy. However, pollakiuria and the abnormal urine odor caused by bacterial degradation of urea usually subside as infection is controlled and uroliths decrease in size (**Table 43-6**). Reduction in ammonia-induced chemical inflammation as a result of ureolysis may also be involved in remission of these clinical signs. **Table 43-7** summarizes mean times for struvite urolith dissolution.

The size of uroliths should be periodically monitored by survey radiography or ultrasonography (typically, monthly intervals are recommended). Survey radiography or ultrasonography

is usually preferred to retrograde double-contrast urocystography because use of transurethral catheters during retrograde radiographic studies may result in iatrogenic UTI. Alternatively, intravenous urography may be considered.

Periodic evaluation of urine sediment for crystalluria also may be considered. Struvite crystals should not form in fresh uncontaminated urine if therapy has been effective in promoting formation of urine that is undersaturated with MAP.

UTIs may persist despite antimicrobial therapy in patients having infection-induced struvite uroliths and consuming the litholytic food. In most patients, however, the magnitude of bacteriuria is markedly reduced (i.e., from more than 100,000 to approximately 1,000 cfu (colony forming units)/ml of urine) and the associated inflammatory response progressively subsides. Difficulty in eradicating the infection while uroliths persist may be related to persistence of viable microbes within the uroliths (Nickel et al, 1985). Diet-induced diuresis should be considered when formulating dosages of antimicrobial agents that will achieve minimum inhibitory concentrations in urine. Excellent success may be achieved in inducing dissolution of struvite uroliths despite persistent bacteriuria during antimicrobial and dietary treatment. Even though the urine is not sterile, reduction in bacterial colony counts by logarithmic magnitudes (e.g., from 10^6 to 10^4 cfu/ml) has a marked effect in reducing the quantity of microbial urease in urine (Griffith and Osborne, 1987). Concomitant use of litholytic foods, antimicrobial agents and acetohydroxamic acid is the most effective method of inducing dissolution of uroliths when UTI complications persist.

Urine collected by cystocentesis should be quantitatively cultured during therapy and five to seven days after antimicrobial therapy is discontinued. Results of urine culture may not be the same as results obtained before therapy or from cultures of the interior of uroliths. Rapid recurrence of UTI caused by the same type of organism (relapse) or a different type of bacterial pathogen (reinfection) following withdrawal of antimicrobial therapy may indicate residual uroliths within the urinary tract or other abnormalities in local host defense mechanisms that predispose the patient to UTI and recurrent struvite urolithiasis (Osborne and Stevens, 1999a).

Because small uroliths may escape detection by survey radiography or ultrasonography, continue the struvite litholytic food and (if necessary) antimicrobial agents for at least one "insurance" month after radiographic or ultrasonographic documentation of urolith dissolution. Recall that survey radiography may not detect uroliths ≤0.3 mm in size. This protocol is likely to prevent recurrence of clinical signs from remaining uroliths that were missed by conventional survey radiography or ultrasonography. Alternate methods of management should be considered if uroliths increase in size during therapy or if urolith size remains unchanged after approximately eight weeks of appropriate dietary and medical therapy. Small uroliths that become lodged in the urethra of male or female dogs during therapy may be readily returned to the urinary bladder lumen by retrograde urohydropropulsion (Figure 38-5 and Table 38-7). They may also be removed by lithotripsy. Complete obstruction of a ureter or renal pelvis with a urolith, especially with concomitant UTI, is an indication for surgical intervention.

Attempts to induce dissolution of struvite uroliths may be hampered if the uroliths are heterogeneous in composition (**Table 43-8**). This has not been a significant problem in dogs with uroliths composed primarily of MAP with lesser quantities of calcium apatite because the solubility characteristics of the two minerals are similar. However, some clinicians have encountered difficulty in dissolving uroliths composed primarily of struvite with an outer shell composed primarily of calcium apatite. Difficulty will also be encountered in attempting to induce complete dissolution of a urolith with a nucleus of calcium oxalate or silica and a shell of struvite because the solubility characteristics of these minerals are dissimilar. This phenomenon should be considered if dietary and medical therapy seems to be ineffective after initially reducing the size of a urolith.

PREVENTION

Table 43-9 lists commercial veterinary therapeutic foods intended for the prevention of recurrence of struvite urolithiasis and compares them to the key nutritional factor targets. Because these foods are intended for long-term feeding, they should also be approved by the Association of American Feed Control Officials (AAFCO), or some other credible regulatory agency. However, recommendations for the use of these foods are not straightforward. Caveats regarding their use depend upon whether the struvite uroliths are infection-induced or form in sterile urine. Also, concurrent or alternative medical management must be considered.

Infection-Induced Struvite Uroliths

Eradication or control of UTIs due to urease-producing bacteria is the most important factor in preventing recurrence of most infection-induced struvite uroliths (Osborne and Stevens, 1999a). If UTI persists or is recurrent, indefinite therapy is indicated with prophylactic dosages of antimicrobial agents eliminated in high concentration in urine. These may include amoxicillin, nitrofurantoin and trimethoprim-sulfadiazine; however, the final choice is best determined by the results of the most recent antimicrobial susceptibility test. In light of the effectiveness of litholytic foods in inducing dissolution of struvite uroliths, use of these same foods (**Table 43-5**) to minimize recurrence of uroliths is logical and feasible. However, the long-term (measured in years) effects of low-protein litholytic foods in dogs that may be predisposed to urolith formation are not yet known. Litholytic foods induce polyuria, varying degrees of hypoalbuminemia and mild alterations in hepatic enzyme activities and morphology. Therefore, long-term use of litholytic foods with severely reduced protein levels should be recommended only if patients develop frequently recurrent urolithiasis despite attempts to control infection, augment fluid intake and urine acidification. In other words, the benefits of therapy should outweigh the risks.

Results of experimental and clinical studies to evaluate the effectiveness of acetohydroxamic acid indicate that this drug

Table 43-7. Mean times for struvite urolith dissolution.

Urolith location and infective status	Mean time for dissolution	Comments and precautions
Infection-induced urocystoliths	Approximately 2.5 months (range two weeks to seven months)	Use appropriate caution in dogs at increased risk for pancreatitis, dogs with renal failure and dogs with hypoalbuminemic edema
Sterile urocystoliths	Three to four weeks	If idiopathic, appropriately monitor for recurrence
Infection-induced struvite urocystoliths in immature dogs	Less than two weeks	If circumstances warrant feeding for a longer period, serial monitor body weight, body condition, serum albumin concentration and packed cell volume for evidence of protein-calorie malnutrition
Infection-induced nephroliths	Approximately 184 days (range 67 to 300 days)	Contraindicated in dogs with concomitant obstruction to urine outflow

Table 43-8. Managing magnesium ammonium phosphate uroliths refractory to complete dissolution.

Causes	Identification	Therapeutic goal
Client and patient factors		
Inadequate dietary compliance	Question owner Persistent struvite crystalluria Urea nitrogen >8-12 mg/dl Urine specific gravity >1.010-1.015 Urinary pH is alkaline during treatment with the litholytic food*	Emphasize need to feed dissolution food exclusively
Inadequate antibiotic administration	Question owner Count remaining antibiotic pills	Emphasize need to administer the full dose of antibiotics Determine if owner is capable and willing to administer medication Demonstrate a variety of methods to administer medication
Clinician factors		
Incorrect prediction of mineral type	Analysis of retrieved urolith	Alter therapy based on identification of mineral type
Inappropriate antibiotic choice	Positive urine culture with poor susceptibility for chosen antibiotic	Choose antibiotics based on susceptibility testing
Inappropriate antibiotic dose for degree of diuresis	Positive quantitative urine culture with same bacterial species and same susceptibility; number of bacteria may be lower (See text.)	Administer antibiotic at the higher recommended dose or consider a higher dose than recommended
Premature discontinuation of antibiotic	Discontinuing antibiotic before complete urolith dissolution Positive urine culture with same bacterial species and the same susceptibility (See text.)	Prescribe full antibiotic dose for the entire period of urolith dissolution
Disease factors		
Change in bacterial susceptibility	Positive urine culture with susceptibility results different from those of previous culture	Choose antibiotic based on susceptibility testing
New bacterial infection	Positive urine culture identifying new bacterial species	Choose antibiotic effective against both bacteria Avoid procedures requiring urinary tract catheterization
Compound urolith	Radiographic density of nucleus and outer layer(s) of urolith is different Analysis of retrieved urolith	Alter therapy based on identification of new mineral type Uroliths not causing clinical signs should be monitored for potentially adverse consequences (obstruction, urinary tract infection, etc.) Clinically active uroliths may require removal Remove small uroliths by voiding urohydropropulsion or lithotripsy

should be considered in an effort to minimize recurrence of infection-induced struvite urolithiasis in dogs with persistent UTI with urease-producing bacteria despite appropriate antimicrobial therapy. Administration of 25 mg of acetohydroxamic acid/kg body weight/day to dogs with urinary bladder foreign bodies (zinc disks) and induced urease-positive staphylococcal UTIs was effective in preventing formation of and minimizing the growth rate of uroliths (Krawiec et al, 1984a). Acetohydroxamic acid has also been reported to be effective in preventing struvite uroliths induced by ureaplasmas in rats.[a]

Previously, acidifying foods with mild to moderately reduced levels of protein, magnesium and phosphorus (**Table 43-9**) have been recommended as part of the therapeutic strategy to minimize recurrence of infection-induced struvite uroliths. However, clinical experience with use of such foods has prompted modification of this recommendation for two primary reasons. First, because infection-induced uroliths cannot form without an infection with urease-producing microbes, eradication of the UTI should be the first priority in context of the pathophysiology associated with this type of urolith. Infection-induced struvite will likely not recur in the absence of a urease-producing microbe. Second, prolonged use of this type of food has been associated with calcium oxalate crystalluria and/or calcium oxalate uroliths, especially in dogs predisposed to calcium oxalate uroliths. In addition, appropriate caution should be used in deciding whether or not to induce prophylactic diuresis in patients with a history of struvite uroliths induced by recurrent UTI. Although formation of less concentrated urine tends to minimize the supersaturation of urine with lithogenic crystalloids (a benefit), it tends to counteract innate antimicrobial properties of urine (a risk). Studies performed in rats and cats indicate that diuresis tends to minimize pyelonephritis, but enhance lower UTIs. This is not an "all or none; always or never" recommendation. However, pending the results of properly controlled clinical trials, this seems to be the safest and most effective ethical course of action.

Sterile Struvite Uroliths

Although apparently uncommon, sterile struvite uroliths have a greater tendency to recur than infection-induced struvite uroliths in which the UTI has been eradicated or controlled. Administration of urine acidifiers should be considered if the urinary pH of patients with sterile struvite uroliths remains persistently alkaline. The prophylactic value of concomitant restriction of dietary phosphorus, magnesium and urine acidification has not yet been conclusively determined primarily because of lack of clinical cases to perform double-blind controlled studies. Unfortunately, the infrequency with which dogs with sterile uroliths are encountered does not lend itself to such clinical studies. Nonetheless, it seems unreasonable and unethical to do nothing for patients with recurrent struvite uroliths until clinical trials are completed. Therefore, pending the availability of appropriate data, therapy should be designed to first do no harm. When considering dietary management (**Table 43-9**), emphasize minimizing recurrence of calcium oxalate and calcium phosphate uroliths, because these types of uroliths cannot be dissolved by dietary and medical management. Should struvite uroliths recur, they often can be dissolved by dietary management and antimicrobial agents (if necessary). When foods designed to produce acidic urine are used, urinary pH

should be closely monitored with the aid of a reliable pH meter rather than commercially available reagent strips with a pH pad. Likewise, urine output should be estimated with the aid of a reliable refractometer designed to provide reproducible urine specific gravity values. Urine sediment should be evaluated for crystals and evidence of infection by microscopic examination of freshly voided urine.

Uncontrollable risk factors (i.e., defective inhibitors of crystal formation and/or defective inhibitors of crystal aggregation) may be present in those situations in which dogs have documented occurrences of either calcium oxalate or calcium phosphate followed by struvite urolithiasis. If struvite urolithiasis is associated with urease-positive UTIs, appropriate therapy should be devised to eradicate the UTI and minimize its recurrence.

CASE 43-1

Dysuria in a German Shepherd Crossbred Dog

Carl A. Osborne, DVM, PhD, Dipl. ACVIM (Internal Medicine)
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota, USA

Patient Assessment

A 12-year-old neutered female German shepherd crossbred dog was examined for dysuria and pollakiuria of two months' duration. Other than nonspecific dermatitis and a perianal adenoma, the dog had no previous history of illness.

Physical examination revealed an alert, active, overweight dog (body weight 27 kg, body condition score 4/5). Multiple uroliths were palpated in the urinary bladder. No other abnormalities were detected. Results of a complete blood count and a serum biochemistry profile were normal except for a mild elevation in alkaline phosphatase activity (**Tables 1** and **2**). Analysis of a urine specimen collected by cystocentesis (**Table 3**) revealed an alkaline pH, struvite crystalluria and findings typical of inflammation (i.e., hematuria, pyuria, proteinuria). Quantitative culture of urine revealed more than 10^5 colony-forming units of urease-producing *Staphylococcus intermedius* organisms per ml of urine. The bacteria were susceptible to most antimicrobial drugs. Survey radiographs of the abdomen revealed three uroliths within the bladder lumen (**Figures 1** and **2**); the sizes of the kidneys and liver were normal.

Assess the Food and Feeding Method

A commercial dry adult maintenance food was offered free choice. Table foods were fed frequently.

Questions

1. What is the probable mineral composition of the uroliths in this dog?
2. What are the advantages and disadvantages of surgical vs. dietary and medical management of these uroliths?
3. How should therapeutic efficacy be monitored?

Answers and Discussion

1. The most likely mineral composition of the uroliths is struvite based on: 1) urease-positive staphylococcal urinary tract infection, 2) alkaline urinary pH, 3) struvite crystalluria (no oxalate, cystine or urate crystals) and 4) detection of radiodense uroliths.
2. Although surgery may be effective, dietary and medical protocols have been developed to dissolve struvite uroliths. Surgical removal of urocystoliths has the obvious advantage of rapid correction of the disease process. Dietary and medical therapy may also be effective and includes using a proven commercial veterinary therapeutic struvite litholytic food.[a] Concurrent treatment of the urinary tract infection with appropriate antimicrobials is an essential part of the treatment protocol. The litholytic food should be fed until radiographic evidence of urolith dissolution is obtained. The food is usually fed for one additional "insurance" month following dissolution because survey radiography is not sufficiently sensitive to detect small uroliths (≤3 mm).
3. Therapeutic efficacy should be monitored by monthly evaluation of clinical signs, radiographs, urinalyses and urine cultures. Clinical signs often resolve within three to five days of initiating therapy. Consumption of the litholytic food is usually associated with polyuria, formation of less concentrated acidic urine, marked reduction in serum urea nitrogen concentration, reduction

in serum magnesium concentration and an increase in serum alkaline phosphatase activity. Hematuria, pyuria and bacteriuria should resolve with dietary and appropriate antimicrobial therapy.

Progress Notes

Therapy was initiated with Prescription Diet s/d Canine (1,150 kcal [4.8 MJ], one can fed twice daily) and ampicillin administered orally (7 mg/kg body weight q12h). Survey radiographs obtained monthly revealed progressive reduction in the size of the uroliths (**Figures 3** to **6**). Radiodense uroliths could not be detected by survey radiography on Day 132 (**Figure 6**).

Following initiation of antimicrobial therapy, bacteria could not be cultured from urine specimens obtained by cystocentesis. Urinalysis revealed acidification of urine and disappearance of pyuria and hematuria (**Table 2**). Consumption of the litholytic food was associated with formation of less concentrated urine, reduction in serum urea nitrogen concentration, reduction in serum magnesium concentration and an increase in serum alkaline phosphatase activity (**Tables 2** and **3**). Results of complete blood counts were normal over the treatment period. Most laboratory parameters returned to baseline values following withdrawal of antimicrobial therapy and a return to a commercial adult maintenance-type food on Day 159 (**Tables 2** and **3**).

Because the dog was overweight at the beginning of therapy, the owners fed a reduced amount of food to promote weight loss. The dog lost 1.6 kg during therapy.

Further Discussion

This case typifies dietary and medical dissolution of large urocystoliths. Reduction in the concentration of urea nitrogen, acidification of urine and formation of urine with a low specific gravity indicate that the owner and the dog were complying with therapy. Microbial sterilization of urine indicated that the proper antimicrobial agent was being given at the correct dosage and was being excreted in effective concentrations in urine. However, urine sterilization is not always achieved during medical therapy designed to induce urolith dissolution. Inability to sterilize urine during therapy may be related to: 1) release of bacteria from the urolith during dissolution, 2) induction of diuresis, which impairs the antimicrobial effects of urine, 3) induction of diuresis, which reduces the concentration of antimicrobial agent in urine and/or 4) reduced clearance of urea, which may impair the antimicrobial effects of urine. However, despite persistence of bacteriuria during therapy, uroliths composed of struvite will dissolve and the associated inflammatory response will subside. Antimicrobial therapy should be continued until the uroliths completely dissolve.

Varying degrees of elevated serum alkaline phosphatase activity frequently occur in dogs fed very low-protein foods such as the veterinary therapeutic food fed to this patient. Studies in dogs indicate that the alkaline phosphatase is of hepatic origin. The greatest increases in serum alkaline phosphatase activity occur in dogs that do not consume an adequate amount of the veterinary therapeutic food. Contrary to the situation in this case, the litholytic food should not be fed with a goal of weight reduction because this practice may contribute to negative nitrogen balance. Weight reduction should be achieved with an appropriate food after resolution of the urocystolith problem.

CASE 43-2

Dysuria in a Puppy

Jody P. Lulich, DVM, PhD, Dipl. ACVIM (Internal Medicine)

Carl A. Osborne, DVM, PhD, Dipl. ACVIM (Internal Medicine)
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota, USA

Patient Assessment

A nine-week-old, male, mixed-breed puppy was examined for dysuria, anorexia, vomiting and depression of one day's duration. The history was incomplete because the owners had acquired the puppy only five days earlier. Physical examination was unremarkable except for an overdistended, painful urinary bladder. Palpation of the urinary bladder induced a micturition reflex, but the puppy was unable to void. The puppy's body weight (5 kg) and condition (body condition score 3/5) were normal.

Survey abdominal radiographs revealed multiple, radiodense uroliths in the penile urethra. Following decompression of the urinary bladder by abdominal cystocentesis, the urethroliths were returned to the urinary bladder lumen by urohydropropulsion (**Figure 1**). Analysis of an aliquot of urine collected by cystocentesis revealed an inflammatory response associated with bacteriuria (**Table 1**). Quantitative aerobic and anaerobic culture of urine revealed >10^5 colony-forming units/ml of urease-positive *Staphylococcus intermedius*. The bacteria were susceptible to most commonly used antimicrobial agents. Results of a complete blood count were normal except for a stress-induced mature neutrophilic leukocytosis. Results of a serum biochemistry profile were unremarkable (**Table 2**).

A small urolith was spontaneously voided and submitted for quantitative mineral analysis one day later.

Assess the Food and Feeding Method

The dog was fed a commercial dry specialty brand growth food (Science Diet Canine Growth[a]) twice daily.

Questions

1. What is the most likely urolith type in this patient?
2. What additional diagnostic tests might be important?
3. Outline an appropriate treatment and feeding plan for this puppy.

Answers and Discussion

1. The most likely urolith type in this patient is magnesium ammonium phosphate (struvite). This "guesstimate" is based on finding a urinary tract infection with a urease-producing staphylococcal bacteria and radiodense uroliths. Infection-induced struvite uroliths can form within days and may occur in dogs at any age including very young dogs.
2. Anatomic defects of the urinary tract can predispose animals to bacterial infection. Ultrasound and/or contrast radiography should be considered to evaluate the lower urinary tract for such defects.
3. Dietary and medical or surgical protocols can be used to treat this puppy. Dietary and medical therapy designed to induce struvite urolith dissolution includes an appropriate orally administered antimicrobial agent and a food with restricted levels of protein, magnesium and phosphorus that is metabolized to produce an acidic urinary pH. Because foods formulated to aid in dissolution of struvite uroliths contain reduced quantities of protein, calcium, magnesium and phosphorus and thus are not designed to meet the long-term nutritional requirements of immature dogs, the feeding plan should be monitored closely. Monitoring serum biochemistry parameters (albumin, phosphorus, calcium, etc.) is an acceptable means of determining nutritional status in young dogs. An alternate treatment method includes a cystotomy to remove the uroliths; however, anesthesia and surgery in an immature dog are also associated with some degree of risk.

Progress Notes

Quantitative analysis of the voided urolith revealed that it was composed of 95% magnesium ammonium phosphate hexahydrate and 5% carbonate apatite. Retrograde positive-contrast urethrocystography and double-contrast cystography revealed a diverticulum located at the bladder vertex (**Figures 2** and **3**). The urethral lumen was also narrowed just distal to the site normally occupied

Key: SUN = serum urea nitrogen, ALT = alanine aminotransferase, Alk phos = alkaline phosphatase.
*Dietary and medical therapy for urinary tract infection and urolith dissolution was initiated on Day 2 and discontinued on Day 10. Antibiotic therapy for urinary tract infection was initiated on Day 2 and discontinued on Day 39.

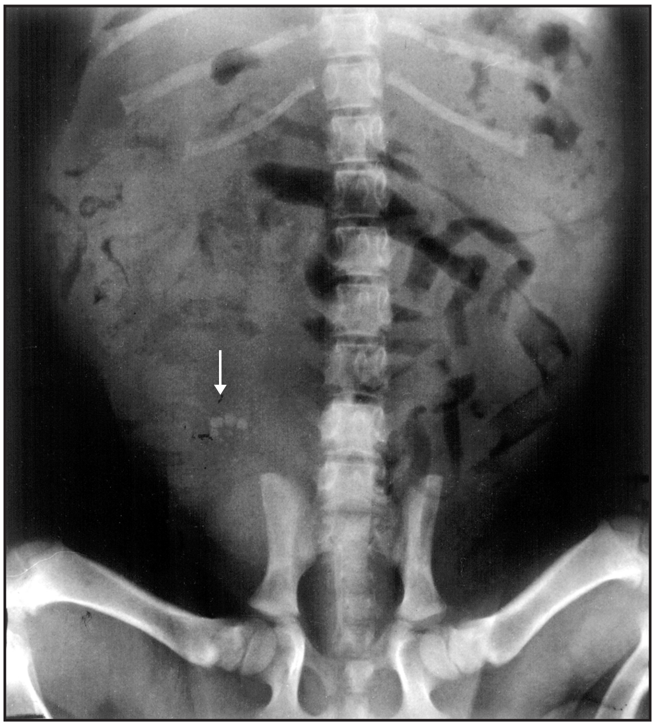

Figure 1. Ventrodorsal survey abdominal radiograph of a nine-week-old male dog with multiple radiodense urocystoliths (arrow).

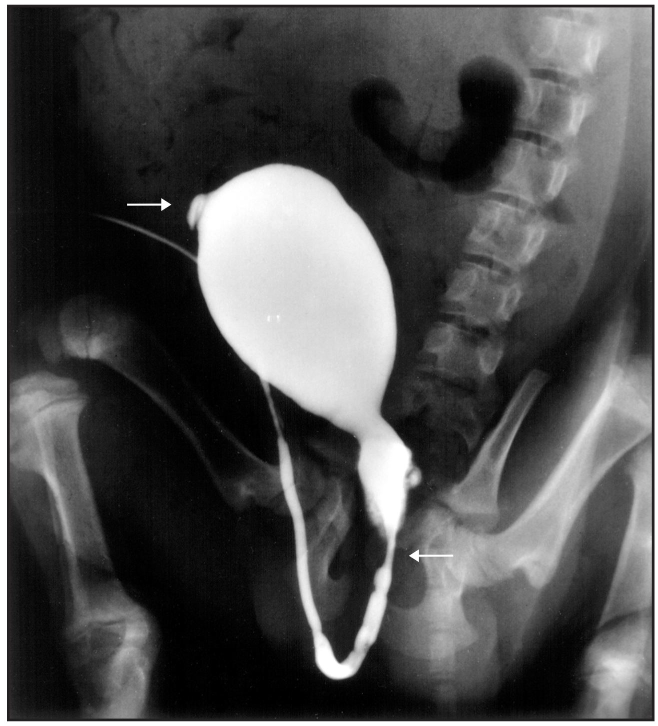

Figure 2. Positive-contrast retrograde urethrocystogram of the same dog described in Figure 1. Note the vesicourachal diverticulum (top arrow) and narrowing of the proximal portion of the urethra (bottom arrow).

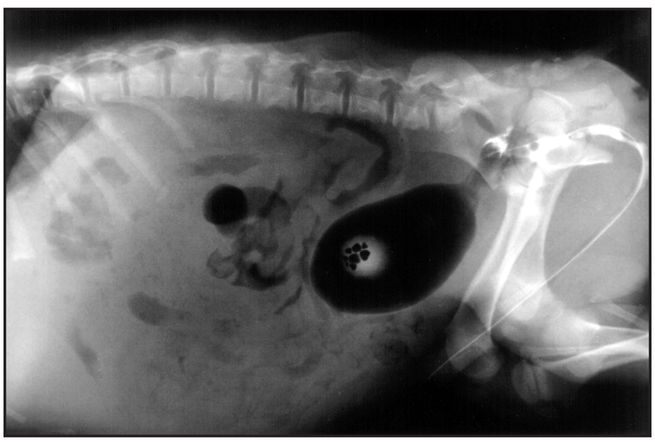

Figure 3. Double-contrast cystogram with at least eight uroliths in the bladder lumen. Radiopaque contrast medium has refluxed into the periurethral tissue in the area of the prostate gland. The urethral lumen contains air bubbles surrounded by contrast medium.

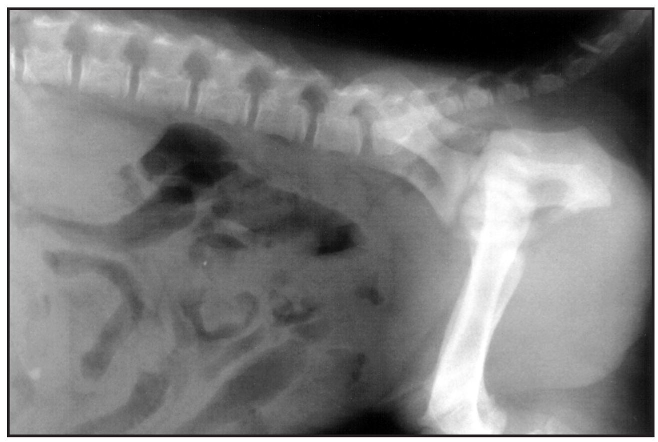

Figure 4. Survey abdominal radiograph obtained 10 days following initiation of therapy with an antibiotic and a food designed to dissolve struvite uroliths. Radiodense uroliths cannot be detected within the urinary tract.

by the prostate gland.

Dietary and medical therapy included a combination of amoxicillin and clavulanic acid (Clavamox[b]) given orally and feeding a food designed to aid in dissolution of struvite uroliths (Prescription Diet s/d Canine[a]). Compared with typical dog foods, Prescription Diet s/d Canine is greatly reduced in protein (7.9% dry matter [DM]), reduced in phosphorus (0.10% DM), calcium (0.31% DM) and magnesium (0.02% DM) and produces a more acidic urine (target urinary pH = 5.9 to 6.1). The puppy was fed one-half can three times daily (700 kcal [2.93 MJ]).

Gross hematuria and dysuria progressively declined. A urine sample collected by cystocentesis 10 days later revealed acidification of the urine and marked reduction in the inflammatory response (**Table 1**). Formation of less concentrated urine (reduction in renal medullary urea concentration) and marked reduction in serum urea nitrogen concentration (**Table 2**) was attributed to the low-protein food. Aerobic culture of urine resulted in no growth. Survey abdominal radiography, positive-contrast urethrocystography and

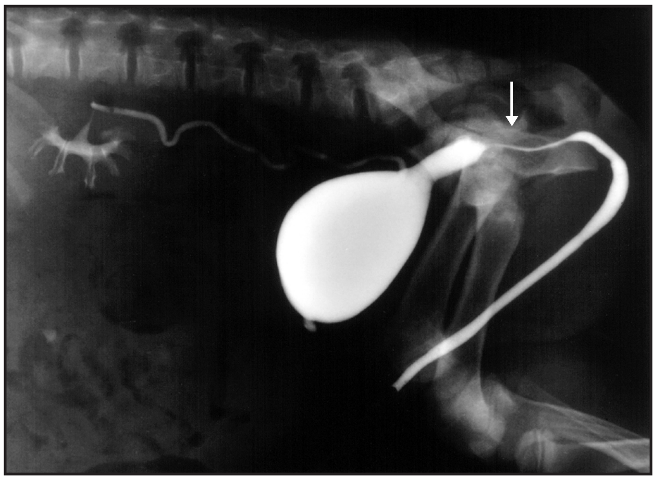

Figure 5. Positive-contrast retrograde urethrocystogram obtained 39 days following diagnosis of uroliths and a vesicourachal diverticulum. There is no evidence of a vesicourachal diverticulum, but narrowing of the lumen of the proximal urethra is still present (arrow).

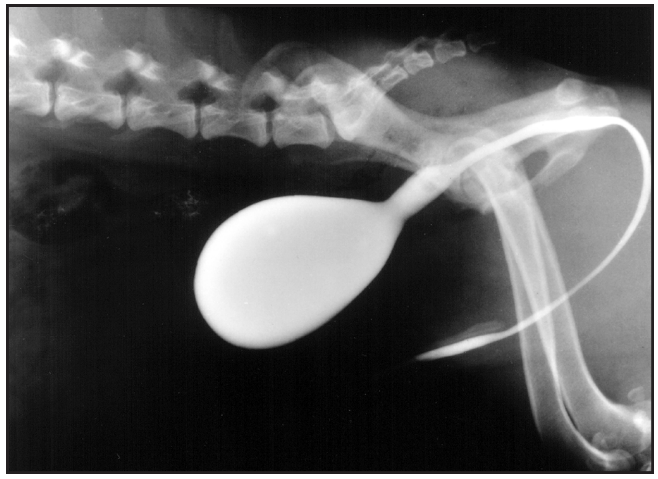

Figure 6. Positive-contrast retrograde urethrocystogram obtained 226 days following initial assessment. The lower urinary tract appears normal.

double-contrast cystography revealed no evidence of uroliths in the lower urinary tract. The vesicourachal diverticulum was still present but reduced in size (**Figure 4**). Serum albumin (2.7 g/dl), phosphorus (6.7 mg/dl) and urea nitrogen (2 mg/dl) concentrations had decreased from initial values (**Table 2**).

Because urolith dissolution was complete and because of diet-related alterations in serum phosphorus and albumin concentrations, the food was changed to a moist product designed for growing dogs (Science Diet Canine Growth), fed twice daily. The oral antimicrobial agent was continued for an additional two weeks.

Reevaluation of the dog 25 days after the initial diagnosis revealed further reduction in the size of the vesicourachal diverticulum. The dog was forming concentrated urine, but still had microscopic hematuria (**Table 1**). Serum albumin and phosphorus concentrations were normal (**Table 2**). Antimicrobial therapy was continued.

Fourteen days later (39 days after the initial diagnosis), survey and contrast radiographs revealed no evidence of the vesicourachal diverticulum or uroliths (**Figure 5**). However, the urethral lumen adjacent to the prostate gland was still reduced. Nevertheless, the dog had no clinical signs of lower urinary tract disease. Although bacteria could not be cultured by aerobic techniques, urinalysis revealed an inflammatory response (**Table 1**).

No clinical or laboratory evidence of disease was present 73 days after the initial diagnosis (**Tables 1** and **2**). Antimicrobial therapy was discontinued. Evaluation at 10 months of age revealed a normal dog with no detectable radiographic abnormalities of the lower urinary tract (**Figure 6**).

CASE 43-3

Recurrent Urinary Tract Infection in a Rottweiler

Carl A. Osborne, DVM, PhD, Dipl. ACVIM (Internal Medicine)
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota, USA

Patient Assessment

A five-year-old, 41-kg, neutered male rottweiler was examined for recurrent dysuria and pollakiuria of six months' duration, presumed to be caused by bacterial urinary tract infection. These clinical signs had been treated intermittently with a variety of orally administered antibiotics given for intervals ranging from 10 to 21 days. Treatment was associated with remission of dysuria and pollakiuria, but these signs recurred a short time following cessation of therapy.

The results of physical examination, including rectal palpation and body condition assessment (body condition score 3/5), were normal. Micturition was normal. Analysis of a urine sample collected by cystocentesis revealed that the urine was slightly concentrated (specific gravity 1.015), had a neutral pH and contained evidence of inflammation, most likely due to an infectious process (**Table 1**). Crystals were not observed. Aerobic culture of an aliquot of urine revealed significant numbers (>10^5 colony-forming units/ml) of urease-producing *Staphylococcus intermedius*, which was susceptible to many antimicrobial agents. Results of a complete blood count and serum biochemistry profile were normal (**Table 1**).

Problems identified on the basis of the animal assessment included bacterial urinary tract infection with staphylococci characterized by dysuria and pollakiuria, possible impaired urine concentrating capacity, and hematuria, pyuria, proteinuria and bacteriuria.

Assess the Food and Feeding Method

The dog was fed a commercial dry adult maintenance food free choice and offered commercial treats/snacks several times each day.

Questions

1. What is the anatomic site or sites of the bacterial urinary tract infection?
2. Are further diagnostic tests justified for this patient?

Answers and Discussion

1. Dysuria and pollakiuria suggest involvement of the lower urinary tract but formation of urine with a specific gravity of 1.015 in absence of azotemia suggests that ascending infection may have involved the medullary portions of the kidney.
2. Additional diagnostic tests should be considered because: 1) the bacterial urinary tract infection appears to be recurrent, 2) the sites of infection and inflammation have not been confirmed and 3) the predisposing causes of infection are unknown. There is no evidence of diabetes mellitus or hyperadrenocorticism, both of which are frequently associated with recurrent bacterial urinary tract infection. Another urinalysis is indicated to assess the concentrating capacity of the kidneys. Survey and contrast abdominal radiography and/or ultrasonography will help evaluate the patient for uroliths, neoplasia and anatomic abnormalities. These imaging procedures will also assist in evaluation of the prostate gland.

Further Assessment

Results of a second urinalysis included a urine specific gravity of 1.021. Hematuria, pyuria, proteinuria and bacteriuria were still present. Survey radiography and ultrasonography of the abdomen revealed a large urolith in the pelvis of the right kidney (**Figures 1** and **2**). Retrograde positive-contrast urethrocystography revealed normal size, shape and position of the lower urinary tract and prostate gland. Double-contrast cystography revealed a few uroliths approximately 1 mm in diameter in the bladder. An intravenous urogram revealed no evidence of outflow obstruction in the ureters (**Figure 2**).

Further Questions

1. On the basis of the available data, what is the most likely mineral composition of this patient's uroliths?
2. Why were crystals not identified in the urine sediment even though the patient had multiple uroliths?
3. Outline a treatment and feeding plan for this dog.

Answers and Discussion

1. The mineral composition of the nephrolith and urocystoliths most likely is infection-induced struvite because: 1) staphylococci may cause formation of struvite uroliths, 2) very large radiodense nephroliths are usually composed of infection-induced struvite, 3) the urinary pH was not acidic and 4) crystals associated with other types of uroliths were not detected.
2. The combination of risk factors necessary for struvite crystals to form was not present at the time urine samples were collected

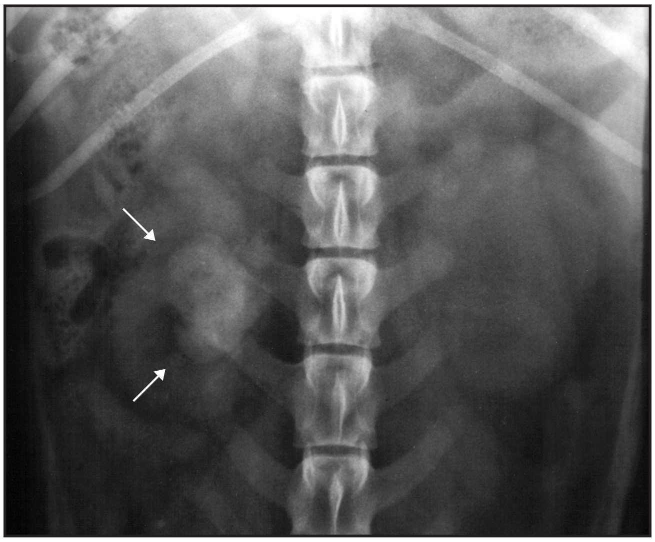

Figure 1. Survey ventrodorsal abdominal radiograph illustrating a large radiodense nephrolith (arrows) in the renal pelvis of the right kidney of a five-year-old neutered male rottweiler.

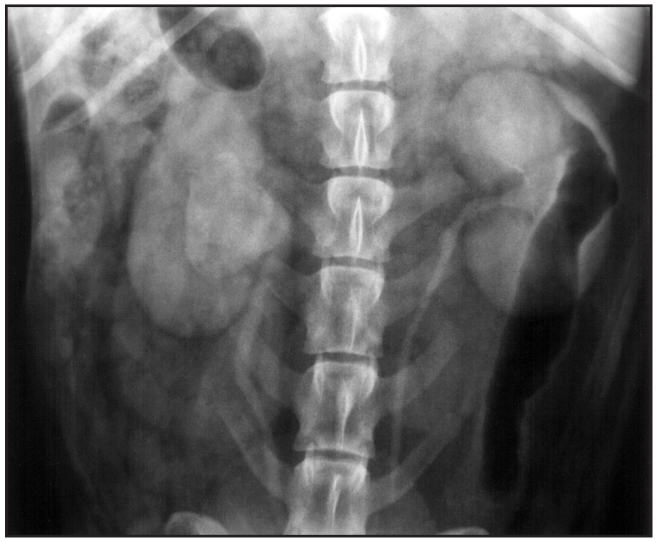

Figure 2. Intravenous urogram of the same dog described in Figure 1 showing both ureters filled with contrast material and no evidence of outflow obstruction.

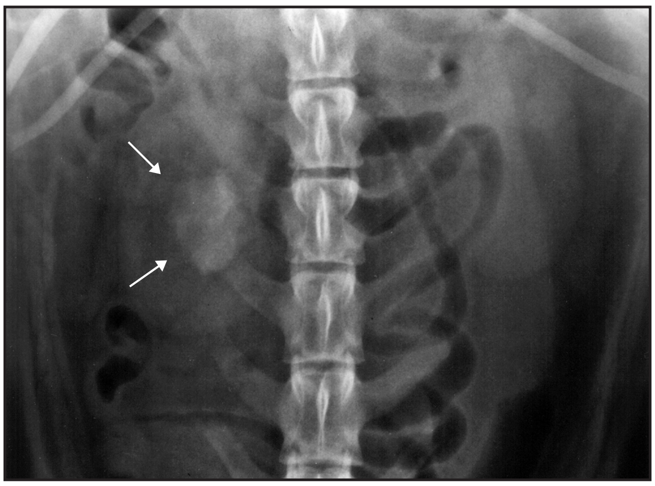

Figure 3. Survey ventrodorsal radiograph obtained five weeks after initiation of therapy with a litholytic food and antibiotics. The nephrolith (arrows) is about 75% of its original size.

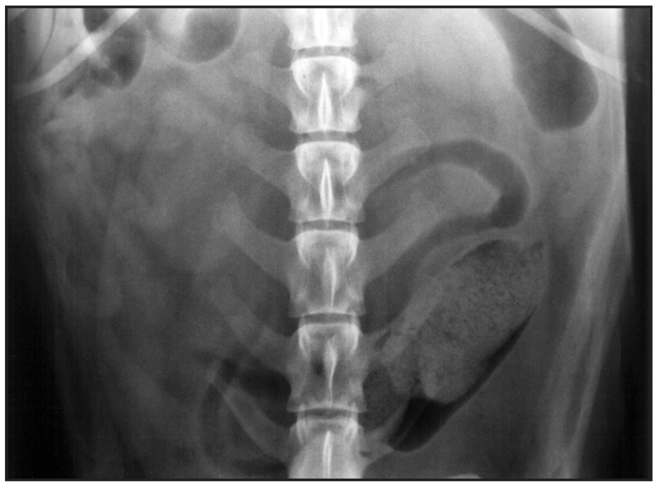

Figure 4. Survey ventrodorsal abdominal radiograph obtained 18 weeks after initiation of therapy. There is no evidence of the nephrolith in the right kidney.

for analysis. Consumption of food that usually results in acidic urine, administration of an antibiotic and formation of poorly concentrated urine may have reduced the likelihood of struvite crystalluria.

3. Dissolution of nephroliths presumed to be composed of infection-induced struvite can be accomplished using a combination of a commercial veterinary therapeutic struvite litholytic food[a] and antimicrobial therapy. In studies conducted at the University of Minnesota, the mean time required for dissolution of infection-induced nephroliths was 26 weeks (range nine to 42 weeks). Nephroliths and/or ureteroliths causing complete outflow obstruction and marked impairment of function in the associated kidney should be managed by surgical intervention. Surgical removal of uroliths has the obvious advantage of rapid correction of the mechanical components of the disease process; however, surgery cannot be relied upon to remove very small uroliths or to prevent their recurrence. Likewise, nephrectomy is always associated with destruction of nephrons, the magnitude of which is influenced by the number of renal end arteries that are transected.

Progress Notes

The owners requested dietary and medical treatment. A combination of a struvite litholytic food and a bactericidal antimicrobial agent (amoxicillin and clavulanic acid[b]), chosen on the basis of antimicrobial susceptibility results, was used. The daily energy requirement was estimated to be approximately 1,800 kcal (7.5 MJ) (1.4 x resting energy requirement) or 1.5 cans of Prescription

Table 1. Results of selected urinalysis and serum biochemistry parameters of a five-year-old neutered male rottweiler with recurrent urinary tract infection.*

Factors	Reference values	Week 0	Week 5	Week 9	Week 13	Week 18	Week 25	Week 29	Week 34
Urine specific gravity	-	1.015	1.007	1.007	1.007	1.015	1.008	1.022	1.015
Urinary pH	-	7	6	6	8	7	7	7.5	6
Hematuria	-	+	+	+	0	0	0	0	0
Pyuria	-	+	0	0	0	0	0	0	0
Bacteriuria	-	+	0	0	0	0	0	0	0
SUN (mg/dl)	7-28	26	5	9	5	6	6	13	11
Creatinine (mg/dl)	0.5-1.5	1.6	1.4	1.4	1.4	1.1	1.1	1.5	1.1
Magnesium (mg/dl)	1.5-2.7	2.3	1.9	1.8	2.0	1.8	1.6	1.8	2.0
Albumin (g/dl)	2.4-3.8	3.5	3.1	3.3	3.3	3.4	2.9	3.5	3.4
Alkaline phosphatase (U/l)	10-149	28	56	67	65	123	164	43	29

Key: + = present, 0 = absent, SUN = serum urea nitrogen.
*Therapy with a litholytic food and antibiotics was initiated during Week 1 and discontinued on Week 25.

Diet s/d Canine[a] twice daily. In order to facilitate dietary compliance, the owners were asked to restrict treats to baked slices of the moist therapeutic food. Therapeutic efficacy was monitored by physical examination and serial evaluation of survey radiographs (a ventrodorsal view is usually best for nephroliths, and a lateral view is usually best for urocystoliths), urinalyses, urine cultures, serum biochemistry profiles and complete blood counts (**Table 1**). Reduction in the serum urea nitrogen concentration and formation of less concentrated urine indicates compliance with the feeding plan.

Survey abdominal radiographs obtained at four- to five-week intervals revealed progressive reduction in the size of the nephrolith (**Figure 3**). Radiodense uroliths could not be detected on Week 18 (**Figure 4**). After initiation of antimicrobial therapy, bacteria could not be cultured from urine samples collected by cystocentesis. Urinalysis revealed progressive reduction in hematuria and pyuria (**Table 1**).

Consumption of the litholytic food was associated with polyuria, formation of less concentrated urine, reduction in the serum concentration of urea nitrogen and magnesium and an increase in serum alkaline phosphatase activity. Clinically significant changes were not observed in serial hemograms. Dietary and antimicrobial therapy was discontinued on Week 25. Most diagnostic parameters returned to baseline values by Weeks 29 and 34 (**Table 1**).

The owners indicated that the dog readily consumed the food and gained 3.5 kg during the treatment period. Decreasing the amount of food offered and consumed during the treatment period may have prevented significant weight gain.

Chapter 44

Canine Silica Urolithiasis: Causes, Detection, Treatment and Prevention

Carl A. Osborne
Jody P. Lulich
Lisa K. Ulrich

"There is a difference between unanswered questions and unquestioned answers."
Carl A. Osborne

TERMINOLOGY

The name silicon (Si) is derived from the Latin word "silicis" meaning flint. Silicon is a naturally occurring nonmetallic element. When combined with oxygen, Si forms SiO_2 and is called silica or silicon dioxide. The term silicate is a noun used to designate a salt derived from silicic acid (as in aluminum silicate and magnesium trisilicate). The term silicon should not be confused with silicone. Silicone refers to any of a group of synthetic resins, oils, greases, plastics, etc. in which the carbon element has been replaced with silicon.

Inorganic Silica

Inorganic silica, whose basic formula is SiO_2, occurs naturally in crystalline, microcrystalline, cryptocrystalline or amorphous forms. The designation SiO_2 as crystalline refers to the orientation of silicon molecules in a fixed, orderly and repetitive pattern resulting in a characteristic shape. Crystals reflect internal order. The term microcrystalline refers to the fact that the crystals are so small that they can only be seen through a microscope. The term cryptocrystalline refers to the fact that the crystals are too small to be seen by light microscopy. The designation as amorphous (without shape) refers to the orientation of SiO_2 molecules in a random or non-periodic pattern. Amorphous minerals are also called mineraloids. Most silica-containing uroliths removed from dogs are composed of amorphous silica.

Inorganic crystalline silica is the basic component of sand, quartz and granite. Microcrystalline silica is found in quartz, chalcedony (agate, onyx, etc.) and chert (flint, jasper, etc.). Amorphous silica is found in glass, opal and diatomaceous earth.

Organic Silica

Although silicate and silica minerals constitute more than 90% of the earth's crust, they occur in very low concentrations in most animals. The low quantities of silica in most animals may be attributable to the low solubility of silica in all but a very few naturally occurring waters. In contrast, plants often contain

higher quantities of silica. For example, grasses contain between 1 and 4% silica by dry weight. Plants notable for their high silica content include rice and scouring rushes (genus *Equisetum*), which contain up to 16% silica (Salisbury and Ross, 1985).

EPIDEMIOLOGY AND MINERAL COMPOSITION

Prevalence

Silica accounted for 0.4% of all canine uroliths submitted to the Minnesota Urolith Center from 1981 to 2007, (1,414 of 350,803 [Table 38-8]) and 0.33% of (134 of 40,612) uroliths submitted in 2007. Silica accounted for 0.34% of all upper tract uroliths analyzed at the Minnesota Urolith Center from 1981 to 2007 (19 of 5,591). Silica uroliths were more commonly removed from the lower urinary tract (99%) than the upper urinary tract (1%) (Table 38-9).

Age and Gender

In approximately 310,000 cases of urolithiasis evaluated at our center, only one case of silica urolithiasis was documented in dogs less than 12 months of age. The mean age of dogs at the time of urolith retrieval was 7.7 years (range eight months to 19 years). Males were affected (95%) more commonly than females (5%). However, female dogs may void small silica uroliths before they induce clinical signs, reducing the detection rate.

Breeds

From 2000 to 2006, 82 different breeds were affected including mixed breeds (19%), German shepherd dogs (13%), golden retrievers (6%), Shih Tzus (6%), black Labrador retrievers (6%), rottweilers (2%), miniature schnauzers (2%) and cocker spaniels (1%). A high prevalence of silica uroliths in German shepherd dogs, Yorkshire terriers, Shih Tzus, Lhasa apsos, golden retrievers, miniature schnauzers and old English sheepdogs has been recognized (Aldrich et al, 1997, Ling, 1995). Several of these breeds also appear to be at risk for calcium oxalate uroliths. This association, and the observation that silica uroliths often contain calcium oxalate, prompt questions about the possibility of epitaxy associated with silica and calcium oxalate urolithiasis.

MINERAL COMPOSITION AND ARCHITECTURE

Of 1,414 canine silica uroliths, 982 were composed entirely (100%) of amorphous silica, and 432 were composed of at least 70% of this mineral. Silica uroliths may contain varying quantities of other minerals, especially calcium oxalate. Ammonium urate and calcium phosphate are encountered less frequently in association with silica.

Most canine silica uroliths have a jackstone configuration (Osborne et al, 1981). The name jackstone was selected because their shape is similar to the small, six-pronged metal pieces used in the children's games of "jacks." Protrusions from different uroliths vary in number (usually from 15 to 30), length (from a few mm to more than one cm) and diameter. Some protrusions are long and slender, whereas others are blunt, imparting a mammillary appearance to the urolith. Protrusions from individual uroliths are usually but not invariably similar in length and diameter. These features of silica uroliths often impart a distinctive appearance, which can often be identified by radiography. Cross sections of canine silica jackstones reveal that they are distinctly laminated; however, these laminations cannot be detected by radiography. In most dogs, silica jackstones occurred in multiples with some patients having more than 30. However, a few dogs had solitary uroliths. Silica uroliths ranged in diameter from less than 1 mm to more than 3 cm. Not all uroliths composed primarily of silica had a jackstone configuration. However, all silica uroliths formed by dogs had some form of surface protrusions at more or less regular intervals, imparting a regularly uneven surface contour to the uroliths. Some silica jackstones were coated with layers of struvite, which altered their characteristic shape. In some instances, struvite completely surrounded silica jackstones.

Calcium oxalate monohydrate, calcium oxalate dihydrate and ammonium urate uroliths may also have a jackstone-like appearance as detected by survey and contrast radiography. However, the macroscopic appearance of non-silica jackstones is typically different than that of silica jackstones.

ETIOPATHOGENESIS AND RISK FACTORS

Overview

Naturally occurring silica jackstones were first reported in dogs living in the United States in the mid-1970s (Osborne et al, 1986). An extensive review of the literature revealed a conspicuous absence of this type of canine urolith before that time. In the mid-1970s, silica uroliths were reported to occur only in dogs from the United States and Canada. However, in 1985, canine silica jackstones were recognized in Japan and shortly thereafter in Europe. Calcium magnesium aluminum silicate uroliths without a jackstone configuration were identified in dogs native to Kenya in 1977 (Brodey et al, 1977).

Relationship of Silica Uroliths to Food

Hypothesis

Several observations prompt the hypothesis that development of canine silica uroliths may be related to hyperexcretion of silica in urine following consumption of an absorbable form of silica in various foods. It is noteworthy that silicic acid is readily absorbed across the intestinal wall (Ammerman et al, 1980; Sutor et al, 1970; White and Porter, 1969). The fact that ingested silica is rapidly cleared by the kidneys from plasma of dogs and other animals following absorption into the body also supports the "dietary risk factor" hypothesis (Benke and Osborn, 1979; King et al, 1933).

Possible Dietary Sources of Silica or Silicate

Silicate minerals occur in very low concentrations in most animals. Therefore, ingredients in pet foods derived from animal

sources are an unlikely source of this mineral. In contrast, plants contain larger quantities of silica. As mentioned above, grasses contain between 1 and 4% silica by dry weight and rice and scouring rushes (horsetails, genus *Equisetum*) contain up to 16% silica (Salisbury and Ross, 1985).

One plausible explanation as to why canine silica uroliths began to be recognized in the mid-1970s is that at that approximate time, the pet food industry initiated use of an increased quantity of plant-derived ingredients in moist and especially dry dog foods. Silicon is taken up by the roots of plants and deposited in their cell walls as silica, soluble silicates and organic combinations. Although unlikely, another factor could have been the addition of fillers, which contain relatively large quantities of silica (e.g., rice or soybean hulls), to some pet foods designed for reduction in obesity (Underwood, 1977).

Corn gluten feed, a by-product of the wet milling and distilling process designed to separate shelled corn into various components, was another suspected source of silica in some pet foods. Corn gluten feed remains after extraction of starch, gluten and germ from shelled corn. The term gluten, meaning "glue" in Latin refers to the sticky characteristic of substances derived from corn, wheat and other grains. Corn gluten feed contains about 40% protein and is contained in some low quality pet foods. We emphasize that corn gluten feed is not the same as corn gluten meal. Corn gluten meal is contained in many higher quality manufactured foods designed for dogs because it is readily digestible and a relatively inexpensive form of protein (approximately 60%), vitamins, minerals and energy. Corn gluten meal is an unlikely source of the silica in uroliths.

Contamination of various types of plants with soil during harvesting is also conceivable. Another possibility that may apply to some dogs is consumption of soil secondary to diet-associated pica.

Caution: studies performed in rats indicate that the type of silica compound ingested influences its absorption from the gastrointestinal tract (Yoko and Saboro, 1979). In addition, other factors (e.g., pH) may be involved (Pyrah, 1979; Yoko and Saboro, 1979). Therefore, detection of a relatively large quantity of silica in food is not itself synonymous with intestinal absorption and urinary excretion of silica.

Dogs and People

Silica uroliths developed in male dogs fed experimental foods containing a high concentration of silicic acid and talc [$Mg_3SiO_{10}(OH)_2$] for several months (Ehrhart and McCullagh, 1973; McCullagh and Ehrhart, 1974). Replacement of dietary silicic acid with purified cellulose prevented further urolith development. In a pilot study, we detected multiple tiny silica uroliths in the urinary bladder of an adult male beagle dog after it was given magnesium trisilicate orally for approximately four months.

Silica uroliths have been reported in several people who consumed large quantities of antacids containing magnesium trisilicate to alleviate signs of peptic ulcers (Farrer and Rajfer, 1984; Forman et al, 1959; Herman and Goldberg, 1960; Levison et al 1982; Pyrah,1979).

The high prevalence of silica urolithiasis in native Kenyan dogs has been hypothesized to be related to consumption of unprocessed Kenyan corn, a common ingredient in their diet garnered primarily by scavenging (Brodey et al, 1977). It is also conceivable that Kenyan dogs could have consumed silica contained in the soil as they scavenged for food.

Another potential source is micro-fine silica, which is used in small quantities as an anti-caking agent in the manufacture of many pet foods. Although a cause and effect relationship between micro-fine silica and silica urolithiasis is unlikely, until additional information becomes available, it seems logical to avoid giving foods containing this ingredient to dogs with recurrent silica urolithiasis.

Ruminants

The association of food and silica urolith formation in ruminants is relevant to consideration of diet-related risk factors in dogs. Silica uroliths are common in range cattle and sheep that consume forage grasses with a high concentration of silica (Bailey, 1970; Emerick and Embry, 1960; Emerick et al, 1959; Pyrah, 1979; White and Porter, 1969). In Canada, prairie grass (*Festuca scabrella*) has been found to contain 4 to 8% silica (Bailey, 1966). It is noteworthy, however, that attempts to induce silica uroliths in sheep with inorganic forms of silica (sodium silicate) have been unsuccessful (Beeson et al, 1943; Emerick et al, 1959).

Dietary risk factors for induced silica urolithiasis in sheep include low phosphorus concentrations, a high calcium-phosphorus ratio and factors contributing to alkalinization (Emerick et al, 1959).

Rats and Guinea Pigs

Silica uroliths have been experimentally induced in rats fed diets containing 2% tetraethylorthosilicate (Emerick, 1984; Emerick et al, 1963; Stewart et al, 1993). Siliceous deposits were detected in the renal tubules of guinea pigs given large oral doses of soluble silica (Coe et al, 1991).

Applications of Observations to Diet Hypothesis

Affected dogs that formed silica uroliths submitted to the Minnesota Urolith Center were consuming a large variety of commercially manufactured moist and dry foods in addition to homemade foods. A widespread change in the formulation of commercially manufactured dog food in the U.S. was probably associated with the onset of silica urolithiasis in the mid-1970s and early 1980s, but this assumption has not yet been confirmed.

We consider foods containing large quantities of plant-derived ingredients as risk factors for silica urolithiasis in susceptible dogs. Corn gluten feed, rice hulls and soybean hulls have also been incriminated as dietary risk factors (Osborne et al, 1986).

Concentrations of lithogenic substances in urine are dependent on urine volume. Because dry foods (~10 to 20% water) are often associated with production of more concentrated urine compared with canned formulated diets (~75 to 80% water),

Table 44-1. Key nutritional factors for foods for canine silica urolithiasis prevention.

Factors	Dietary recommendations
Water	Water intake should be encouraged to achieve a urine specific gravity <1.020 Moist food will increase water consumption and formation of less concentrated urine
Protein	Restrict high quality dietary protein to 10 to 18% dry matter
Silica	Avoid foods with corn gluten feed, rice hulls and soybean hulls listed on the ingredient panel of the product label
Urinary pH	Feed a food that maintains an alkaline urine (urinary pH = 7.1 to 7.7)

consumption of dry diets may also be considered as a risk factor for silica urolith formation.

BIOLOGIC BEHAVIOR

The time required for naturally occurring silica uroliths to develop in susceptible dogs is unknown. Silica uroliths were induced in dogs four months after consuming foods containing large quantities of silicic acid (McCullagh and Ehrhart, 1974). Silica uroliths have been produced in rats within eight weeks after consumption of tetraethylorthosilicate (Forman et al, 1959; Emerick, 1984; Emerick et al, 1963). Silicious uroliths have also been observed in calves by the time they were approximately four months old (Forman et al, 1959). Evaluation of case reports of people who developed silica uroliths while consuming silicate-containing antacids suggests that the uroliths developed over a period of years (Farrer and Rajfer, 1984; Levinson et al, 1982).

We have observed recurrence of silica uroliths in five dogs following surgical removal of silica uroliths from the lower urinary tract. Struvite urocystoliths developed in at least two dogs as a consequence of infection with urease-producing staphylococci following surgical removal of silica urocystoliths. Formation of struvite uroliths in this situation is not surprising because urease-producing staphylococci are lithogenic in dogs.

KEY NUTRITIONAL FACTORS

Because initiating and perpetuating causes of silica urolithiasis are unknown, only supportive and symptomatic measures designed to reduce the degree of supersaturation of urine with lithogenic substances can be recommended for prevention. These key nutritional factors are discussed below and summarized in **Table 44-1**.

Water

Concentrations of lithogenic substances in urine depend on urine volume. For dogs with recurrent silica urolithiasis, increasing the volume of urine produced by increasing water consumption will increase the volume of urine in which lithogenic substances are dissolved or suspended. Moist foods rather than dry foods should be considered. Oral administration of sodium chloride has been a favored empirical method to induce diuresis in dogs with uroliths. However, the use of sodium chloride to promote diuresis in dogs that form silica uroliths cannot be routinely recommended without evidence of safety and efficacy because of the unpredictable but marked occurrence of calcium oxalate in silica uroliths and because orally administered sodium chloride is associated with hypercalciuria. Strive to promote formation of urine with a specific gravity value less than 1.020.

Protein

Moderate restriction of dietary protein (10 to 18% dry matter) has the advantage of contributing to obligatory polyuria by decreasing renal medullary urea concentration and is therefore, recommended.

Besides the amount of protein, the predominant protein source can be important. Some protein supplying ingredients for pet foods are higher in silica than others. Animal-derived protein ingredients are an unlikely source of silica. In contrast, some plant-derived protein sources contain larger quantities of silica. As mentioned above, corn gluten feed is an example. On the other hand, many higher quality commercial pet foods contain corn gluten meal because it is readily digestible and is a relatively inexpensive source of protein. Corn gluten meal is an unlikely source of the silica in uroliths. Check the ingredient label. Foods listing "corn gluten feed" as one of the first four non-water ingredients should be avoided.

Silica

Foods with large quantities of plant-derived ingredients are suspected to be risk factors for silica uroliths in susceptible dogs. Consumption of dry foods may also be considered a risk factor for silica urolith formation. Corn gluten feed, rice hulls and soybean hulls have been incriminated (Osborne et al, 1986). Although an unlikely source, ingestion of micro-fine silica used as a de-caking agent in the manufacture of some foods is a possibility. Avoid foods whose product label ingredient panel lists corn gluten feed, rice hulls or soybean hulls.

Urinary pH

Silica is less soluble in acidic than alkaline water, and currently available information suggests that silica is less soluble in acidic than alkaline biologic environments. It is noteworthy that the urinary pH of eight non-infected dogs with silica uroliths was acidic to neutral at the time of diagnosis (mean = 6.0; range = 5.0 to 7.0). Whether or not alkalinization of urine is beneficial in increasing the solubility of silica or silicates in urine is unknown. However, until more research evidence is available, we recommend that the urinary pH produced by a food or a food and urine alkalinizing agents be in the range of 7.1 to 7.7.

FEEDING PLAN

Effective dietary and medical protocols to induce dissolution of canine silica jackstones have not yet been developed. At this time, surgery is the only practical option to remove large silica

uroliths. Voiding urohydropropulsion may be used to remove small urocystoliths (Figure 38-5 and Table 38-7) (Lulich et al, 1993). Lithotripsy may be considered to remove urethroliths. Litholytic foods that do not contain large quantities of plant ingredients and that induce diuresis may prevent further growth of silica uroliths.

At this time, our recommendations include change of diet, augmentation of urine volume and consideration of altering urinary pH (**Table 44-1**) (Osborne et al, 1986; Osborne et al, 1999).

Assess and Select the Food

Although the role of food in the genesis of canine silica uroliths is still somewhat speculative, it seems reasonable to recommend that food(s) of affected patients be changed, especially if the problem is recurrent. Although empirical, this maneuver is unlikely to be harmful and may be helpful. Based on the assumption that the primary source of excessive silica in foods is vegetable in origin, selection of a food with reduced quantities of specific vegetable protein and other plant-based ingredients is recommended. Our empirical experience with this method of prevention has been favorable. **Table 44-2** lists selected veterinary therapeutic foods that can be considered for prevention of silica urolithiasis and compares their key nutritional factor content to the recommended levels. Select the food that is most similar to the key nutritional factor profile. Because these foods are intended for long-term feeding, they should also be approved by the Association of American Feed Control Officials (AAFCO), or some other credible regulatory agency. Dogs consuming dry foods may be at greater risk for urolithiasis than dogs consuming moist foods. Dry foods are often associated with higher urine concentrations of urolith constituents (in the case of silica urolithiasis, more plant origin ingredients) and more concentrated urine. Therefore, when possible, moist foods should be selected.

Assess and Determine the Feeding Method

A few dogs with silica uroliths have a history of pica and coprophagia associated with consumption of dirt and/or compost in one form or another. The relationship of the onset of pica with the diet history should be investigated with the goal of correcting this problem.

Transitioning a patient from the current food to a new food selected for the prevention of silica urolithiasis should be done gradually over a period of a few days. Begin the transition by feeding 75% of the current food and 25% of the new food on Day 1. On Day 2, feed half of each food. On Day 3, feed 75% new food and 25% old food. By Day 4 or 5, feed only the new food.

Because moist foods tend to increase water intake and produce a less concentrated urine, recommend the client feed specific amounts (meal fed) two to three times per day rather than free-choice feeding. Moist foods can spoil if left at room temperature for several hours (Chapter 11). Opened containers of moist foods should be refrigerated and the feeding bowl should be kept clean.

Table 44-2. Levels of key nutritional factors in selected commercial foods used to minimize recurrence of silica uroliths in dogs compared to recommended levels.*

Dry food	Protein (%)	Urinary pH**
Recommended levels	**10-18**	**7.1-7.7**
Hill's Prescription Diet u/d Canine	11.2	7.70
Moist food		
Hill's Prescription Diet u/d Canine	13.3	7.40

*Manufacturer's published values; protein expressed as % dry matter; when possible recommend moist foods; where possible, check the ingredient panel of the product label and avoid foods that list corn gluten feed, rice hulls or soybean hulls.
**Protocols for measuring urinary pH may vary.

Besides offering moist foods, there are several additional ways to facilitate increased water intake. These include: 1) Ensuring multiple water bowls are available in prominent locations in the dog's environment; this may mean providing several bowls outside in a large enclosure or a bowl on each level of the house. 2) Bowls should be clean and, if possible, kept full of fresh water. 3) Small amounts of flavoring substances (e.g., salt-free bouillon) can be added to water sources to increase consumption. 4) Ice cubes can be offered as treats or snacks. 5) If a dry food is selected, advise the client to add liberal quantities of water; however, as with moist foods left at room temperature for too long, be aware that there are also potential food safety issues that might arise from leaving moistened dry foods out for prolonged intervals (Chapter 11).

If the patient has a normal body condition score (BCS 2.5/5 to 3.5/5), the amount of the previous food being fed was probably appropriate. On an energy basis, a similar amount of the new food would be a good starting point.

Oral administration of sodium chloride has been a favored empirical method to induce diuresis in dogs with uroliths. However, the use of sodium chloride to promote diuresis in dogs that form silica uroliths cannot be routinely recommended without evidence of safety and efficacy because of the unpredictable but marked occurrence of calcium oxalate in silica uroliths and because orally administered sodium chloride is associated with hypercalciuria.

ADJUNCTIVE MEDICAL MANAGEMENT

Urine Alkalinizing Agents

Silica is apparently less soluble in acidic than alkaline water, and currently available information suggests that silica is less soluble in acidic than alkaline biologic environments. It is noteworthy that the urinary pH of eight non-infected dogs with silica uroliths was acidic to neutral at the time of diagnosis (mean = 6.0; range = 5.0 to 7.0). Whether or not alkalinization of urine is beneficial in increasing the solubility of silica or silicates in urine is unknown. Likewise, the effects of orally administered alkalinizing agents (e.g., sodium bicarbonate) on the absorbability of silica from the gastrointestinal tract have not been evaluated. Nonetheless, it seems prudent to recommend that efforts

Table 44-3. Summary of recommendations for prevention of canine silica uroliths.

1. Perform appropriate diagnostic studies including complete urinalysis, quantitative urine culture and diagnostic radiography. Determine precise location, size and number of uroliths.
2. If uroliths are available, determine their mineral composition. If unavailable, determine their composition by evaluation of appropriate clinical data.
3. Small urocystoliths may be removed by voiding urohydropropulsion (Figure 38-5 and Table 38-7). Consider surgical removal of larger uroliths causing clinical disease.
4. To prevent further growth of existing silica uroliths or to prevent recurrence of silica uroliths after surgical removal:
   a. Avoid use of foods containing large quantities of plant proteins, and especially avoid those containing rice hulls, soybean hulls or corn gluten feed.
   b. Enhance diuresis by adding moisture to the food.
   c. Avoid efforts to deliberately acidify urine.
5. If necessary, eradicate or control urinary tract infections with appropriate antimicrobial agents.

to deliberately acidify the urine of dogs with recurrent silica uroliths be avoided. The observation that silica may occur in uroliths in association with calcium oxalate is additional support for the recommendation to avoid acidification of urine. Mild alkalinization (pH range 7.1 to 7.7) of the urine (but not of the digestive system) might be considered for dogs affected by silica uroliths that recur frequently. Prevention of systemic acidosis is recommended to minimize calcium oxalate urolith formation.

REASSESSMENT

Therapy should be initiated in a stepwise fashion (**Table 44-3**). The goal of therapy is to prevent silica urolith recurrence. Dietary management should minimize exposure to minerals predisposing to silica uroliths and result in formation of less concentrated urine; strive to promote formation of urine with a specific gravity less than 1.020. A urinalysis and lateral abdominal radiograph should be evaluated periodically. Initially, every three to four months seems reasonable. Depending on results, the interval may be increased or decreased. The goal is to detect recurrent urocystoliths when they are small enough to be removed by voiding urohydropropulsion (Lulich et al, 1993) or lithotripsy.

Canine Compound Urolithiasis: Prevalence, Significance and Management

Carl A. Osborne
Jody P. Lulich
Lisa K. Ulrich

"The best veterinary teaching hospitals in the world not only use contemporary data, they create it."
Carl A. Osborne

Compound uroliths (nucleus composed of one mineral type and shells of a different mineral type) occurred in approximately 7% of the canine uroliths analyzed at the University of Minnesota (Table 38-8). Examples include: 1) a nucleus of 100% calcium oxalate monohydrate surrounded by a shell of 80% magnesium ammonium phosphate and 20% calcium phosphate, 2) a nucleus composed of 95% magnesium ammonium phosphate and 5% calcium phosphate surrounded by a shell of 95% ammonium acid urate and 5% magnesium ammonium phosphate and 3) a nucleus composed of 95% silica and 5% calcium oxalate monohydrate surrounded by a shell of 100% calcium oxalate monohydrate.

Voiding urohydropropulsion may be used to remove small compound urocystoliths (Figure 38-5 and Table 38-7) (Lulich et al, 1993). Lithotripsy may be considered to remove uroliths lodged in the urethra. For most practitioners, surgery remains the most reliable method to remove large compound urocystoliths.

Because risk factors that predispose patients to precipitation (nucleation) of different minerals vary, the occurrence of compound uroliths poses a unique challenge in terms of preventing recurrence. In the absence of clinical evidence to the contrary, it seems logical to recommend management protocols designed primarily to minimize recurrence of minerals composing the nucleus (rather than those in shells) of compound uroliths (Lulich and Osborne, 2000; Osborne, 2003). (See specific chapters for recommendations [Chapters 39 through 44]). Followup studies designed to evaluate efficacy of preventive protocols should include complete urinalyses, radiography or ultrasonography and if available, evaluation of the urine concentration of lithogenic metabolites.

CASE 45-1

Inappropriate Urination in a Yorkshire Terrier Cross

Jody P. Lulich, DVM, PhD, Dipl. ACVIM (Internal Medicine)

Carl A. Osborne, DVM, PhD, Dipl. ACVIM (Internal Medicine)
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota, USA

Patient Assessment

An 11-year-old, neutered female Yorkshire terrier cross weighing 5 kg was examined for inappropriate urination. The dog had been urinating in the house during the day while the owners were at work. Sometimes the urine appeared red. Physical examination was normal except for dental calculus and gingivitis. Body condition was normal (body condition score 3/5).

Urinalysis of a voided sample revealed alkaline urine with hematuria, proteinuria, pyuria, bacteriuria and a few struvite crystals (**Table 1**). A presumptive diagnosis of bacterial urinary tract infection was made. Urine collected by cystocentesis was submitted for aerobic bacterial culture. Pending culture results, the dog was given a combination of amoxicillin and clavulanic acid (14 mg/kg body weight, per os, q12h). Urine culture results identified *Staphylococcus intermedius*, which was susceptible to the prescribed antimicrobial.

One week later the dog was examined for continued hematuria and dysuria. Bacterial culture of urine was negative indicating that antimicrobial therapy was successful. Survey abdominal radiographs (**Figure 1**) revealed a large solitary radiodense urocystolith with a distinct central core (outside diameter = 2.9 cm, core diameter = 1.3 cm). The urolith core was denser than the outer layer. A urinalysis was not performed.

Table 1. Urinalyses of an 11-year-old female Yorkshire terrier crossbred dog with inappropriate urination.*

Factors**	Day 1	Day 14***	Day 28	Day 60

†††Per low power field (x100).

Assess the Food and Feeding Method

The dog ate a commercial moist grocery brand food supplemented with milk, turkey and chicken meat.

Questions

1. What is the probable mineral composition of this dog's urolith?
2. What are the advantages and disadvantages of surgical vs. dietary and medical management of this urolith?

Answers and Discussion

1. Based on the clinical findings, the outer portion of the urolith was probably composed of magnesium ammonium phosphate (struvite) (**Table 2**). Because of the difference in radiodensity, the nidus may be composed of a different mineral salt, likely calcium oxalate.
2. Although struvite urocystoliths are amenable to dietary and medical dissolution, surgical removal is probably the best treatment option in cases of suspected compound uroliths.

Table 2. The advantages and disadvantages of dietary and medical urolith dissolution and surgical urolith removal can be accurately assessed after the mineral composition of the urolith is known or predicted. This table lists factors used to predict mineral composition of radiodense uroliths when no uroliths are available for quantitative analysis vs. clinical findings in the patient described in this case.*

Factors	MAP	CaOx	CaP	Silica	Cystine
Typical urinary pH	Yes	No	Possible	No	No
Typical crystalluria	Yes	No	No	No	No
Typical urine culture	Yes	No	No	No	No
Typical radiographic density	Yes	Yes	Yes	Yes	No
Typical radiographic contour	Yes	Possible	Possible	No	No
Typical breed	No	Yes	Yes	No	No
Typical gender	Yes	No	No	No	No
Typical age	No	Yes	Yes	No	No

Key: MAP = magnesium ammonium phosphate, CaOx = calcium oxalate, CaP = calcium phosphate.
*Characteristics of urate uroliths were not considered because they are typically radiolucent.

Progress Notes

Results of a serum biochemistry profile were normal. The urolith was removed surgically

and antimicrobial therapy was continued for an additional two weeks. Quantitative mineral analysis of the urolith by polarizing light microscopy and infrared spectroscopy revealed that the nidus was composed of 100% calcium oxalate monohydrate and the outer layer was composed of 95% magnesium ammonium phosphate and 5% calcium phosphate carbonate.

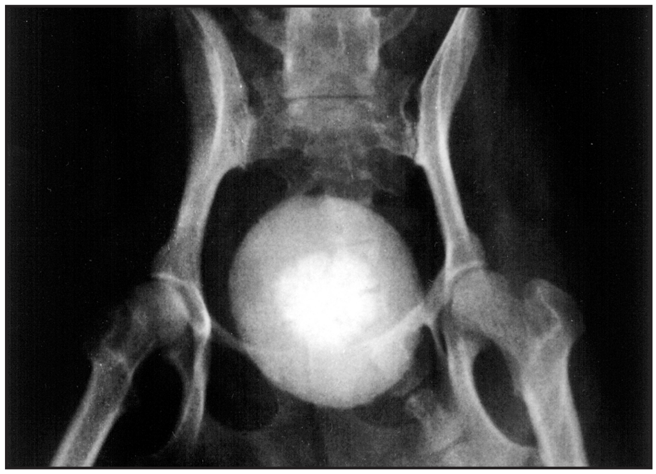

Figure 1. Survey abdominal radiograph (ventrodorsal view) showing a solitary urocystolith. Note that the urolith nidus is radiographically denser than the outer layer.

Further Questions

1. How does a compound urolith develop?
2. How can recurrence of urolithiasis be minimized in this patient?

Answers and Discussion

1. Although the exact mechanisms responsible for calcium oxalate urolith formation are unknown, supersaturation of urine with calcium and oxalic acid is a prerequisite. The calcium oxalate nidus probably disrupted local defense mechanisms predisposing this patient to a staphylococcal bacterial infection of the urinary bladder. These bacteria produce the enzyme urease, leading to urine alkalinity and oversaturation with struvite. The calcium oxalate nidus served as template for struvite crystal deposition (heterogeneous nucleation).
2. Some strategies designed to prevent calcium oxalate urolith formation increase the risk for struvite urolith formation. The reverse is also true. When managing patients with compound uroliths containing both mineral salts, minimizing calcium oxalate urolith recurrence is given priority over minimizing struvite urolith formation because struvite uroliths can be nutritionally and medically dissolved. At present, there is no strategy to dissolve calcium oxalate uroliths.

   Dietary recommendations to minimize recurrence of calcium oxalate uroliths include reducing calcium, oxalate, protein and sodium, providing additional water and citrate and maintaining adequate phosphorus and magnesium. One therapeutic goal to prevent calcium oxalate recurrence is alkalinization of urine, which minimizes calcium excretion and augments citrate excretion. Although urine alkalinization increases saturation for struvite, other factors appear to have a greater impact on struvite urolith formation in dogs. In this patient, struvite formed as a result of a urinary tract infection with bacteria that produce urease. Therefore, it is unlikely that struvite will reform without recurrence of a urease-positive urinary tract infection. Urine cultures should be evaluated periodically to detect and eradicate urinary tract infections early so that struvite uroliths do not form.

Progress Notes

A commercial veterinary therapeutic food (Prescription Diet u/d Canine[a]) was recommended (one-half can per day, 375 kcal [1.57 MJ]) and the owners were instructed to avoid feeding human foods, commercial dog treats and vitamin-mineral supplements (especially those containing vitamins C and D and calcium). Urinalysis, urine culture and survey abdominal radiographs were recommended at regular intervals (i.e., every six months).

Chapter 46

Feline Lower Urinary Tract Diseases

S. Dru Forrester
John M. Kruger
Timothy A. Allen

"There is a great difference between knowing and understanding: you can know a lot about something and not really understand it."
Charles F. Kettering

CLINICAL IMPORTANCE

Diseases of the feline lower urinary tract involve the urinary bladder or urethra and may be associated with varying combinations of signs including dysuria, hematuria, pollakiuria, stranguria and periuria (i.e., urinating in inappropriate locations). Feline lower urinary tract diseases (FLUTD) encompass many diverse causes; however, this chapter will focus primarily on the three most common: 1) idiopathic lower urinary tract disease, often called feline idiopathic cystitis (FIC), 2) urolithiasis and 3) urethral plugs. Nutritional management is an important component in the treatment of cats with these lower urinary tract disorders. Nutritional management is recommended for cats with FIC together with environmental enrichment and behavioral management. Nutritional management also is indicated for dissolving struvite uroliths and decreasing risk for recurrence of struvite uroliths and urethral plugs and calcium oxalate uroliths.

The true incidence of the various forms of FLUTD is unknown; however, previous estimates in the United States and the United Kingdom have been approximately 0.85 and 1.5% per year, respectively (Lawler et al, 1985; Willeberg, 1984). These estimates were based on presence of clinical signs and did not consider subsets of cats with specific diagnoses, such as struvite urolithiasis or FIC. In a 1995 survey of primary care veterinary hospitals in the U.S., prevalence of lower urinary tract disorders among 15,226 cats was 3% (Lund et al, 1999). The proportional morbidity ratio (i.e., frequency with which cases are seen at a veterinary hospital) of cats with lower urinary tract diseases has been reported to be 4.6% of those evaluated in primary care hospitals and 7 to 8% of those at North American veterinary teaching hospitals (Bartges, 1997; Kirk et al, 2001; Lekcharoensuk et al, 2001). Proportional morbidity ratios, however, are not reliable estimates of disease incidence because they are affected by other parameters including type of veterinary hospital, interest and expertise of veterinarians at the hospital and economic status of clients served by the hospital.

Another measure of the importance of a clinical problem is the degree of owner concern and recognition. In an animal health survey prepared for the Morris Animal Foundation, 1,211 owners indicated that their top feline health concerns were urinary diseases (n = 576; 48%), dental problems (29%), cancer (27%) and feline leukemia virus infection (27%) (MAF, 1998). In a survey of current and previous donors, kidney and urinary disease (43%) were the most common feline health concerns identified by respondents (MAF, 2005). According to

data from VPI Pet Insurance, lower urinary tract disease was the most common reason pet owners filed a claim for reimbursement of veterinary expenses for their cats in 2006; gastric upsets and kidney disease were the second and third most common reasons (2007). Finally, inappropriate elimination often accompanies FLUTD and is the most common behavioral problem for which pet owners seek professional counsel. It also is the primary behavioral reason why pet owners relinquish their cats to shelters (Beaver, 1989; Neilson, 2003; Salman et al, 2000). Therefore, correct diagnosis and management of underlying causes of periuria are important for maintaining the pet-family bond.

CAUSES OF FLUTD

Many different lower urinary tract diseases occur in cats; however, only a few are common and these may differ depending on the cat's age, presence of concomitant diseases and geographic location. If clinical signs are present and a specific cause is not identified after appropriate evaluation, FIC is the most likely diagnosis. Based on findings from four clinical studies, the three most common lower urinary tract diseases in cats are FIC, urolithiasis and urethral plugs (Lekcharoensuk et al, 2001; Kruger et al, 1991; Buffington et al, 1997; Gerber et al, 2005) (**Table 46-1**). In cats older than 10 years, urinary tract infection (UTI) and uroliths were the most common causes of lower urinary tract signs (**Table 46-2**) (Bartges, 1997). In a study from Norway, 33% of 134 cats with stranguria, dysuria, hematuria and pollakiuria were diagnosed with UTI based on culture of urine obtained by cystocentesis, catheterization or voiding (Eggertsdóttir et al, 2007). No significant difference existed in occurrence of UTI based on methods of sampling in this study. In contrast to previous studies, in which most cats were evaluated at teaching hospitals, 97% of cats in the Norwegian study were first-opinion cases and only 3% were referred. Before the approach to management of cats with signs of FLUTD is modified, further evaluation is needed to determine if UTI is a common occurrence in first-opinion cases, and whether there are geographic differences.

Uroliths and urethral plugs are named based on their mineral composition, which is determined by quantitative analysis.

Usually one mineral type predominates; however, the composition may be mixed in some uroliths and plugs. Different mineral types may be dispersed throughout the urolith (i.e., mixed urolith) or organized into separate, discrete bands or layers (i.e., compound urolith). The most common mineral types identified in feline uroliths are struvite (magnesium ammonium phosphate) (**Figures 46-1** and **46-2**) and calcium oxalate (**Figure 46-3**) (Houston et al, 2003; Cannon et al, 2007).[a] Rarely, uroliths are composed of non-mineral substances (e.g., dried solidified blood) (Westropp et al, 2006). Although there have been changes in trends over the past 25 years, struvite and calcium oxalate have remained the most common uroliths in cats (**Table 46-3**). The most recently collected data reveal that struvite is the most common feline urolith followed by calcium oxalate and purine (e.g., urate) (**Table 46-4**). Since 1981, struvite has consistently been the most common mineral type identified in urethral plugs, representing 81 to 87% of plugs analyzed in the U.S. and Canada (**Table 46-5**) (Houston et al, 2003).[a]

Over the past 25 years, several changing trends have been noted in occurrence of feline uroliths (Cannon et al, 2007; Picavet et al, 2007).[a] In 1981, 78% of feline uroliths evaluated at the Minnesota Urolith Center (University of Minnesota) were struvite and only 2% were calcium oxalate.[a] From 1994 to 2001, however, occurrence of calcium oxalate uroliths increased to 55% and struvite decreased to 33%. In 1994, 77% of uroliths from cats in Benelux (Belgium, The Netherlands and Luxemburg) were struvite and 12% were calcium oxalate; however, by 2003, struvite uroliths had decreased to 32% and calcium oxalate had increased to 61% (Picavet et al, 2007). At the Canadian Urolith Centre (University of Guelph, Ontario), approximately 50% of feline urinary bladder uroliths analyzed from 1998 to 2003 were calcium oxalate and 44% were struvite (Houston et al, 2003). Since 2001, the number of struvite uroliths analyzed at the Minnesota Urolith Center has consistently increased whereas the number of calcium oxalate uroliths has decreased (**Figure 46-4**). At the Gerald V. Ling Urinary Stone Analysis Laboratory (University of California, Davis), struvite-containing uroliths were the predominant mineral type analyzed from 1985 to 1993. Thereafter, calcium oxalate became more common (Cannon et al, 2007). From 2002 to 2004; however, 44% of feline uroliths submitted were struvite and 40% were calcium oxalate. The cause(s) for these changing trends is unknown and needs further study.

Urethral obstruction is a complication of both uroliths and urethral plugs, particularly in male cats (Bovee et al, 1979; Kruger et al, 1991; Gerber et al, 2007). During the past 20 years, the number of perineal urethrostomies performed at veterinary teaching hospitals in the U.S. and Canada has declined, which has paralleled a similar decline in the frequency of urethral obstructions, urethral plugs or urethroliths (**Figure 46-5**) (Lekcharoensuk et al, 2002). These trends coincide with widespread use of specially formulated foods to minimize struvite crystalluria in cats. This is important considering that struvite has consistently been the predominant mineral type in feline urethral plugs during the same time period.

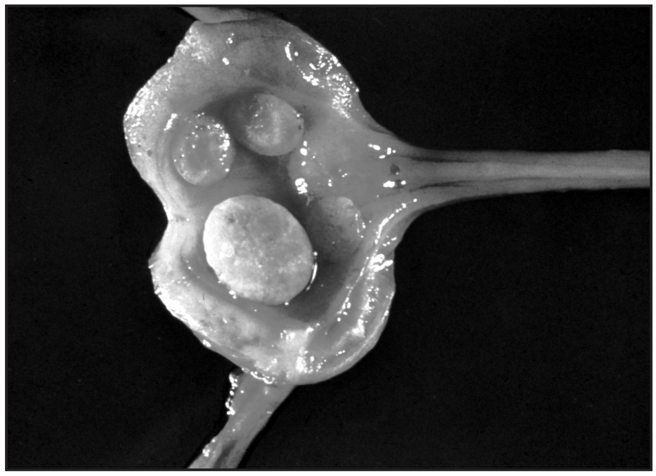

Figure 46-1. Urinary bladder from a cat with struvite urolithiasis. Note the thickened urinary bladder wall and several struvite uroliths within the urinary bladder lumen.

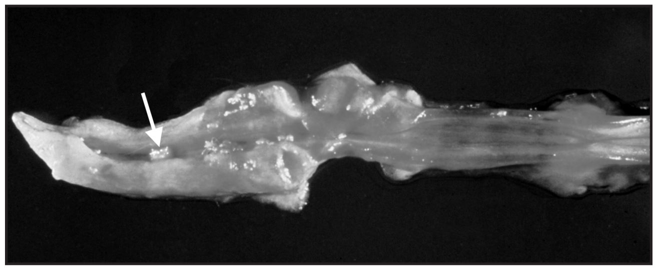

Figure 46-2. Penis and urethra from a cat with urethral obstruction. Note the small struvite urolith (white arrow) in the penile urethra. Uroliths consist of small amounts of matrix and macroscopic crystalline mineral concretions. They are less common causes of urethral obstruction in male cats than urethral plugs (**Figure 46-12**).

Figure 46-3. Calcium oxalate dihydrate urolith removed from the urinary bladder of a cat with hematuria and dysuria.

Although data from urolith centers are helpful, this information cannot be used to determine incidence (i.e., rate of occurrence of new cases in the population) or prevalence (i.e., total number of urolith cases during a given time) of urolith types. Not all cats with uroliths are diagnosed or treated (e.g., they may not receive veterinary care). In addition, not all uroliths are submitted for quantitative analysis and not all laboratories routine-

ly report urolith data annually. In addition, some urolith types are more likely to be submitted for evaluation than others. For example, struvite uroliths can be dissolved with nutritional management; however, calcium oxalate uroliths are more likely to be removed and submitted for quantitative analysis. This could result in an underestimation of the occurrence of struvite uroliths and overestimation for calcium oxalate uroliths.

Regarding trends in occurrence of feline uroliths, several relevant questions remain unanswered: 1) What is the incidence (i.e., rate of occurrence among all cats, not only those presented for veterinary evaluation) of uroliths and has it changed over the past decades? 2) How has the apparent aging feline popu-

lation affected the relative frequency of different urolith types (e.g., has this contributed to increased diagnosis of calcium oxalate uroliths)? 3) Does the occurrence of calcium oxalate uroliths appear greater because fewer struvite uroliths are submitted for analysis due to the availability of struvite dissolution protocols? 4) What role has nutritional management played in managing or causing uroliths? 5) Are there common factors that explain increased occurrence of calcium oxalate uroliths in cats, dogs and people? 6) During the time that calcium oxalate uroliths were more common in cats from North America, why were struvite uroliths more common elsewhere (e.g., Australia, Japan)? and 7) Why have most urethral plugs been composed of struvite for more than 25 years whereas other mineral types of uroliths have changed?

PATIENT ASSESSMENT

Each cat presenting with lower urinary tract signs should be thoroughly evaluated to identify the underlying cause(s). To guide initial assessment and need for emergency treatment (e.g., urethral obstruction), it is helpful to categorize patients into one of four clinical presentations, realizing that some cats may have features of several presentations (**Table 46-6**) (Lulich, 2007). A thorough history, physical examination and diagnostic evaluation including urinalysis and some form of diagnostic imaging (i.e., abdominal radiography and/or ultrasound) are indicated for every patient. Individualized treatment recommendations can be made based on these findings.

History

The nutritional history should include information about specific brand(s) of food fed, form (dry, moist, semi-moist or a combination), method of feeding (meal fed, free choice) and

whether table food, supplements or treats are offered. Access to other food should also be determined (e.g., other pets in the household that eat different foods, access to food at other households or in the outdoor environment). Trends in water consumption (i.e., increased, decreased, unchanged) should also be noted.

Pet owners should be questioned carefully about: 1) duration and progression of clinical signs (same, better, worse), 2) whether the episode was the patient's first or a recurrence, 3) interval between episodes, 4) previous treatments (medical, surgical, nutritional) and response to therapy, 5) presence of other illnesses, injuries or trauma (current or previous) and 6) presence of systemic signs (e.g., inappetence, vomiting, diarrhea, weight loss). Questions should be asked to determine presence or absence of dysuria, pollakiuria, urinary incontinence, periuria, discolored urine and uroliths or urethral plugs voided during urination. Approximate urine volume and any changes in volume should be determined to distinguish between pollakiuria and polyuria. Owners should be asked about pharmaceutical agents that may be risk factors for urolithiasis (e.g., allopurinol may predispose to xanthine uroliths, excessive use of urinary acidifiers may predispose cats to calcium-containing uroliths).

Physical Examination

The urinary bladder should be palpated carefully to evaluate its size, shape, surface contours and thickness of the bladder wall. The presence of pain or masses within the urinary bladder lumen should also be assessed. Most feline urocystoliths cannot be detected by abdominal palpation; however, hearing a "grating" sound during palpation of the urinary bladder strongly suggests their presence. In male cats, the penis and prepuce should be examined for urethral abnormalities. The kidneys should be evaluated for size, shape, surface contour and symmetry. If possible, the patient should be observed during urination to evaluate the size of its urine stream and detect abnormalities such as discolored urine, pollakiuria, dysuria and stranguria.

Diagnostic Evaluation

Initial diagnostic evaluation of all cats with lower urinary tract signs should include urinalysis and some form of diagnostic imaging (i.e., plain abdominal radiographs, abdominal ultrasound). Additional tests may be indicated in some patients. Because urine sediment examination is an unreliable means of detecting UTI, quantitative urine culture should be performed in all cats with lower urinary tract signs. (See Urine Culture below.) Contrast urethrocystography should be performed to exclude small or radiolucent uroliths, urethral plugs and anatomic defects. If available, cystoscopy can also be used to detect and evaluate disorders of the lower urinary tract (e.g., uroliths, neoplasia). In cats with systemic signs of illness (e.g., inappetence, vomiting, weight loss), a complete blood count and serum biochemistry analysis are indicated; however, these tests are unlikely to be helpful in cats with signs limited to the lower urinary tract.

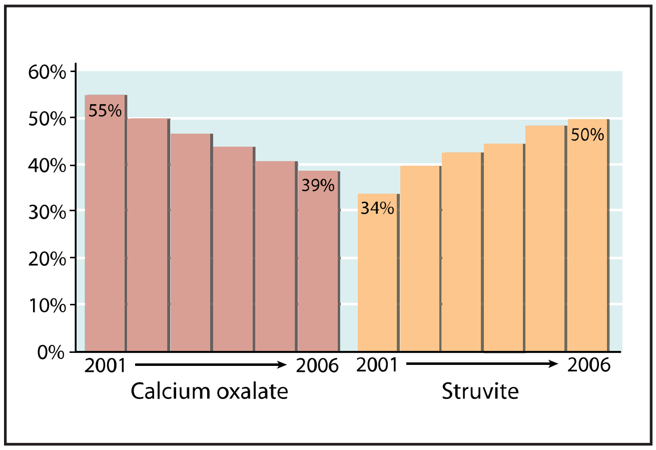

Figure 46-4. Occurrence of calcium oxalate and struvite uroliths analyzed at the Minnesota Urolith Center from 2001-2006. During this six-year period, the number of calcium oxalate uroliths gradually declined with a concomitant increase in struvite uroliths. (Adapted from Osborne CA, Lulich JP. Unpublished data. Minnesota Urolith Center, University of Minnesota, St Paul, 2007.)

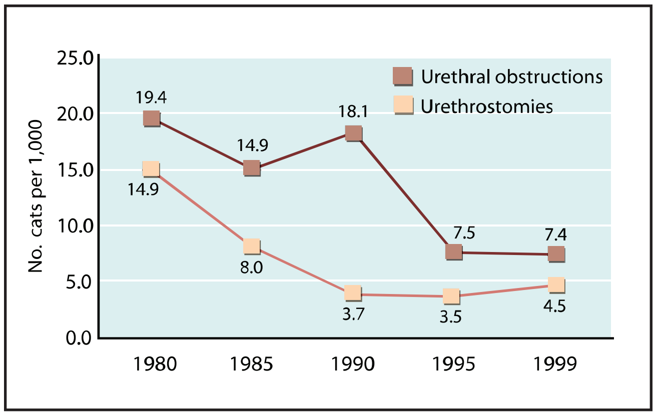

Figure 46-5. The frequency of feline perineal urethrostomies performed at veterinary teaching hospitals in Canada and the United States declined during a 20-year period and paralleled a similar decline in frequency of urethral obstructions and urethral plugs or urethroliths. (Adapted from Lekcharoensuk C, Osborne CA, Lulich JP. Evaluation of trends in frequency of urethrostomy for treatment of urethral obstruction in cats. Journal of the American Veterinary Medical Association 2002; 221: 502-505.)

Urinalysis

Complete urinalysis including determination of specific gravity, dipstick analysis and sediment examination is indicated in all cats with lower urinary tract signs. Because many cats with lower urinary tract diseases have pollakiuria, obtaining an adequate sample for urinalysis may be challenging. Whenever possible, urine should be collected before treatment and evaluated as soon as possible. This is especially important for patients with crystalluria because crystals may begin to form immediately in urine as its temperature decreases. Microscopic examination of urine sediment is essential to confirm the presence of hematuria, pyuria and crystalluria. Examination of unstained urine sediment, however, is an unreliable method of detecting bacteriuria. When compared

**May occur with or without hematuria and signs of urinary tract inflammation.

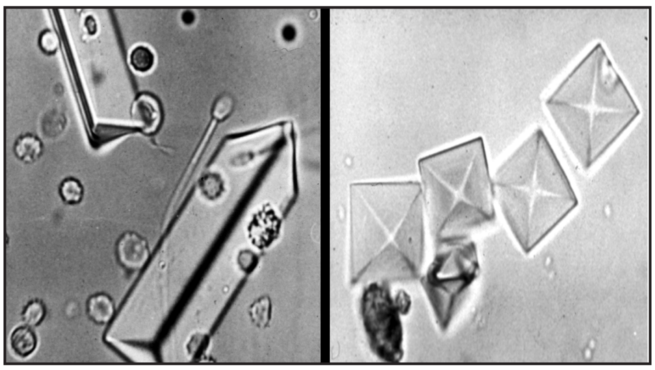

Figure 46-6. Magnesium ammonium phosphate (struvite) crystals (left) typically are colorless, orthorhombic, coffin-like prisms. Struvite crystals may have square or rectangular dimensions, vary in size, may have three to six sides and often have oblique ends. Calcium oxalate dihydrate crystals (right) typically are colorless and have a characteristic octahedral or envelope shape; they resemble small squares with corners connected by intersecting diagonal lines.

with quantitative urine culture, microscopic examination of unstained urine sediment was associated with only an 11% positive predictive value (i.e., the proportion of cats with a positive test that were correctly diagnosed) (Swenson et al, 2004). Bacteria may also be difficult to visualize by routine microscopic examination of urine sediment. Approximately 10,000 rod-shaped bacteria per ml of urine are required for visualization by light microscopy in unstained preparations of urine sediment. Cocci may not be consistently detected if fewer than 100,000 per ml are present. Inability to detect bacteria in urine sediment, therefore, does not exclude their presence. Staining of urine sediment with Wright's, Gram's or new methylene blue stain may significantly improve detection of bacteriuria (Swenson et al, 2004a).

Results of urinalysis are used to: 1) help determine underlying cause(s) of lower urinary tract signs, 2) detect conditions that may predispose to formation of uroliths or urethral plugs, 3) infer mineral composition of uroliths or urethral plugs (**Figure 46-6**) and 4) evaluate response to treatment or preventive measures. Hematuria is a common finding in cats with most lower urinary tract disorders; however, it is uncommon in cats with behavioral periuria (unless it results from a previous medical disorder). Pyuria is uncommon in cats with nonobstructive FIC and behavioral periuria and more often occurs with urolithiasis, urethral obstruction and UTI (Kruger et al, 1991; Osborne et al, 1990).

Several factors influence the number of crystals present in the urine sediment. Because storage at room temperature or refrigeration of urine samples may cause in vitro crystal formation, fresh urine samples should be evaluated ideally within 30 minutes of collection (Sturgess et al, 2001; Albasan et al, 2003). Other factors that affect the presence of crystalluria include volume of urine centrifuged, centrifugation speed and volume of sediment re-suspended and transferred to the microscope slide for evaluation. Consequently, it is difficult to attach clinical significance to the number of crystals observed. In addition to evaluating crystal type, sediment should be evaluated for tendencies of crystals to aggregate. Detection of large aggregates of struvite or calcium oxalate crystals is an important finding when monitoring effectiveness of preventive measures. Crystals only form when urine is supersaturated with crystallogenic materials. Therefore, crystalluria is a risk factor for formation of uroliths and urethral plugs. However, crystalluria alone is not diagnostic for uroliths or urethral plugs (**Box 46-1**). Conversely, urolithiasis is possible without associated crystalluria (Kruger et al, 1991). Crystalluria should be interpreted in the context of the patient's medical history, laboratory methods used and complete diagnostic findings.

Box 46-1. Managing Cats with Crystalluria.

Detection of crystalluria on microscopic examination of urine sediment does not mean a cat subsequently will develop urolithiasis; however, it does indicate increased risk for urolith development. Crystalluria in cats with normal anatomy and physiology of the urinary tract is usually of no clinical significance; these crystals are voided before they grow to sufficient size to interfere with urinary tract function and health.

Crystals that form in vitro after a urine specimen is collected are often of no clinical importance. Temperature, evaporation and pH are in vitro variables that may cause a urine specimen to become oversaturated, leading to crystal formation. Importantly, in vitro conditions may cause crystals to dissolve or grow. It is possible that urine kept at room temperature after collection may lose carbon dioxide into the atmosphere, which could affect pH, and subsequently, presence of crystalluria. However, a recent study found that urinary pH was not affected by storage time or temperature. Analysis of stored urine from cats consuming a mixture of moist and dry food was associated with significant increases in struvite crystalluria compared with evaluation of a fresh urine sample. In another study that included 31 dogs and eight cats, calcium oxalate and struvite crystals formed in vitro in urine that was stored at either room or refrigeration temperature. However, this phenomenon occurred more commonly at refrigeration temperature. In addition, length of crystals that formed in vitro was significantly increased in urine stored at refrigeration temperature compared with samples stored at room temperature.

Bacterial contamination of urine specimens also may affect crystalluria. Urease-producing bacteria (e.g., *Staphylococcus* spp., *Proteus* spp.) alkalinize urine, possibly altering crystal composition and disrupting cellular components in urine (e.g., red and white blood cells). Other bacteria produce acid metabolites with similar consequences. To prevent bacterial overgrowth, urine samples should be refrigerated if they cannot be evaluated promptly. However, this is not ideal for evaluation of crystalluria.

The nutritional history, including water intake, must be considered when evaluating significance of crystalluria. Cats consuming moist food are less likely to have crystalluria than those eating dry food exclusively. In addition, results of urine sediment examination may not accurately reflect what occurs in the home environment if cats are fed different foods in the hospital before urine collection.

Crystalluria should not be used as the sole criterion to predict mineral type of confirmed uroliths; only quantitative analysis of a retrieved urolith can provide that information. However, crystalluria can be used along with other factors (e.g., history, age, breed, urinary pH, radiographic appearance, other urinalysis findings and biochemistry profile results) to predict mineral type. Uroliths may be present in cats without crystalluria. In this case, factors that influenced formation and growth of crystals may be absent transiently. Factors typically responsible for this phenomenon include food changes, anorexia, increased water intake, different urinary pH values and in vitro changes in urine specimens that are not fresh. The crystal type may be different from the urolith type in some cases. This dichotomy exists when cats are assumed to have one urolith type, which is not confirmed by quantitative analysis (e.g., assumed to have struvite uroliths and fed according to struvite dissolution or preventive protocols, when in reality the cat has calcium oxalate uroliths and calcium oxalate crystalluria). Finally, cats may have more than one crystal type concurrently (e.g., struvite and calcium oxalate crystals may be identified in the same urine sample).

Struvite crystals may occur in: 1) normal cats, 2) cats with infection-induced struvite uroliths, 3) cats with sterile struvite uroliths, 4) cats with non-struvite uroliths, 5) cats with uroliths of mixed mineral type and 6) cats with urinary tract disease other than uroliths (e.g., feline idiopathic cystitis). Calcium oxalate dihydrate crystals occur uncommonly in normal cats. Large quantities of these crystals alone or in combination with calcium oxalate monohydrate crystals in fresh urine specimens probably indicate a hypercalciuric or hyperoxaluric disorder (e.g., ethylene glycol toxicity, calcium oxalate urolithiasis).

Should all cats with crystalluria be treated? In the absence of urolithiasis or a history of urolithiasis, cats with struvite or calcium oxalate crystalluria should be monitored serially. Cystine, ammonium urate or xanthine crystalluria should be investigated and the cause treated. Frequent detection of large crystals and aggregates of crystals in a fresh urine sample may be clinically important, especially if the cat has a history of urolith formation. In this case, preventive nutritional management should be implemented, and the cat should be encouraged to increase water intake. Finally, urine sediment examination should be performed periodically to monitor effectiveness of preventive therapy in patients with a history of uroliths.

The Bibliography for **Box 46-1** can be found at www.markmorris.org.

Urinary pH

Urinary pH influences formation of several crystal types. Although exceptions occur, crystal types tend to form and persist at certain urinary pH ranges (**Table 46-7**) (Osborne et al, 1995). In general, struvite uroliths are associated with more alkaline urinary pH values (>6.4) and calcium oxalate uroliths are associated with lower urinary pH values. Overlapping values can be detected; however, in cats with either urolith type. The method of measuring urinary pH should be considered because the urine dipstick method is not as accurate as a pH meter. In addition, urinary pH varies throughout the day due to the influence of food, time of eating, method of feeding and amount of food consumed. Consequently, it is difficult to interpret a single urinary pH value, especially if the type of food and time of eating are unknown. Furthermore, it has been reported that simply putting a cat in a carrier and traveling to a veterinary hospital can increase urinary pH (Buffington and Chew, 1996).

In laboratories, pH meters with glass and reference electrodes are used to make pH measurements. The electrode must be calibrated periodically against buffers of known pH. For clinical purposes, urinary pH can be measured with pH meters or indicator paper. Most multi-test reagent strips and test tapes use indicator paper impregnated with two indicator dyes: methyl red and bromthymol blue. The typical pH range is

roughly from 5.0 (orange) to 9.0 (blue). According to most manufacturers, pH values measured with indicator paper are only accurate to within 0.5 pH units. For best results, indicator squares on reagent strips should be compared with the manufacturer's color standards in well-illuminated areas, as directed by product instructions. Urine reagent strips may be used to estimate pH for routine urinalysis; however, they should not be relied on when accurate pH measurements are needed for diagnosis, prevention and management of disease (Johnson et al, 2007).

Relatively inexpensive microprocessor-based, pocket-sized pH meters[b] have become available and are more accurate for measuring urinary pH than reagent strips (Heuter et al, 1998; Raskin et al, 2002; Johnson et al, 2007). These instruments can be used in veterinary hospitals or by pet owners at home. A study in cats revealed that portable pH meters were more accurate than pH paper or reagent test strips for measuring urinary pH in healthy cats (Raskin et al, 2002). Another study of hospitalized dogs compared hand-held pH meters, pH paper and reagent strips with a bench top pH meter, considered the gold standard for measuring pH. Results revealed that pH paper and reagent strips had poor to moderate agreement with the reference method, whereas, hand-held pH meters had nearly perfect agreement (Johnson et al, 2007). Based on these studies, a portable or bench top pH meter should be used when accurate urinary pH measurements are crucial for diagnosis or treatment.

Urine Culture

Urine culture should be done in all cats with lower urinary tract signs or in asymptomatic cats when there is increased risk of UTI (**Table 46-8**). Quantitative bacterial culture of urine collected by cystocentesis is the gold standard for diagnosis of UTI. For most accurate results, urine should be cultured with-

in 30 minutes of collection or refrigerated because multiplication or destruction of bacteria may occur within one hour. If urine samples cannot be processed immediately, other alternatives such as inoculating culture plates in the hospital or using special storage media should be considered (Bartges, 2004). Growth of any bacteria from a sample of urine collected by cystocentesis is abnormal; contamination during collection should be suspected if multiple organisms are cultured. If a UTI is diagnosed, antimicrobial susceptibility testing is indicated to select appropriate treatment, especially in cats with pyelonephritis, recurrent infections or those that have been receiving antimicrobials.

Radiography

Radiography of the urinary tract (including the entire urethra in male cats) is a valuable diagnostic procedure that allows for detection of most feline uroliths and crystalline-matrix urethral plugs (Johnston et al, 1996). Radiography can determine the size, shape, location and number of uroliths. Relative radiodensity of uroliths can be used to make a rough guess of mineral composition (**Table 46-7**). Struvite and calcium oxalate uroliths are usually radiodense, whereas urate uroliths often are radiolucent. Radiographic shape, contour and size can be used as an inexact predictor of mineral composition. Struvite uroliths can be smooth or rough, round or faceted. Calcium oxalate dihydrate uroliths are usually small, rough and round to oval. Calcium oxalate monohydrate uroliths are usually small, smooth and round. Occasionally, calcium oxalate monohydrate uroliths have a "jackstone" appearance. The size and number of urocystoliths does not predict whether medical dissolution (if applicable) will be successful. Survey radiography or ultrasonography may fail to detect small uroliths (i.e., less than three mm in diameter); however, uroliths greater than one mm in diameter usually can be detected with double-contrast cystography if excessive contrast medium is not infused (Osborne et al, 1996).

Radiographic abnormalities also may be detected in the kidneys and ureters, especially in feline patients with calcium oxalate urolithiasis. The overwhelming majority of feline nephroliths are composed of calcium salts; only a small percentage of nephroliths are struvite (Kyles et al, 2005; Cannon et al, 2007).[a] Nephroliths must be differentiated from dystrophic or metastatic calcification of renal parenchyma, calcified mesenteric lymph nodes and ingesta or medications in the intestinal tract.

Contrast radiography is indicated in cats with recurrent or persistent clinical signs that do not respond to appropriate treatment. Contrast studies can be used to identify radiolucent uroliths, small uroliths or space-occupying lesions of the urinary tract such as neoplasia. Double-contrast radiography is helpful in evaluating urinary bladder wall thickness. Retrograde urethrography may be necessary in cases of urethral disease or obstruction. Patients with FIC may have normal findings or abnormalities including focal or diffuse thickening of the urinary bladder wall, irregularities of the urinary bladder mucosa or filling defects (Scrivani et al, 1998).

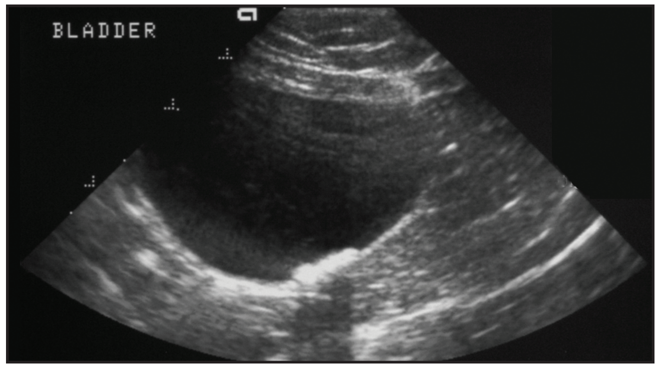

Figure 46-7. Sagittal plane urinary bladder sonogram of a cat with a history of lower urinary tract signs and several previous episodes of urethral obstruction. Note the presence of several hyperechoic densities in the urinary bladder, with acoustic shadowing below. These findings are typical of urinary bladder uroliths. After surgical removal, the uroliths were confirmed to be composed of calcium oxalate.

Ultrasonography

Ultrasonography is a rapid, safe, noninvasive imaging technique for evaluating the urinary bladder. Results often are unique, or at least complementary, compared with other diagnostic procedures; however, ultrasonography should not be viewed as a replacement for other tests including survey radiography (Widmer et al, 2004; Lulich, 2007). Factors affecting accuracy of ultrasonographic evaluation of the lower urinary tract include size and superficial location of the urinary bladder, inaccessible location of much of the urethra within the bony pelvis, degree of urinary bladder distention and presence of urinary bladder disease. Caudal abdominal structures are most readily visualized when the urinary bladder is full. In addition, when there is minimal distention, the urinary bladder mucosa develops folds that misrepresent wall thickness and mucosal contour (Widmer et al, 2004). Minimal transducer pressure should be used when scanning the urinary bladder to avoid displacement away from the transducer; this is especially important in cats with minimal urinary bladder distention.

Urinary bladder ultrasonography may be used to identify uroliths, masses or signs of chronic inflammation. Radiopaque and radiolucent uroliths in the urinary bladder have high echogenicity with characteristic acoustic shadowing (**Figure 46-7**). They tend to gravitate to the most dependent part of the urinary bladder with movement of the patient. Small uroliths may be difficult to distinguish from mineralization of the urinary bladder wall and should be displaced by shaking the urinary bladder during ultrasonography (Widmer et al, 2004). Blood clots also shift location with patient movement; however, they do not cause acoustic shadowing. Diffuse thickening of the urinary bladder mucosa is typical of chronic inflammation from any cause; however, it also may occur with neoplasia, especially lymphoma in cats. Thickening of the mucosa must be interpreted carefully in patients that have a partially filled urinary bladder because mucosal folds may appear in this situation in the absence of disease. Discrete

masses, often located in the apex of the body of the urinary bladder, suggest urinary bladder neoplasia, which is rare in cats (Forrester, 2006; Wilson et al, 2007).

Urethrocystoscopy

Transurethral cystoscopy (or urethrocystoscopy) is becoming an increasingly important diagnostic method for evaluating the urethra and urinary bladder of cats. However, its availability may be limited to certain specialty hospitals. Patients with recurrent or persistent lower urinary tract signs despite normal findings on routinely available diagnostic tests (i.e., urinalysis, urine culture and diagnostic imaging) are candidates. The lower urinary tract of nearly all female cats weighing more that 3.0 kg can be evaluated with one of several small rigid cystoscopes. Urethrocystoscopy may be the method of choice for evaluating female cats with signs of periuria, pollakiuria, dysuria or stranguria. Observation of submucosal petechial hemorrhages (glomerulations), in the absence of other lesions, supports a diagnosis of FIC.

Serum Biochemistry Profiles

Serum biochemistry profiles are not generally helpful in most cats with FLUTD unless there are systemic signs of illness, urolithiasis or frequent recurrences of FLUTD with no obvious cause (**Table 46-7**). Hypercalcemia has been reported to occur in 14 to 35% of cats with calcium oxalate uroliths (Osborne et al, 1996a; Kyles et al, 2005). These patients should be evaluated for underlying causes of hypercalcemia (e.g., hyperparathyroidism, neoplasia and hypervitaminosis D); in most cases, however, a cause is not evident and idiopathic hypercalcemia is diagnosed (McClain et al, 1999; Midkiff et al, 2000; Savary et al, 2000). Presumably, persistent hypercalcemia increases the risk of forming calcium-containing uroliths by increasing excretion of calcium in urine. However, it is possible that processes involved with formation of calcium-containing uroliths and hypercalcemia are unrelated. Acidemia and serum total CO_2 less than 18 mEq/l, were reported in 64% of non-azotemic cats with calcium oxalate uroliths and 92% of cats with concurrent azotemia and uroliths (Osborne et al, 1996a). Metabolic acidosis may contribute to calcium-containing urolith formation because it promotes mobilization of calcium from bone and inhibits renal tubular reabsorption of calcium. Most urate uroliths in cats do not have an identifiable cause; however, serum biochemistry abnormalities (e.g., low urea nitrogen, increased ammonia) may occur in those with concurrent hepatic disease or portosystemic shunts.

Urolith Analysis

Recommendations for urolith dissolution and prevention are based on mineral composition of uroliths; therefore, it is important to analyze uroliths whenever possible. In addition to surgical removal, several less invasive techniques for obtaining uroliths should be considered. These methods include retrieval with a urinary catheter, voiding urohydropropulsion and voiding into an empty or plastic bead-filled litter box (Lulich et al, 1993). Ideally, all uroliths retrieved from a cat should be analyzed by a urolith diagnostic laboratory to determine specific mineral type(s) (**Table 46-9**).

Uroliths can be analyzed qualitatively or quantitatively. Qualitative analysis uses spot tests to identify radicals and ions; however, these tests do not reveal the proportion of mineral types and do not detect certain mineral crystals (e.g., silica) and drug crystals (e.g., sulfadiazine). Qualitative tests lack sensitivity and specificity for analyzing feline and canine uroliths (Osborne et al, 1996; Bovee and McGuire, 1984; Ruby and Ling, 1986). Investigators at the Minnesota Urolith Center examined 223 uroliths by qualitative and quantitative methods

Table 46-10. Reported risk factors for selected feline lower urinary tract diseases.*

Parameters	**Feline idiopathic cystitis**	**Struvite uroliths**	**Calcium oxalate uroliths**
Patient characteristics	Four to 10 years old Breeds (purebred, longhaired, Persian) Neutered Overweight Lazy/little exercise	Younger cats (<7 years) Breeds (**Table 46-7**) Female Neutered Urinary tract infection (urease positive)	Older cats (>7 years) Breeds (**Table 46-7**) Male Neutered
Environmental conditions	Multi-cat household Less freedom to leave house Provided with litter box Living in conflict with another cat Moving within last three months High number of rainfall days in month before signs		Indoor environment
Nutritional factors	Fed dry cat food Decreased water intake	Alkalinizing foods (urinary pH >6.5) Magnesium content 0.14 to 0.56% (0.36 to 1.4 mg/kcal) Phosphorus content 1.27 to 1.88% (3.17 to 4.70 mg/kcal) Sodium content 0.57 to 1.48% (1.43 to 3.7 mg of Na/kcal) Fiber content ≥2.7 (≥0.71 g/100 kcal)	Dry foods 7 to 7.9% moisture Excessively acidifying foods (urinary pH = 5.8 to 6.29) Feeding single brand Sodium content 0.2 to 0.3% (0.48 to 0.77 mg/kcal) Potassium content 0.04 to 0.06% (0.95 to 1.6 mg/kcal) Protein content 21 to 32% (5.15 to 7.98 g/100 kcal) Magnesium content 0.04 to 0.07% (0.09 to 0.18 mg/kcal) or 0.14 to 0.56% (0.36 to 1.4 mg/kcal) Phosphorus content 0.34 to 0.70% (0.85 to 1.76 mg/kcal) or 1.27 to 1.88% (3.17 to 4.70 mg/kcal) Calcium content 0.39 to 0.82% (0.97 to 2.05 mg/kcal) or 1.5 to 2.0% (3.76 to 5.06 mg/kcal)

*Nutrient values expressed on a percent dry matter basis and assume a food energy density of 4 kcal metabolizable energy/g (17.6 kJ/g); however, dry matter nutrient content of foods with energy densities substatially higher or lower than 4 kcal/g will be under- or overreresented, respectively. Thus, the energy basis nutrient values in this table (parenthetical values) are more accurate.

and found that qualitative methods yielded false-negative results in 38.1% of the uroliths and false-positive results in 6.7% (Ulrich et al, 1996). These two methods agreed in only 43.1% of the analyses. Uroliths, therefore, should be analyzed quantitatively to obtain the most accurate information about mineral content.

Quantitative analytical methods include optical crystallography, x-ray diffraction, infrared spectroscopy and electron scanning microscopy (Ulrich et al, 1996). In optical crystallography, crystalline material is removed from representative areas of the urolith using a dissecting microscope. The optical characteristics (e.g., refractive index and birefringence) of the crystalline material then are determined by polarizing microscopy and compared with known standards to determine mineral composition. Methods such as infrared spectroscopy are used if results of optical crystallography are inconclusive.

Different minerals may be deposited in layers (i.e., compound) or mixed throughout the urolith. Although one mineral type predominates, the composition of uroliths frequently is mixed. Thus, sampling and reporting results from different parts of the urolith become important when considering urolith dissolution and prevention. The following terms are sometimes used: the "nidus" is where growth of the urolith apparently started; it is not necessarily the geometric center. "Shells" are one or more complete outer layers of the urolith. "Surface crystals" refer to an incomplete outermost layer. Grossly visible layers do not always mean different mineral composition. The layers represent different phases of deposition and may be composed of the same or different minerals.

Risk Factors

Many studies have evaluated risk factors for FLUTD including patient characteristics, environmental conditions and various nutritional factors (**Table 46-10**) (Buffington et al, 1997, 2006; Houston et al, 2003; Kirk et al, 1995; Cameron et al, 2004; Lekcharoensuk et al, 2000, 2001, 2001a; Walker et al, 1977; Jones et al, 1997; Thumchai et al, 1996). For some risk factors, findings are consistent between studies, whereas others are different (e.g., living in a multi-cat household has been associated with increased risk of FIC in some studies but not in others). It is important to keep in mind that risk factors identified in epidemiologic studies show associations between certain factors and the disease of interest; additional study is necessary to show a cause-and-effect relationship. For exam-

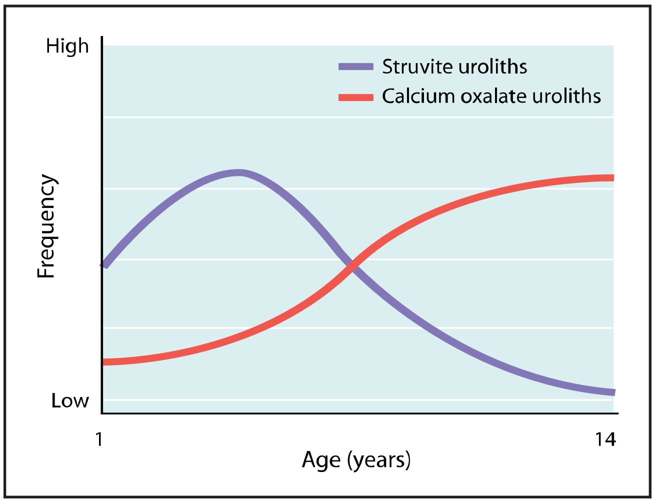

Figure 46-8. Relationship between urolith mineral type and age in cats. Note that struvite urolithiasis occurs more frequently in younger cats, whereas calcium oxalate urolithiasis occurs more frequently in older cats.

ple, it is likely that feeding a therapeutic renal food is associated with (i.e., is a risk factor for) chronic kidney disease; however, this does not mean it causes kidney disease. Finally, individual cats in a population are rarely exposed to a single risk factor; it is likely that FIC is a multifactorial disease and effects of interaction between multiple risk factors are challenging to evaluate (Willeburg, 1984).

Patient Characteristics

Patient factors that may affect risk for various types of FLUTD include age, breed, gender, neuter status, body condition and miscellaneous factors.

AGE

Review of data from the Veterinary Medical Database (1980-1990) revealed that lower urinary tract disease is most prevalent in cats between one and 10 years of age (Bartges, 1997). Another study using information from the same database (1980-1997) revealed that cats between four and seven years of age had the highest risk of lower urinary disease in general (Lekcharoensuk et al, 2001). Cats between four and 10 years of age had increased risk for urocystolithiasis, urethral obstructions and FIC, whereas, cats older than 10 years were at increased risk for UTI and neoplasia (Lekcharoensuk et al, 2001). Compared with younger to middle-aged cats, UTI is more commonly diagnosed in older cats (Lees, 1984; Bartges, 1997; Lekcharoensuk et al, 2001). In one study of cats with lower urinary tract disease that were 10 years of age and older, 63% had UTI (46% had UTI only and 17% had UTI combined with uroliths) (Bartges, 1997).

In general, cats with struvite uroliths tend to be younger and those with calcium oxalate uroliths older (**Figure 46-8**) (Thumchai et al, 1996; Cannon et al, 2007). In one study, cats with struvite uroliths (5.75 ± 3.12 years [mean age ± standard deviation]) were significantly younger than cats with calcium oxalate uroliths (7.5 ± 3.42 years) (Lekcharoensuk et al, 2000). Cats four years of age and older but younger than seven years had the highest risk of developing struvite uroliths. Cats older than seven years, but younger than 10 years, had the highest risk of developing calcium oxalate uroliths.

BREED

Several breeds of cats have increased risk for lower urinary tract disorders; however, there is so much overlap that it is difficult to draw meaningful conclusions (**Tables 46-7** and **46-10**) (Thumchai et al, 1996; Lekcharoensuk et al, 2000; Cannon et al, 2007). In one study, Persian, Himalayan and manx cats had increased risk for lower urinary tract diseases in general, whereas Siamese cats had decreased risk (Lekcharoensuk et al, 2001). Breeds with increased risk of developing urocystoliths were Persian, Himalayan and Russian blue (Lekcharoensuk et al, 2001). No breed predilection was observed for urethral obstruction (Lekcharoensuk et al, 2001). Breeds reported to have decreased risk for struvite uroliths include Burmese, Persian, Himalayan, Rex, Abyssinian, Russian blue, Birman, Siamese and mixed-breed cats (Thumchai et al, 1996; Lekcharoensuk et al, 2000). However, Siamese cats were reported to have significantly more struvite uroliths than other breeds in another study (Cannon et al, 2007). Birman, Abyssinian, Siamese and mixed-breed cats had significantly lower risk of developing calcium oxalate uroliths in one study (Lekcharoensuk et al, 2000). Persian cats had significantly fewer urate uroliths than other breeds in another study (Cannon et al, 2007).

GENDER

Neutered males and females had increased risk of lower urinary tract diseases overall and intact females had decreased risk in one epidemiologic study (Lekcharoensuk et al, 2001). Male cats are at increased risk for calcium oxalate uroliths, whereas females are at greater risk for struvite uroliths (Thumchai et al, 1996; Lekcharoensuk et al, 2000; Houston et al, 2003; Cannon et al, 2007). In one study, however, there was no gender predilection for cats with calcium oxalate uroliths (Kirk et al, 1995). Neutered cats are reported to have increased risk for both struvite and calcium oxalate uroliths compared with sexually intact cats (Lekcharoensuk et al, 2000). Neutered males are at increased risk for urethral obstruction (Lekcharoensuk et al, 2001). UTI is more common in female than male cats (Bailiff et al, 2006; Lekcharoensuk et al, 2001).

BODY CONDITION

Being overweight or obese has been a risk factor for lower urinary tract diseases in older and more recent studies (Walker et al, 1977; Cameron et al, 2004; Willeburg, 1984). Overweight cats (defined as ≥6.8 kg) had increased risk for lower urinary tract diseases when compared with cats weighing less than 6.8 kg (Lekcharoensuk et al, 2001). In a study of more than 8,000 cats in the U.S., nearly 29% were overweight, which was associated with urinary tract disease (Lund et al, 2005).

MISCELLANEOUS FACTORS

Cats described as lazy, or that exercise little, appear at increased risk for lower urinary tract disorders (Walker et al, 1977; Jones et al, 1997). It may be that these cats are overweight, which also is a risk factor for lower urinary tract diseases. In a study of indoor-housed cats, significantly more owners of those with lower urinary tract signs observed gastrointestinal signs, scratching and fearful, nervous or aggressive behaviors than owners of healthy cats (Buffington et al, 2006).

Environment

Living in a multi-cat household has been identified as a risk factor for lower urinary tract disorders in some studies (Walker et al, 1977; Jones et al, 1997). Cats that live indoors (or have restricted access to the outdoors) and/or are provided a litter box are also at increased risk for lower urinary tract diseases (Walker et al, 1977; Jones et al, 1997; Kirk et al, 1995). Conditions that may cause increased stress (e.g., living in conflict with another cat or moving to another home) have been associated with FIC (Jones et al, 1997; Cameron et al, 2004).

Nutritional Factors

Decreased moisture content of foods (feeding dry food) and/or decreased water intake have been associated with increased risk of FIC and calcium oxalate uroliths but not struvite uroliths (Walker et al, 1977; Kirk et al, 1995; Lekcharoensuk et al, 2001a). In one study, cats fed foods with a high moisture content (74.4 to 81.2%) were about a third as likely to develop calcium oxalate uroliths as were cats fed foods low in moisture (7 to 7.9%) (Lekcharoensuk et al, 2001a). In another study, cats with FIC were significantly more likely to eat dry pet food exclusively (59%) compared with cats in the general population (19%); however, this study did not include a control group (Buffington et al, 1997). Instead, results of a survey conducted by another organization regarding feeding practices of pet owners were used. These survey results differ from other studies, which show 95 to 99% of cat owners feed either dry food exclusively or a mixture of dry and moist (Habits and Practices, 2002; Gunn-Moore and Shenoy, 2004). Eating dry cat food has been associated with increased occurrence of FIC, whereas eating food with higher moisture content (e.g., canned food) has been associated with decreased occurrence (Walker et al, 1977; Jones et al, 1997; Willeberg, 1984). In addition, feeding moist food to cats with FIC has been associated with reduced recurrence of clinical signs compared with feeding dry food (Markwell et al, 1999). Additional study, however, is needed to determine if dry food causes FIC. As noted previously, more than 95% of owners feed their cats dry food exclusively or a combination of dry and moist food, yet the reported incidence of lower urinary tract diseases overall is less than 2% (Habits and Practices, 2002; Gunn-Moore and Shenoy, 2004; Lawler et al, 1985; Willeberg, 1984).

The source of water (e.g., tap vs. well) is not believed to be a contributing factor in cats with lower urinary tract disorders; however, it has not been carefully evaluated. In an epidemiologic study, water sources for cats with calcium oxalate uroliths (i.e., municipal, well or bottled) were similar to those for hospital control cats; more than 80% of cats in both groups received water from municipal supplies (Kirk et al, 1995). Mineral content of water is expressed as parts per million whereas mineral content of food is expressed as parts per hundred. Therefore, even water with high mineral content (i.e., "hard water") would contribute little to the total daily mineral intake compared with the amount supplied in food (Kirk et al, 1995).

A case-control study was performed to identify nutritional factors associated with struvite and calcium oxalate uroliths in cats (Lekcharoensuk et al, 2001a). Data were collected from cats whose uroliths were submitted to the Minnesota Urolith Center between 1990 and 1992. A content-validated questionnaire was mailed to owners to obtain information about their cat's food (e.g., types and quantities fed), feeding methods, mineral and vitamin supplements and source of drinking water. Nutrient information and expected urinary pH ranges for each food were obtained from pet food manufacturers. Data from 290 cats with magnesium ammonium phosphate uroliths and 216 cats with calcium oxalate uroliths were compared with data from 827 control cats without urinary tract disease. Distributions for breed, age, gender, body condition and living environment were significantly different between case and control cats; therefore, multivariate analyses were performed to adjust for potential confounding variables. The authors identified several associations between food components and occurrence of uroliths. Cats fed foods with high amounts of magnesium, phosphorus, fiber, calcium, sodium, chloride or potassium, or moderate protein content had increased risk of struvite uroliths (Lekcharoensuk et al, 2001a). In addition, cats fed foods formulated to produce urinary pH values between 6.5 and 6.9 were two times as likely to develop struvite uroliths as cats fed foods formulated to produce a urinary pH between 5.99 and 6.15. Cats fed foods with low amounts of sodium, potassium or protein, low or high amounts of magnesium, phosphorus or calcium, or those formulated to produce an overly acidified urinary pH had increased risk for calcium oxalate uroliths (Lekcharoensuk et al, 2001a) (**Table 46-10**). Increased dietary magnesium was previously associated with struvite urolith formation; however, presence of a concomitant alkaline urinary pH was likely a more important factor (Taton et al, 1984; Buffington et al, 1985, 1990).

To date, the strongest association with occurrence of calcium oxalate urolithiasis has been use of acidifying foods (Kirk et al, 1995; Lekcharoensuk et al, 2001a). It has been hypothesized that uniform use of these foods for managing struvite disease may be the cause for increased occurrence of calcium oxalate uroliths in cats (Buffington et al, 1994; Kirk et al, 1995; Thumchai et al, 1996; Lekcharoensuk et al, 2001a). In one epidemiologic study, cats with calcium oxalate urolithiasis were more than three times as likely as hospital control cats to have been fed foods that typically promote urinary pH equal to or lower than 6.29 (Kirk et al, 1995). In another study, cats fed foods formulated to produce urinary pH values between 5.99 and 6.15 were three times as likely to develop calcium oxalate uroliths as cats fed foods formulated to produce urinary pH val-

ues ranging from 6.5 to 6.9 (Lekcharoensuk et al, 2001a). Although two studies have identified that feeding acidifying foods is associated with calcium oxalate uroliths in cats, additional evaluation is necessary to show a cause-and-effect relationship and to determine what specific nutritional factors (e.g., magnesium content, degree of acidifying potential) are involved. It is of interest to note that normal urinary pH values in feral cats are reported to be 5.97 ± 0.10 (range, 5.54 to 6.57) in females and 6.37 ± 0.07 (range, 5.73 to 7.39) in males (Cottam et al, 2002). Both studies described above evaluated data collected from 1990 to 1992, when occurrence of calcium oxalate uroliths was increasing. Since 2001, occurrence of struvite uroliths has been increasing and calcium oxalate has been decreasing. Therefore, additional study is needed to identify more current risk factors and causes for recent trends of feline urolithiasis. It seems likely that multiple factors (e.g., nutritional, presence and function of urolith inhibitors, genetic predisposition) play a role in formation of calcium oxalate uroliths in susceptible cats.

Pathogenesis

Feline Idiopathic Cystitis

The clinical course of FIC is characterized by episodes of lower urinary tract signs that usually resolve spontaneously within three to five days, with or without treatment (Barsanti et al, 1982; Gunn-Moore and Shenoy, 2004). Although not evaluated in a large number of cases, it appears that 39 to 65% of cats with FIC will have recurrence of signs within a six- to 12-month period (Barsanti et al, 1982; Markwell et al, 1999; Kruger et al, 2003; Gunn-Moore and Shenoy, 2004). Many cats have multiple recurrences within a year. In a study involving 70 cats with FIC, 63 (90%) had multiple episodes of lower urinary tract signs; 30 (43%) cats had at least three episodes in the year before diagnosis (Buffington et al, 1997). In a study of 15 untreated cats with acute FIC, eight (53%) had one or more episodes of recurrent signs of lower urinary tract disease with 22 events reported over a period of 7,942 days at risk (Kruger et al, 2003). The overall incidence rate was 2.6 events per 1,000 days at risk. Survival analysis revealed that increasing number of prior episodes of lower urinary tract signs was associated with a significantly higher risk, whereas increasing age was associated with a significantly lower risk of recurrence of clinical signs. In another study, cats with FIC experienced a mean of five recurrences in six months (Gunn-Moore and Shenoy, 2004).

FIC shares many features in common with human interstitial cystitis and has been called feline interstitial cystitis when cystoscopic examination reveals characteristic findings (Buffington et al, 1997, 1996a, 1996b). Comparisons are based on clinical signs and diagnostic features. All of the National Institutes of Health (NIH) criteria (i.e., history, laboratory evaluation, cystoscopy and cystometrics) for interstitial cystitis in human patients have been applied to cats (Gao et al, 1994). Affected people and cats present as adults with symptoms/signs of variable severity that are influenced by stress. Spontaneous remissions occur in people and cats. According to NIH criteria, the diagnosis in people also requires cystoscopic lesions, either glomerulations or Hunner's ulcer. Glomerulations are submucosal petechial hemorrhages, whereas Hunner's ulcer is a small area of brownish-red mucosa, surrounded by a network of radiating vessels. Veterinary investigators report that lesions indistinguishable from glomerulations are observed commonly during cystoscopic examination of cats with FIC (Osborn et al, 1994; Buffington et al, 1997). A single case report describes a cat with FIC and findings of Hunner's ulcer (Clasper, 1990).

The pathogenesis of FIC appears to involve a variety of abnormalities affecting the urinary bladder, nervous system and hypothalamic-pituitary-adrenal axis (Westropp et al, 2004, 2005). One study of patients with FIC revealed abnormally low amounts of urinary glycosaminoglycans (GAG) compared with normal controls (Buffington et al, 1996b). In contrast, studies of urinary GAG in human patients with interstitial cystitis have yielded variable results (Akcay et al, 1999; Erickson et al, 1997; Hurst et al, 1993). The surface layer covering the urinary bladder mucosa includes GAG. A defective GAG layer or damaged urothelium may allow irritating substances in the urine to contact sensory nerve endings, which transmit action potentials through the spinal cord to the brain, resulting in perception of pain. In addition, there may be local release of neurotransmitters (e.g., substance P) and other inflammatory mediators (e.g., histamine) within the urinary bladder mucosa, which interact with receptors on vessel walls causing vascular permeability and leakage (i.e., neurogenic inflammation) (Westropp et al, 2005). Studies have shown that patients with FIC have increased urinary bladder permeability and leakage of ions across the urothelium compared with normal cats (Lavalle et al, 2000; Gao et al, 1994; Westropp et al, 2006a). Histologic changes associated with FIC generally are nonspecific and may include an intact or damaged urothelium with submucosal edema, dilatation of submucosal blood vessels, submucosal hemorrhage and sometimes increased mast cell density (Westropp et al, 2005). There is no correlation between histologic lesions, cystoscopic findings and clinical signs in patients with FIC. Cats may have remission of clinical signs but persistently abnormal cystoscopic findings (Westropp et al, 2005).

Several neurohormonal abnormalities have been described in patients with FIC and may play a role in its pathogenesis. A significant increase in tyrosine hydroxylase immunoreactivity was identified in the locus coeruleus (a nucleus in the brainstem) of patients with FIC compared with findings in healthy control cats (Reche Júnior and Buffington, 1998; Welk et al, 2003). Urinary bladder distention stimulates neuronal activity in the locus coeruleus, the origin of the descending excitatory pathway to the urinary bladder. Tyrosine hydroxylase is the rate-limiting enzyme involved in synthesis of catecholamines (e.g., norepinephrine). Chronic stress can increase tyrosine hydroxylase activity in the locus coeruleus with subsequent increases in autonomic outflow. It is possible this may play a role in the waxing and waning of clinical signs observed in patients with FIC, particularly in response to environmental stressors (Westropp et al, 2005). Patients with FIC also have increased plasma norepinephrine concentrations (Buffington and Pecak, 2001; Westropp et al, 2006a). In a study evaluating

effects of stress, patients with FIC had significantly increased plasma concentrations of catecholamines, including norepinephrine, compared with healthy cats (Westropp et al, 2006a).

Abnormalities also have been identified in the hypothalamic-pituitary-adrenal axis of cats with FIC. Those with FIC had significantly decreased cortisol response to administration of synthetic adrenocorticotropic hormone compared with that of healthy cats (Westropp et al, 2003). In the same study, adrenal gland volume was significantly lower in cats with FIC compared with healthy cats; however, there were no correlations between adrenal size and cortisol production (Westropp et al, 2003, 2005). In another study of the effects of stress, there was no significant difference in urinary cortisol:creatinine ratios between patients with FIC and healthy cats (Westropp et al, 2006a). Based on studies conducted to date, it appears there is dissociation between the response of the sympathetic nervous system and the hypothalamic-pituitary-adrenal axis to stress in patients with FIC.

Although many risk factors have been identified in patients with FIC, additional evaluation is likely needed to identify its definitive cause(s). Based on current understanding of pathogenesis, it appears that abnormalities are not limited to the urinary bladder and interactions between other systems (e.g., nervous and endocrine) are likely involved. This possibility must be considered when formulating a treatment plan, which should include a multimodal approach (i.e., decreasing environmental stress, nutritional management, behavioral modification, pain management) for all patients with FIC.

Urolithiasis

Uroliths, or urinary calculi, are composed primarily of crystalline mineral concretions with a small amount of organic matrix. Urolithiasis is a multifaceted process that begins with microcrystals in urine and ends with mature uroliths somewhere in the urinary tract (Osborne and Kruger, 1984). Urolith formation occurs in two separate phases-initiation of the crystal nidus and continued growth to form a urolith. In general, there are four factors involved in formation of uroliths: 1) oversaturation of urine with calculogenic crystalloids, which may result from increased urinary excretion of these substances or increased urine concentration (e.g., due to decreased water intake), 2) decreased solubility of crystalloids in urine (e.g., struvite is less soluble in alkaline urine), 3) presence or absence of crystallization inhibiters or promoters in urine and 4) retention of crystals/uroliths within the urinary tract.

In its simplest form, initiation and growth of uroliths involves chemical precipitation of dissolved ions or molecules from a solution that has become oversaturated with respect to those components (**Figure 46-9**). From a physiochemical perspective, the degree of saturation or undersaturation of urine influences the probability that precipitates will form, or if already present, will dissolve. Relatively simple diagrams depict states of saturation of any solution (**Figures 46-10** and **46-11**). These diagrams provide the framework for understanding the concept of how nutritional management influences probability of urolith formation or dissolution. Units and numerical values

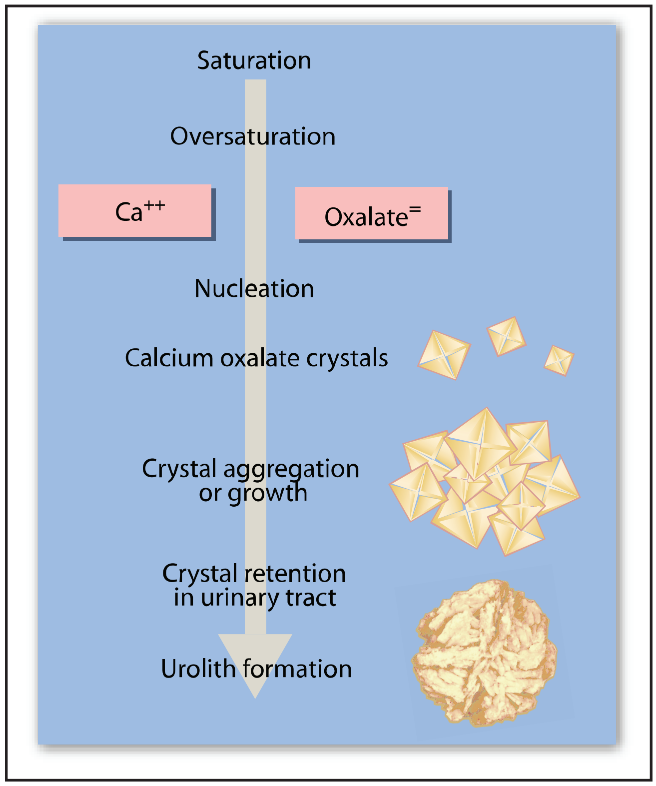

Figure 46-9. Increasing saturation of urine with urolith-forming constituents (e.g., calcium, oxalate) results in crystal growth, aggregation and ultimately urolith formation, if the components are retained in the urinary tract. (Adapted from Bartges JW, Osborne CA, Lulich JP, et al. Methods for evaluating treatment of uroliths. Veterinary Clinics of North America: Small Animal Practice 1999; 29: 46.)

are not included in these diagrams because they differ for each of the urolith components and measurement technique; however, the general features apply to all crystalline materials. At concentrations below the solubility product (i.e., in the undersaturation zone), it is impossible for crystals to form and crystals added to such a solution would dissolve. However, crystals may grow if added to a solution with a concentration greater than the solubility product. The formation product is the concentration at which crystals will begin to spontaneously precipitate in the absence of preformed crystalline material. Although the solubility product is constant for a pure crystalline material, the formation product is much more difficult to demonstrate; therefore, this area is illustrated by a shaded band rather than a line (**Figure 46-11**). Strictly speaking, the ionic activities (not concentrations) of the species govern the described solubility principles. Ionic activities are influenced by the presence of other ions in solution (i.e., ionic strength) and by the presence of other species that form complex ions, thereby reducing their “free” concentrations in solution.

The metastable zone is of most interest clinically; in this concentration range crystal growth and aggregation may occur or other factors (e.g., crystallization inhibitors) may impede or prevent crystallization (**Figure 46-11**). Risk factor reduction

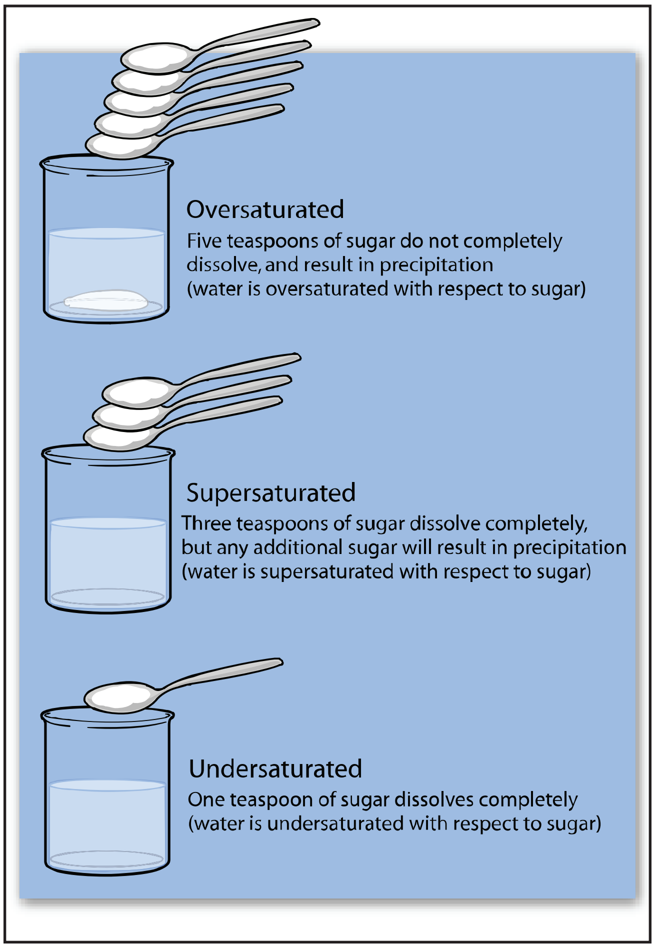

Figure 46-10. This diagram depicts a simplified explanation of effects of different levels of urine saturation (oversaturation, supersaturation [metastable] or undersaturation) on formation of uroliths. In this example, the liquid is tea and the mineral or crystalloid is sugar. As the amount of added sugar increases, the solution (tea) goes from being undersaturated (all the sugar completely dissolves) to being oversaturated (some of the sugar precipitates). Similar phenomena occur with mineral salts in urine. However, just as there are different outcomes when dissolving sugar in iced vs. hot tea, other factors (e.g., temperature, pH, crystalloid inhibitors) also affect saturation of urine with crystalloids. (Adapted and modified from Bartges JW, Osborne CA, Lulich JP, et al. Methods for evaluating treatment of uroliths. Veterinary Clinics of North America: Small Animal Practice 1999; 29: 47.)

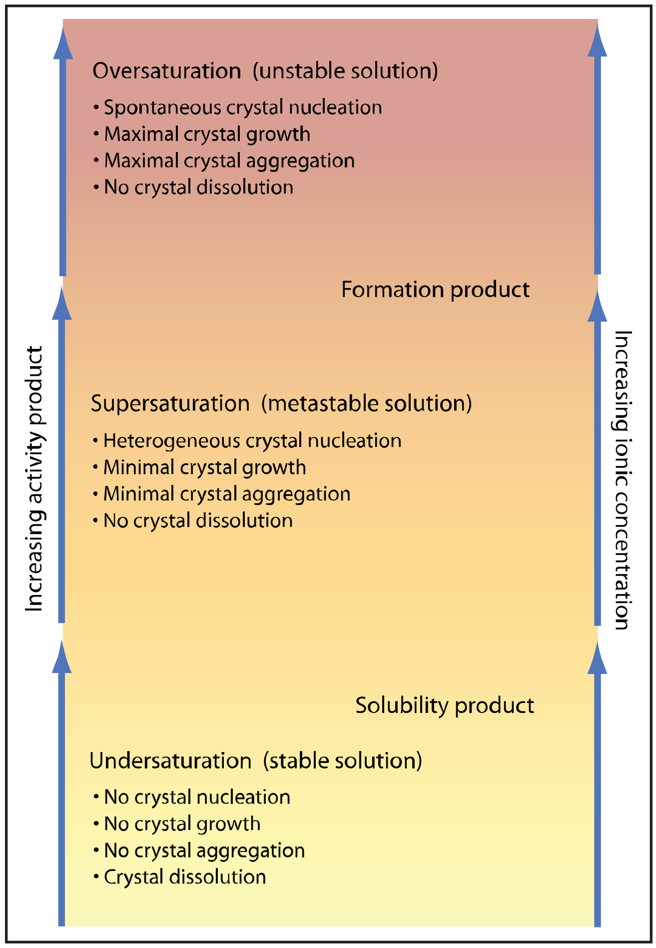

Figure 46-11. This diagram illustrates effects of differing degrees of urine saturation on risk of urolith formation. Increasing concentrations of urolith-forming substances result in metastable (supersaturated) and eventually, oversaturated urine. Crystal growth and aggregation may occur in the metastable zone. Presence of a nidus promotes nucleation (i.e., heterogeneous nucleation) and subsequent crystal formation. Inhibitors in urine may impede or prevent crystallization in the metastable zone. Spontaneous or homogenous nucleation occurs, however, when concentrations of urolith-forming substances increase to the point of oversaturation. After oversaturation occurs, inhibitors of crystal formation generally are ineffective. (Adapted from Bartges JW, Osborne CA, Lulich JP, et al. Methods for evaluating treatment of uroliths. Veterinary Clinics of North America: Small Animal Practice 1999; 29: 48.)

and nutritional intervention may be most beneficial with urine in this region. A precarious balance exists between crystal formation and inhibition in the metastable zone. Anatomic defects within the urinary tract that allow for stasis of metastable urine will lead to formation and growth of crystals. Urine containing microscopic impurities will facilitate crystal formation and growth. This process is called "heterogeneous nucleation." Crystal formation is much less likely in urine without impurities (i.e., homogeneous solution) (Bartges et al, 1999). **Box 46-2** discusses laboratory techniques used to measure these changes in urine. A more detailed description of this entire process is found in Chapter 38.

STRUVITE UROLITHS

Struvite uroliths form as a result of oversaturation of urine with magnesium ammonium phosphate. This oversaturation can occur in the presence of infection with a urease-producing organism. However, in contrast to the situation in dogs, most struvite uroliths in cats form in sterile urine (Osborne et al, 1996a). Urinary magnesium levels are related to dietary intake; as the amount of dietary magnesium increases, urinary magnesium excretion increases linearly (Sauer et al, 1985; Pastoor, 1993). **Box 46-3** provides more information about the effects of urinary pH on struvite urolith formation.

Box 46-2. Determining Risk for Urolith Formation or Recurrence.

Analytical data indicate that urine often is supersaturated with respect to most common urolith components. Thus, the question is not why a specific patient formed a urolith, but rather why doesn't every patient form uroliths? Inhibitors in urine probably explain the less than predicted prevalence of urolith formation. The current therapeutic strategy is to reduce risk factors by decreasing the degree of supersaturation because we know less about changing urinary inhibitors. One way to express urinary saturation is to determine the relative supersaturation (RSS) of a calculogenic substance (e.g., struvite or calcium oxalate). RSS is determined by measuring the concentration of a number of urinary analytes, including sodium, calcium, oxalate, magnesium and potassium. The concentrations of these analytes are entered into a computer program that calculates the saturation of the urolith elements compared with a standard human urine sample. RSS has limitations because it is highly dependent on urine volume and involves comparison with standard values for human urine.

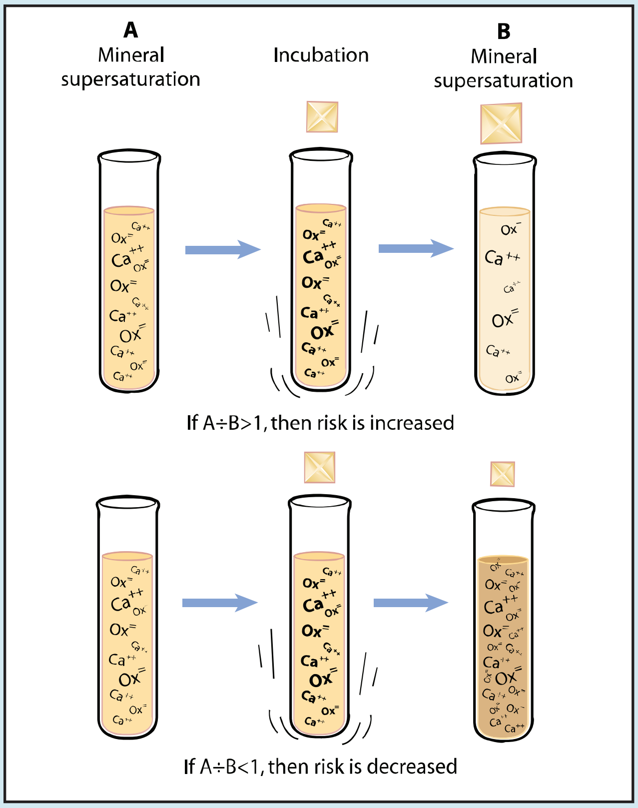

Figure 1. Schematic depicting how APRs are calculated. Urine from a cat is analyzed for pertinent minerals (Tube A) and then is incubated with a seed crystal. After incubation, the urine is analyzed for the same mineral constituents (Tube B). Dividing the pre-incubation activity product by the post-incubation activity product yields the APR. The risk of urolith formation increases with an APR greater than 1. This means the seed crystal has grown and the urine is supersaturated and/or contains inadequate concentrations of crystal inhibitors. The risk of urolith formation decreases with an APR less than 1. This means the seed crystal became smaller during the incubation process and the urine is undersaturated or contains adequate concentrations of crystal inhibitors.

Another technique for predicting likelihood of crystal formation is the activity product ratio (APR) (**Figure 1**). The APR for calcium oxalate is the mathematical product of the activity of calcium and the activity of oxalate. Activity is different than simple concentration of the substance of interest in an aqueous solution. Activity refers to the ionic activity, which is influenced by the concentration of the substance of interest, other substances in urine and factors such as pH and temperature. Like RSS, APR involves measurement of a number of analytes (e.g., sodium, potassium, calcium, oxalate, magnesium) in urine that are entered into a computer program. Unlike RSS, however, the APR technique requires incubation of seed crystals (e.g., calcium oxalate) in an aliquot of urine. After incubation, urinary analytes are measured again and the post-incubation activity product is determined. Dividing the pre-incubation activity product by the post-incubation activity product yields the APR. An APR less than one indicates that crystals dissolved during incubation. The APR provides a better indication of risk of crystal formation than RSS because APR considers the influence of unmeasured inhibitors and promoters and is not unduly influenced by urine volume. APRs can be used to evaluate quantitatively the influence of nutrients, complete foods and drugs on the risk of crystal formation.

Several studies have reported effects of various foods on urinary saturation values for calcium oxalate and struvite (APR and/or RSS) in healthy cats; however, only one has reported these values in cats with a history of forming uroliths. Although decreasing values for urine saturation indicate decreased risk for urolith formation, these values serve as surrogate markers. There are no reported studies correlating urine saturation values (APR or RSS) in urolith-forming cats with rate of urolith recurrence.

CALCIUM OXALATE UROLITHS

Based on a small study of cats with calcium oxalate uroliths and information extrapolated from canine and human patients, it seems reasonable that factors promoting hypercalciuria and/or hyperoxaluria are involved in the pathogenesis of calcium oxalate urolithiasis in cats (Lulich et al, 1991, 2004; Stevenson et al, 2004; Seiner et al, 2003, 2005). Hypercalciuria was identified in 10 cats with calcium oxalate uroliths; feeding a therapeutic food[c] formulated to prevent urolith recurrence was associated with a significant decrease in urine calcium excretion and urine calcium oxalate saturation compared with feeding their regular food. Hypercalcemia promotes urinary excretion of calcium and therefore may increase the risk of calcium oxalate urolithiasis. Mild hypercalcemia (11.1 to 13.5 mg/dl) has been identified in approximately 35% of cats with calcium oxalate uroliths (Osborne et al, 1996a). Radiopaque uroliths were diagnosed in seven of 20 cats (35%) with idiopathic hypercalcemia in one study; uroliths were removed from two

Box 46-3. Urinary pH, Ammonium and Anionic Phosphate.

Normal urinary concentration of total phosphate ions is high and not subject to great variation by dietary manipulation. Although complexes are formed between phosphate ions and calcium and magnesium ions, these complexes do not markedly decrease free phosphate ion concentration. The urinary variable that has the greatest impact on trivalent phosphate ion concentration is urinary pH. Urinary pH influences formation of struvite precipitates because it influences the amount of total urinary phosphorus present as the free trivalent phosphate ion. Concentration of the free trivalent ion depends on the position of the acid-base equilibria of the two principal phosphate species that exist in the normal urinary pH range: HPO_4^{2-} and $H_2PO_4^-$. As urinary pH increases, concentration of free trivalent ions increases, as monobasic and dibasic phosphates are deprotonated.

$$H_2PO_4^- = HPO_4^{2-} + H^+$$

$$HPO_4^{2-} = PO_4^{3-} + H^+$$

According to the above equations, an increase in hydrogen ion concentration will shift both equilibria to the left, resulting in lower concentrations of free trivalent phosphate (PO_4^{3-}). Decreasing urinary pH from 8.5 to 5.5, the approximate physiologic range for cats, results in a 14,000-fold decrease in free trivalent ion concentration, with no change in total urinary phosphate.

Urinary pH also influences concentration of ammonium ions. Ammonia generated by urease enzymes provides necessary ions that react with available hydrogen ions to increase urinary pH:

$$NH_3 + H^+ = NH_4^+$$

Reduction in urinary pH from the upper to the lower end of the physiologic range changes the ratio of NH_4^+ to NH_3 from 3.4:1 to 3,400:1. Thus, foods that produce moderately acidic urine increase urinary ammonium concentration. However, because the effect on free trivalent phosphate ion concentration is greater, the net effect of moderate urinary acidification is a reduced likelihood of struvite precipitation.

The Bibliography for **Box 46-3** can be found at www.markmorris.org.

cats and were confirmed to be calcium oxalate (Midkiff et al, 2000). In another study of 71 cats with hypercalcemia, eight of 11 had calcium oxalate uroliths; nine of the 11 cats with uroliths also had chronic kidney disease (Savary et al, 2000). The role of hypercalcemia in the pathogenesis of calcium oxalate uroliths requires further study; it is appropriate to screen patients for hypercalcemia and, when possible, manage the underlying cause.

Hyperoxaluria may result from increased dietary intake or endogenous production of oxalate from metabolism of ascorbic acid (vitamin C), glycine, glyoxylate or other substances. A study in healthy cats fed differing amounts of vitamin C ranging from 40 to 193 mg vitamin C/kg of food for approximately one month found no significant change in urinary oxalate excretion (Yu and Gross, 2005). However, the effects of vitamin C supplementation have not been studied in cats at risk for calcium oxalate urolithiasis. A large part of the metabolic pool of glyoxylate is transaminated to glycine by the enzyme alanine glyoxylate aminotransferase, which requires pyridoxine (vitamin B_6) as a cofactor (Menon and Koul, 1992). Pyridoxine deficiency has been associated with increased oxalate production and urinary excretion in cats but has not been associated with calcium oxalate uroliths in cats (Bai et al, 1989, 1991). Primary hyperoxaluria, due to reduced activity of hepatic D-glycerate dehydrogenase, has been recognized in a family of cats; however, the role of primary hyperoxaluria in cats with calcium oxalate uroliths is unknown (McKerrell et al, 1989).

Urinary oxalate is an important determinant of urinary calcium oxalate saturation because small increases in oxalate excretion profoundly influence the activity product ratio. Oxalate forms a number of complexes and salts in solution; the calcium salt is relatively insoluble and pH does not influence its solubility over the physiologic range. The calcium salt of oxalate is just as insoluble in the luminal content of the intestinal tract as in other complex solutions. Consequently, dietary calcium is an important determinant of oxalate availability and intestinal absorption. Sufficiently available dietary calcium in the intestinal lumen combines with oxalate to form insoluble complexes of calcium oxalate. This phenomenon reduces intestinal absorption and subsequently less renal excretion of calcium oxalate. In contrast, if dietary calcium is reduced without a concomitant reduction in dietary oxalate, intestinal absorption and urinary excretion of oxalate may increase.

Urine normally contains substances that modify and inhibit nucleation, growth and aggregation of crystals. This likely explains, in part, why urine of most human beings is continuously saturated with calcium oxalate, yet only a small percentage of the human population will form calcium oxalate uroliths during their lifetime. Inhibitors such as citrate, magnesium and pyrophosphate can form soluble complexes with calcium or oxalic acid, making them unavailable to form insoluble salts such as calcium oxalate (Khan et al, 1993). Low concentrations of urinary citrate are common in human patients with calcium oxalate uroliths and some recurrent urolith formers may have defective inhibitory substances (Hess et al, 1991; Parks and Coe, 1986). Magnesium is a potent inhibitor of calcium oxalate crystallization in vitro. Low excretion of magnesium in urine has been suggested as a possible risk factor for development of calcium-containing uroliths. In an experimental study in rats, administration of magnesium oxide prevented renal deposition of calcium oxalate crystals in hyperoxaluric rats (Khan et al, 1993). Magnesium presumably increased urinary pH and excretion of citrate and decreased urinary oxalate excretion. This effect of magnesium depends on which specific salt is used (e.g., magnesium oxide has an alkalinizing effect, whereas magnesium sulfate has an acidifying effect). Other substances such as mucoproteins (e.g., Tamm-Horsfall mucoprotein), nephrocalcin and osteopontin (uropontin) also may inhibit crystal nucleation, growth and/or aggregation; however, their role in preventing calcium oxalate uroliths in cats has not been evalu-

Table 46-11. Potential factors associated with formation of uncommon feline uroliths.

Factors	Causes	Pathogenesis
Urate		
Hyperuricosuria	Portosystemic shunt or severe hepatic disease	Decreased hepatic conversion of uric acid to allantoin, which is more soluble in urine
	Excessive purine intake	Promotes hyperuricemia with subsequent hyperuricosuria
Hyperammonuria	Excessive protein intake	Additional urea and glutamine available for conversion to ammonium (NH_4)
	Metabolic acidosis	Promotes metabolism of glutamine to NH_4
	Acidic urine	Ammonia (NH_3) is converted to NH_4, which is excreted in urine
	Hypokalemia	Results in intracellular acidosis (potassium exchanged for hydrogen) and subsequent excretion of NH_4
	Urinary tract infection with urease-producing organism	Converts urea in urine to NH_3 and NH_4
Aciduria	Acidic urine	Decreased solubility of uric acid in urine
Decreased urine volume	Decreased water intake	Increased urine concentration and saturation with uric acid Decreased urination causes retention of crystals and uroliths
Calcium phosphate		
Hypercalciuria	Hypercalcemia	Increased urinary calcium excretion
	Excessive vitamin D	Increased intestinal calcium absorption and suppressed parathyroid hormone secretion, which promotes calcium excretion
	Hypophosphatemia	Stimulates vitamin D production, which augments intestinal absorption of calcium
	Acidosis	Promotes skeletal release of calcium and inhibits renal tubular reabsorption of calcium
	Excessive calcium intake	Increases urinary calcium excretion
	Excessive sodium intake	Increases urinary calcium excretion
Hyperphosphaturia	Excessive phosphorus intake	Increased urinary phosphorus excretion
	Alkaline urine	Increases urine concentration and saturation of phosphate
Alkaline urine	Alkaline urine	Reduces solubility of calcium phosphates, especially brushite
Decreased urine volume	Decreased water intake	Increased urine concentration and saturation with calcium phosphate Decreased urination causes retention of crystals and uroliths

ated (Nakagawa et al, 1987; Hess, 1991; Asplin et al, 1991).

Although a cause-and-effect relationship remains to be established, feeding foods formulated to maintain an acidic urinary pH (≤6.29 in one study and between 5.99 and 6.15 in another study) has been associated with calcium oxalate uroliths in two epidemiologic studies of cats (Kirk et al, 1995; Lekcharoensuk et al, 2001a). Acidosis may cause mobilization of calcium from bone (along with buffers), resulting in increased urinary calcium excretion. In addition, metabolic acidosis is associated with decreased urinary citrate excretion and increased citrate metabolism by renal tubular cells.

OTHER UROLITHS

Pathogenesis of less commonly diagnosed urolith types is not well understood, although several factors may be involved in formation of uroliths composed of purine (e.g., ammonium acid urate, uric acid) or calcium phosphate (**Table 46-11**). An underlying metabolic disorder is likely in these patients; however, often one is not identified. Detection of certain crystals (i.e., ammonium urate, cystine and xanthine), even in patients without clinical signs, suggests an important underlying metabolic defect, but not all cats with these crystals will develop uroliths. UTI may be associated with uncommon urolith types, but there is little evidence to support that UTI is the cause of these uroliths. Xanthine uroliths have been reported to occur in seven cats that had not received allopurinol; an underlying cause was not obvious (Osborne et al, 1996a). Cystinuria, presumably due to a defect in renal tubular transport of certain amino acids including cystine, has been identified in a small number of cats with cystine uroliths (DiBartola et al, 1991; Osborne et al, 1996a).

Urethral Plugs

It is likely that urethral plugs result from different pathogenic mechanisms than uroliths. In contrast to uroliths, urethral plugs typically contain large amounts of matrix and tend to be soft, compressible and friable (**Figure 46-12**). Although most plugs contain crystalline minerals, some do not. On occasion, plugs can be composed almost completely of matrix, blood cells, inflammatory cells and sloughed tissue (**Table 46-5**). Matrix is the nondialysable portion of urethral plugs that remains after mild solvents have dissolved crystalline components. Matrix may provide the "glue" for urolith and plug formation (Osborne et al, 1996b). The exact composition of feline urethral plug matrix is unknown. It is possible that a major component of matrix is Tamm-Horsfall mucoprotein based on the observation that the urinary concentration of Tamm-Horsfall mucoprotein is increased in cats with a history of forming uroliths (Rhodes et al, 1992). Tamm-Horsfall mucoprotein may be a local host defense against bacterial and viral UTIs. Excess mucus may be secreted by cells within the urinary bladder and urethra in response to an irritant or inflammatory stimulus.

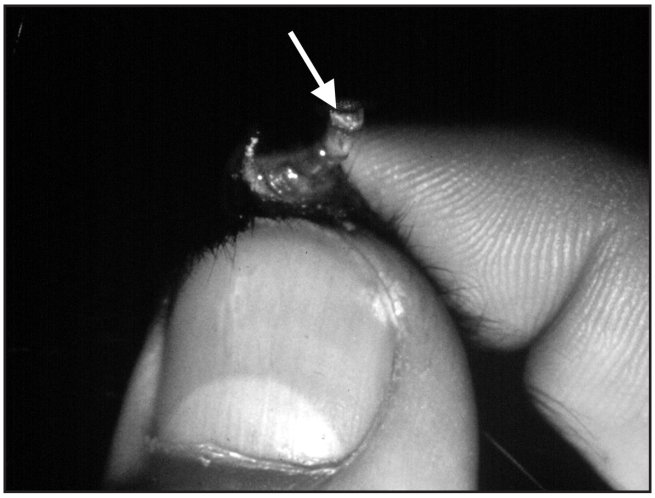

Figure 46-12. Note urethral plug (white arrow) extruding from the tip of the penis in a cat with urethral obstruction. Most urethral plugs are soft, compressible, friable and composed of large amounts of matrix mixed with smaller amounts of crystalline minerals. Although urethral plugs are diagnosed more often in male cats, due to occurrence of urethral obstruction, they also may occur in female cats.

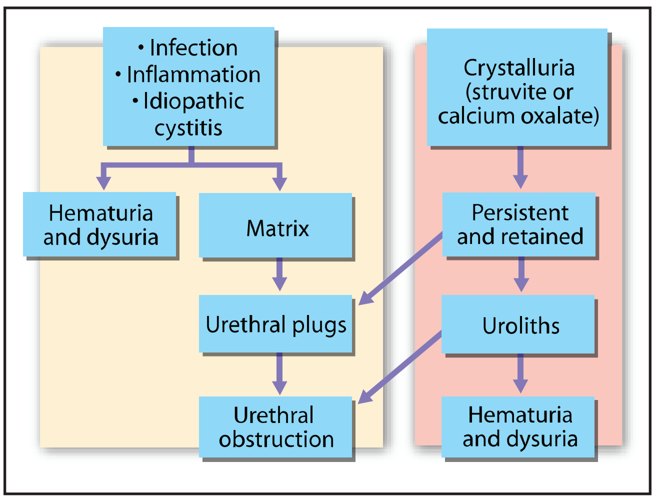

Figure 46-13. Unifying concept for pathogenesis of feline lower urinary tract disease. Infection or inflammation (e.g., idiopathic cystitis) results in clinical signs of lower urinary tract disease and production of excess matrix. Persistent crystalluria can combine with matrix to form urethral plugs or contribute to urolith formation and typical clinical signs. (Adapted from Osborne CA, Kruger JM, Lulich JP. Feline lower urinary tract disorders: Definition of terms and concepts. Veterinary Clinics of North America: Small Animal Practice 1996; 76: 169-179.)

Formation of matrix-crystalline urethral plugs hypothetically requires two simultaneous but unrelated events (**Figure 46-13**) (Osborne et al, 1992, 1996b, 1996c). One event is the formation of matrix that may result from some inflammatory process (e.g., idiopathic, bacterial or viral UTI). The other event is the formation of crystalline precipitates, most often struvite. If matrix forms without concomitant crystals, the noncrystalline gel is voided; however, nonobstructive dysuria and hematuria result. A more rigid plug forms in the presence of crystals that may cause urethral obstruction. The mineral composition of crystals can serve as the basis for preventive efforts. This process of plug formation has been compared with the formation of casts in renal tubular lumina. Urinary mucoprotein provides a gel that traps intact cells (producing cellular casts) or disintegrating cellular elements (producing granular casts). A more trivial analogy is the creation of fruit gelatin (**Figure 46-14**). The "gelatin" (i.e., matrix) traps pieces of "fruit" (i.e., crystals) as it forms.

Urinary Tract Infection

BACTERIAL INFECTION

Infection with urease-producing bacteria (e.g., *Staphylococcus* spp. and *Proteus* spp.) causes persistently alkaline urine, which may be associated with formation of struvite uroliths. It appears that most cats with struvite uroliths do not have UTI; however, urolith-induced changes in host-defense mechanisms may lead to bacterial colonization of the urinary tract (Osborne et al, 1996a). Thirty percent of feline patients with urocystoliths in one study had positive urine cultures (Osborne et al, 1990). In a study of uroliths from 150 cats, investigators cultured bacteria from a urolith or urine in 30 (41%) of 74 cats. Coagulase-positive staphylococci were cultured from uroliths or urine in 17 cats, representing 45% of bacteria isolated (Ling et al, 1990). In some cases, culture of urine may be negative or yield the same or different organisms than cultures from uroliths.

Although a cause-and-effect relationship has not been established, there is an increased occurrence of UTI in cats with systemic diseases. Of cats with chronic kidney disease, 10 to 50% are reported to have UTI; it isn't known if kidney disease causes UTI or if other factors (e.g., older age) are responsible (Lulich et al, 1992; McMahon et al, 2006; Mayer-Roenne et al, 2007). UTI also has been reported to occur in 12 to 13% of cats with diabetes mellitus and 12% of cats with hyperthyroidism (Bailiff et al, 2006; Mayer-Roenne et al, 2007).

Perineal urethrostomies are associated with significant postoperative sequelae, including urethral strictures, bacterial UTI and struvite urolithiasis (Osborne et al, 1991; Griffin et al, 1992; Bass et al, 2005). These postoperative sequelae can produce lower urinary tract signs. In a prospective clinical study of 30 male cats with intraluminal urethral obstruction and negative urine cultures, investigators randomly assigned cats to receive one of three treatments following relief of the obstruction: 1) nutritional management with a struvite dissolution food, 2) perineal urethrostomy or 3) nutritional management and perineal urethrostomy. During the one-year followup period, none of the cats receiving nutritional management alone had episodes of UTI, whereas episodes of bacterial UTI were documented in 50% of the group managed by surgery alone, and 40% of the group receiving nutritional management and surgery. Three of the infected cats from the urethrostomy-only group subsequently developed urocystoliths (Osborne et al, 1991). In a more recent study, one-year followup of 39 cats that had perineal urethrostomy revealed that 51.3% had complications (UTI in nine, stricture in two) or recurrent signs due to

urolithiasis (five cats) or FIC (four cats) (Bass et al, 2005).

Several factors associated with perineal urethrostomies have been incriminated as risk factors for bacterial UTI. These include decreased length of the urethra after surgery, loss of normal penile urethral mucosal defense mechanisms, transurethral catheterization, wider external urethral orifices, impaired function of the striated urethralis muscle and decreased intraluminal pressure. Some cats have decreased postprostatic urethral pressure and decreased activity of the striated muscle sphincter after perineal urethrostomy, as determined by urethral pressure profiles and electromyographic changes (Gregory and Vasseur, 1983). These changes were linked to extensive tissue dissection and damage to the pudendal nerve during surgery.

A modified surgical procedure, designed to preserve function of the striated urethral sphincter, was evaluated in a group of healthy neutered male cats and a group of cats with persistent or recurrent urethral obstruction. All cats had normal urethral pressure profiles and electromyographic results postoperatively. Twenty-two percent of the cats with persistent or recurrent urethral obstruction had bacterial UTIs vs. none of the normal cats. These findings suggest that decreased urethral pressure does not predispose cats to ascending UTI (Griffin et al, 1989).

Vesicourachal diverticula were reported to occur in one of every four cats with dysuria, hematuria and/or urethral obstruction (Osborne et al, 1987). Vesicourachal diverticula can be congenital or acquired. Diverticula alter the normal flow of urine; thus in theory, they may predispose patients to UTI, infection-related urolithiasis and formation of urinary precipitates. It has been suggested that acquired diverticula occur as a result of increased intraluminal pressure due to urethral obstruction or hyperactivity of the detrusor muscle associated with inflammation. Spontaneous resolution of diverticula has been observed in cats (Osborne et al, 1987, 1989).

VIRAL INFECTION

Although not a consistent finding in cats with lower urinary tract signs, viral infections have been implicated as causative agents based on isolation of feline cell-associated herpesvirus, feline calicivirus (FCV) and syncytia-forming virus from cats with hematuria and dysuria alone or in combination with urethral obstruction (Kruger and Osborne, 1990). Calicivirus-like viral particles have been identified in crystalline/matrix urethral plugs from cats with obstructive lower urinary tract disease. Although standard cell culture inoculation methods with urine were negative for virus, investigators were able to induce bovine herpesvirus type 4 (BHV-4) infections experimentally in feline urinary bladders using tissue explantation techniques. However, the pathogenic role of BHV-4 in FLUTD remains unclear because the prevalence of BHV-4 antibodies in affected cats was not significantly different from that of clinically normal control cats (Kruger et al, 1991). In a study of 40 cats, researchers identified FCV in one female cat with FIC and one male cat with obstructive FIC; the FCV (FCV-U1 and FCV-U2) were genetically different from known field and vaccine strains (Rice et al, 2002). In a more recent epidemiologic study of 47 cats with nonobstructive FIC, 22 cats with obstructive FIC, 56 cats with signs of upper respiratory tract disease and 46 asymptomatic cats, FCV was detected by reverse transcription-polymerase chain reaction (RT-PCR) in urine from approximately 6% of cats with FIC or upper respiratory tract disease. FCV was not detected in urine from any asymptomatic cat. Mean FCV virus neutralizing antibody titers for cats with nonobstructive FIC, obstructive FIC and upper respiratory tract disease were significantly higher than the mean titers of asymptomatic control cats (Larson et al, 2007). Despite increasing evidence that FCV invades the urinary system and that cats with FIC have increased exposure to FCV, establishing a cause-and-effect relationship between FCV and FIC requires further investigation.

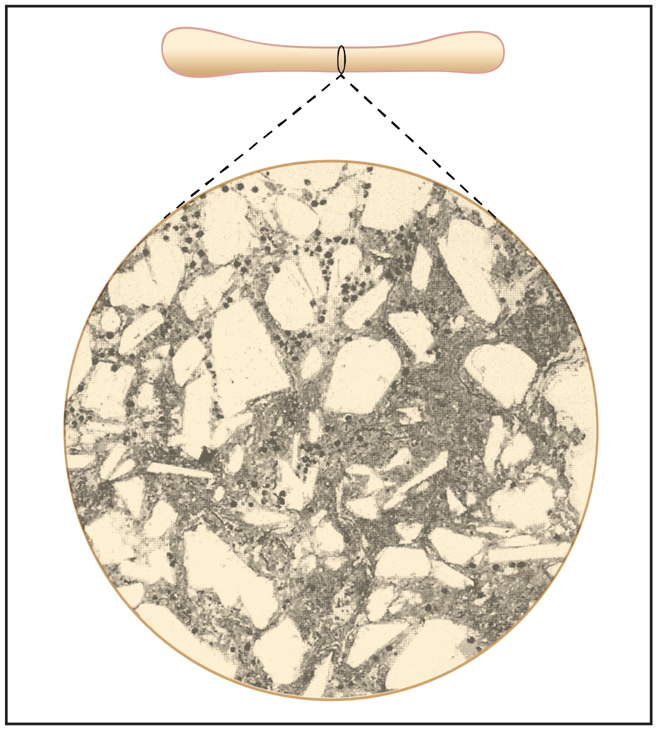

Figure 46-14. Diagram showing a cross-section of a matrix-crystalline urethral plug. Note the spaces previously occupied by struvite crystals are surrounded by matrix containing amorphous material, cellular debris and a small number of inflammatory cells. This phenomenon is analogous to a gelatin salad that contains various fruits or vegetables (depicting crystals, cells, cellular material) embedded in a gelatin matrix.

FUNGAL INFECTION

Fungal UTI is rarely diagnosed in cats; *Candida* spp. are the organisms most often isolated (Pressler et al, 2003; Jin and Lin, 2005). *Candida* spp. are considered a normal part of the genital mucosal flora and most patients with fungal UTI have underlying disorders that alter host defenses against opportunistic infection. Some treatments and concomitant disorders diagnosed in cats with fungal UTI have included administration of antimicrobials or corticosteroids, diabetes mellitus, kidney disease, indwelling urinary catheters, perineal urethrostomy and

Table 46-12. Key nutritional factors and recommended levels for managing cats with common lower urinary tract diseases.*

Factors	Dietary recommendations				
	FIC	**Struvite dissolution**	**Struvite prevention**	**Calcium oxalate uroliths**	**Combined FIC, struvite and calcium oxalate prevention**
Water	Moist foods are best	Moist foods are best	Moist foods are best	Moist foods are best	Moist foods are best
Magnesium (%)	–	0.04 to 0.09	0.04 to 0.14	0.07 to 0.14	0.07 to 0.14
Phosphorus (%)	–	0.45 to 1.1	0.5 to 0.9	0.5 to 1.0	0.5 to 0.9
Calcium (%)	–	–	–	0.6 to 1.0	0.6 to 1.0
Protein (%)	–	30 to 45	30 to 45	≥32	32 to 45
Sodium (%)	–	0.3 to 0.6	0.3 to 0.6	0.3 to 0.6	0.3 to 0.6
Urinary pH	–	5.8 to 6.2	6.0 to 6.4	≥6.2	6.2 to 6.4

Table 46-13. Key nutritional factors for preventing uncommon feline uroliths.

Factors	Dietary recommendations
Purine uroliths (urate, uric acid)	
Water	Promote water intake by using a moist food or other measures
Protein	Avoid excess dietary protein Recommend foods with 28 to 30% DM protein Recommend foods with low purine content Avoid proteins with high purine content such as liver, sardines and anchovies
Urinary pH	Use foods that maintain less acidic urine (6.6 to 6.8)
Calcium phosphate uroliths	
Water	Promote water intake by using a moist food or other measures
Calcium	Avoid excess dietary calcium Recommend foods with 0.6 to 0.8% DM calcium
Phosphorus	Avoid excess dietary phosphorus Recommend foods with <0.8% DM phosphorus
Sodium	Avoid excess dietary sodium Recommend foods with <0.30% DM sodium
Vitamin D	Avoid excess dietary vitamin D Recommend foods with <2,000 IU of vitamin D/kg DM

Key: DM = dry matter.

Table 46-14. Water intake and urine volume in cats fed dry or moist food.*

Volume (ml/day)	Moist food	Dry food
Water (in food)	246	6
Water (in addition to food)	32	221
Total water intake	278	227
Fecal water	27	44
Urine	166	79

other lower urinary tract disorders (e.g., uroliths).

Key Nutritional Factors

Nutritional management plays a key role in successful treatment and/or prevention of the most common FLUTDs. Nutrition may be helpful for decreasing urine concentration of crystallogenic minerals and inflammatory mediators, increasing solubility of crystalloids in urine, promoting increased concentrations of crystallization inhibiters in urine and decreasing retention of crystals and/or uroliths within the urinary tract. When designing a therapeutic regimen for patients with FIC, struvite uroliths or urethral plugs, or calcium oxalate uroliths, consider the key nutritional factors discussed below. **Table 46-12** summarizes these key nutritional factors and recommended nutrient ranges for managing patients with common lower urinary tract disorders. **Table 46-13** summarizes key nutritional factors for cats with less common urolith types. Recommended ranges of nutrient levels of the key nutritional factors were determined by: 1) considering nutrient levels in foods evaluated in cats with various lower urinary tract diseases, 2) using information about risk factors from epidemiologic studies of cats with lower urinary tract signs and 3) extrapolation from studies in other species. Available evidence supporting effectiveness of different foods should be considered when planning treatment as well as each patient's response to treatment.

Water

The volume of water cats consume daily depends on the composition and quantity of food ingested and possibly feeding frequency. Although somewhat variable, most dry cat foods contain less than 10% water and moist foods (most often packaged in cans or pouches) contain more than 72% water. Healthy cats drink more water when eating dry food compared with moist food. The total volume of water ingested (i.e., drinking water plus water in food); however, is significantly greater and more water is excreted in urine than in feces when cats are fed moist food (**Table 46-14**) (Gaskell, 1989; Burger and Smith, 1987). The solute load of food also influences water consumption; urea is a major contributor to the renal solute load. Increasing the

protein content of food increases the solute load (e.g., urea). Therefore, foods with higher protein content are associated with higher water intake. Metabolism of energy substrates yields endogenous water but the daily volume of endogenously produced water is small (approximately 10 to 15%) compared with the total daily water intake. Metabolism of fats provides the most water per gram whereas carbohydrate metabolism results in the most water per calorie. The amount of water generated differs slightly depending on the source of fat, chain length and degree of saturation. Feeding frequency also appears to affect water intake in cats. In a study of healthy adult cats, water intake (in addition to that consumed in the food) increased significantly when cats were fed two or three meals compared with a single meal each day. However, the study did not note whether the food was dry or moist (Kirschvink et al, 2005).

Of all treatments evaluated in controlled studies, the only one that has been associated with a statistically significant difference in recurrence of clinical signs in cats with FIC is feeding moist food (Barsanti et al, 1982; Gunn-Moore and Shenoy, 2004; Gunn-Moore and Cameron, 2004; Kruger et al, 2003; Kraijer et al, 2003; Osborne et al, 1996d; Markwell et al, 1999). During a one-year nonrandomized clinical study of cats with FIC, clinical signs recurred less often in cats fed moist food compared with cats fed the dry formulation of the same food[c] (**Figure 46-15**) (Markwell et al, 1999). In a six-month FIC study evaluating glucosamine hydrochloride[d] vs. placebo, cats receiving either treatment improved significantly compared with evaluations at the beginning of the study (**Figure 46-16**) (Gunn-Moore and Shenoy, 2004). Before the study, 95% of cats were fed either dry food exclusively or at least half of their daily intake was dry food. After starting the study, however, 36 (90%) owners increased the amount of moist food given to their cats, so that at least 50% of their daily intake was moist food. Owners began feeding moist food exclusively to 33 (82.5%) cats. In both studies described above, it is likely that increased consumption of moist food caused urine dilution, which was associated with clinical improvement in cats with FIC. However, other beneficial effects of feeding moist food (e.g., increased owner/cat interactions associated with delivery of canned meals) cannot be excluded.

Moist foods also are recommended in the management of urolithiasis and urethral plugs because they lead to production of less concentrated urine that is less saturated with crystalloids. Increased water consumption has been used as an effective strategy for controlling calcium oxalate uroliths in people, dogs and cattle. A case-controlled study of nutritional factors associated with urolithiasis in cats unexpectedly found no association between high-moisture foods and decreased risk for struvite uroliths (Lekcharoensuk et al, 2001a). However, cats fed high-moisture (74.4 to 81.2%) foods were about a third as likely to develop calcium oxalate uroliths as were cats fed low-moisture (7.0 to 7.9%) foods. The authors concluded that it is possible that increases in urine volume produced by moisture content of food may have less influence on struvite urolith formation than on calcium oxalate urolith formation.

Based on available information, patients with FIC and calcium oxalate uroliths should be fed foods that contain more than 74% moisture, as fed (e.g., foods in cans or pouches). Current evidence is less clear regarding beneficial effects of moist food for cats with struvite disease. However, it seems reasonable to also recommend moist foods for these cats as well, especially if

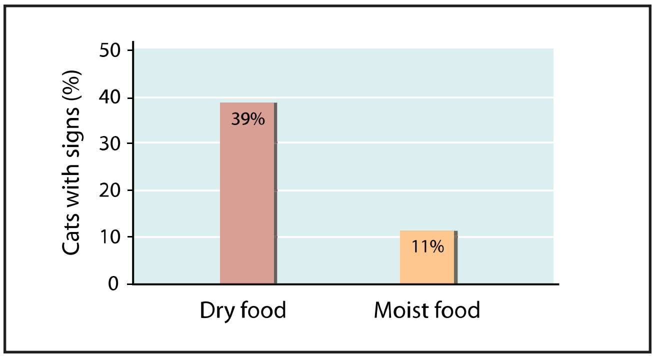

Figure 46-15. Results of a one-year study of 46 cats with feline idiopathic cystitis showed that recurrence of clinical signs was significantly greater in cats fed a dry food[c] (n = 28) compared with cats fed the moist version of the food (n = 18) (p = 0.04). After feeding the dry food, mean urine specific gravity values (measured at 2 weeks, 16 weeks, 6 months and 12 months) ranged from 1.050 to 1.051 whereas mean urine specific gravity values in cats eating moist food ranged from 1.032 to 1.041. (Adapted from Markwell PJ, Buffington CA, Chew DJ, et al. Clinical evaluation of commercially available urinary acidification diets in the management of idiopathic cystitis in cats. Journal of the American Veterinary Medical Association 1999; 214: 361-365.)

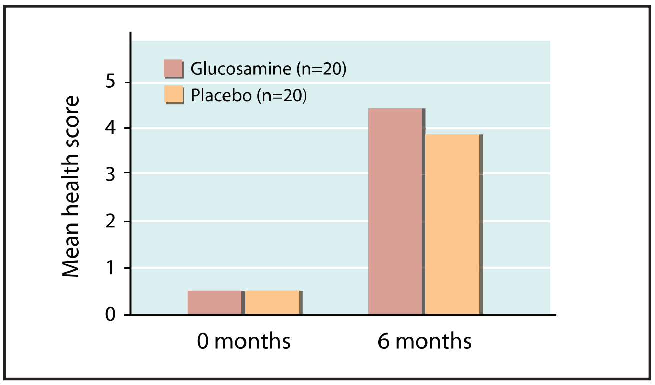

Figure 46-16. Mean health scores (0 = very severe cystitis, 5 = normal) from owner ratings at the beginning (0 months) and end (6 months) of a clinical study evaluating effects of glucosamine[d] compared with placebo in cats (n = 40) with feline idiopathic cystitis (FIC). There was no significant difference between groups (glucosamine or placebo) at baseline or after six months of treatment; however, mean health scores were significantly higher in both groups of cats at six months compared with baseline (p <0.001). Mean urine specific gravity at the beginning of the study was 1.050 and it was significantly lower (1.036) when reassessed one month later. Most owners switched from feeding dry food to moist food after receiving educational material at the beginning of the study that included benefits of feeding moist food to cats with FIC. (Adapted from Gunn-Moore DA, Shenoy CM. Oral glucosamine and the management of feline idiopathic cystitis. Journal of Feline Medicine and Surgery 2004; 6: 219-225.)

there is recurrent disease in the face of feeding a dry struvite preventive food.

Magnesium

Avoiding excess dietary magnesium intake can reduce urinary concentration of magnesium, which decreases risk for struvite disease. In an epidemiologic study, risk of struvite uroliths was increased in cats fed foods higher in magnesium (Lekcharoensuk et al, 2001a). Excess magnesium is present in some commercial cat foods because they contain ingredients high in magnesium (e.g., high-ash meat and bone, fish and poultry meals). The recommended range of dietary magnesium for dissolving struvite uroliths in cats is 0.04 to 0.09% (dry matter [DM]). For preventing recurrence of struvite uroliths or urethral plugs, the recommended range of magnesium is 0.04 to 0.14% DM (**Table 46-12**).

Magnesium is considered to be an inhibitor of calcium oxalate crystal formation. Potential mechanisms for this inhibitory effect include increased urinary pH, increased urinary excretion of citrate and formation of magnesium oxalate complexes in urine, which are more soluble than calcium oxalate. Formation of magnesium oxalate, in theory, reduces the concentration of oxalate available for precipitation as calcium oxalate. Low urinary magnesium concentration has been suggested as a potential risk factor for formation of calcium-containing uroliths in cats (Lekcharoensuk et al, 2000, 2001). Clinical studies evaluating effectiveness of magnesium supplementation on recurrence of calcium oxalate uroliths in people have yielded conflicting results (Johansson et al, 1980; Ettinger et al, 1988; Schwartz et al, 2001). Addition of magnesium was associated with reduced calcium oxalate saturation in urine as demonstrated with in vitro studies using synthetic human urine (Kohri et al, 1988). In vitro studies demonstrated that physiologic concentrations of magnesium decreased rate of nucleation and growth of calcium oxalate crystals (Kohri et al, 1988; Li et al, 1985). However, excessive dietary magnesium may result in hypercalciuria, a risk factor for calcium oxalate urolithiasis (Fetner et al, 1978).

An epidemiologic study of nutritional factors associated with urolithiasis in cats demonstrated that foods with the lowest magnesium content (0.04 to 0.07% DM; 0.09 to 0.18 mg/kcal) were associated with increased risk of forming calcium oxalate uroliths when compared with foods that had moderate magnesium content (0.08 to 0.14% DM; 0.19 to 0.35 mg/kcal) (Lekcharoensuk et al, 2001a). Foods with the highest magnesium content (0.14 to 0.56% DM; 0.36 to 1.40 mg/kcal) also were associated with increased risk of developing calcium oxalate uroliths when compared with foods containing moderate amounts of magnesium. In another study of cats with calcium oxalate uroliths, the mean magnesium content (0.19 mg/kcal) of the food being fed at the time of urolith diagnosis was similar to that of the magnesium content of a urolith-prevention food[e] (0.2 mg/kcal), which significantly decreased urine calcium oxalate saturation compared with the regular food (Lulich et al, 2004). To minimize risk of calcium oxalate uroliths, foods should contain a moderate amount of magnesium (0.07 to 0.14% DM). Individual foods intended to reduce the recurrence of both struvite and calcium oxalate urolithiasis should also be within this range.

Phosphorus

Varying dietary phosphorus levels can alter urinary phosphate concentrations in cats, thereby influencing likelihood of urinary struvite precipitates. High-phosphorus foods have been associated with increased risk of struvite uroliths in cats (Lekcharoensuk et al, 2001a). The recommended range of dietary phosphorus for dissolving struvite uroliths is 0.45 to 1.1% DM phosphorus; for struvite prevention the recommended range is 0.5 to 0.9% DM (**Table 46-12**).

Urinary phosphate can exist in several states; anionic phosphate (PO_4^{-3}) is the important form in precipitation and dissolution of struvite. Urinary concentration of anionic phosphate is reversibly influenced by pH. (See Urinary pH below and **Box 46-3.**) Thus, as urine becomes more acidic, anionic phosphate is converted to monobasic and dibasic phosphate, thereby reducing the concentration of anionic phosphate available for forming struvite precipitates. As urine becomes more alkaline, the reaction proceeds in the opposite direction and concentration of anionic phosphate increases.

Compared with foods containing moderate amounts of phosphorus, both low- and high-phosphorus foods are associated with increased risk of calcium oxalate uroliths in cats. Reduction in dietary phosphorus may cause activation of vitamin D, which promotes intestinal absorption of calcium and subsequent urinary calcium excretion. Rats fed a very low-phosphorus food (0.07% DM) had marked hypercalciuria (Werness et al, 1981). Feeding this level of phosphorus for one week resulted in urine that was oversaturated with calcium oxalate and contained large amounts of calcium oxalate crystals. A possible explanation for increased risk of calcium oxalate uroliths associated with increased phosphorus intake is that excessive dietary phosphorus could form insoluble salts with dietary calcium, which in turn could increase availability of noncomplexed oxalic acid for intestinal absorption and renal excretion (Lekcharoensuk et al, 2001a).

The recommended range of dietary phosphorus for decreasing risk of calcium oxalate urolithiasis is 0.50 to 1.0% DM phosphorus (**Table 46-12**). The recommended range for the phosphorus content of foods intended for prevention of both struvite and calcium oxalate should be between 0.5 and 0.9% DM.

Calcium

Calcium availability from the gastrointestinal tract may be influenced by non-dietary and dietary factors. Intestinal absorption of calcium occurs primarily in the duodenum; transport of calcium across the gut is a saturable process that is vitamin D-dependent. In general, calcium absorption from the intestinal tract is inversely proportional to dietary intake. In other words, absorption is high from low-calcium foods and low from high-calcium foods. Other dietary factors (e.g., vitamin D, sucrose, fructose, glucose, xylose, dietary fiber, oxalic acid, phytic acid, protein and phosphorus) reportedly affect cal-

cium availability.

Excessive dietary calcium should be avoided to prevent recurrence of calcium oxalate uroliths. The most important sources of excess calcium are commercial foods and mineral supplements containing high calcium levels. High intake of dietary calcium may lead to hypercalciuria and urolith formation in patients with intestinal hyperabsorption of calcium. Calcium-rich human foods (**Table 46-15**) should be avoided in patients at risk for calcium oxalate uroliths. In addition to foods naturally high in calcium, a number of different human foods (e.g., breads and breakfast cereals) and beverages are fortified with calcium. The amount of calcium added to these foods can be found on the product label.

Another potential unrecognized source of excess dietary calcium is vitamin-mineral supplements, especially calcium supplements. A wide variety of calcium supplements are available over the counter. These supplements differ in the amount of elemental calcium provided. Calcium carbonate, for example, contains 40% calcium (by weight), whereas calcium lactate and calcium gluconate contain 13 and 9% calcium, respectively. Little is known about the relative availability of calcium from different supplements. Calcium supplements differ not only in their calcium content, but also in their solubility. Increasing dietary calcium intake prevents dietary hyperoxaluria in human patients eating oxalate-rich foods (Pak, 1990). This finding presumably is due to decreased intestinal absorption of oxalate. However, women taking calcium supplements had a 79% increased risk of calcium oxalate uroliths (Curhan et al, 1995). The increased risk associated with calcium supplements may be due to timing of ingestion. If not taken with meals, calcium supplements may lead to increased urinary calcium excretion, without decreasing oxalate absorption in the gastrointestinal tract.

Excessive restriction of calcium should also be avoided; it may cause negative calcium balance and contribute to hyperoxaluria, which increases risk for calcium oxalate uroliths. Cats fed foods containing moderate amounts of calcium had decreased risk of developing calcium oxalate uroliths compared with cats fed either low or high amounts of calcium (Lekcharoensuk et al, 2001a). The recommended range of dietary calcium for decreasing risk of calcium oxalate uroliths is 0.6 to 1.0% DM. This is also the recommended range for the calcium content of foods intended for prevention of both struvite and calcium oxalate urolithiasis.

Table 46-15. Calcium-rich foods that should be avoided in cats at risk for calcium oxalate urolithiasis.*

Food item	Serving size	Calcium (mg)
Yogurt	1 cup (8 oz.)	415
Whole milk	1 cup (8 oz.)	291
Cheese	1 oz.	200-270
Ice cream or ice milk	1 cup (8 oz.)	176
Cottage cheese, creamed	1 cup (8 oz.)	136
Broccoli, cooked	1 large stalk	88

*Mineral supplements and some commercial cat foods contain much more calcium than these foods; therefore, a thorough and complete nutritional history is important for managing these patients.

Protein

Excessive dietary protein intake should be avoided in patients at risk for struvite uroliths. Protein provides additional urea and glutamine, which are metabolized to ammonia and ammonium, respectively. Urinary excretion of ammonia and ammonium increases their availability to combine with magnesium and phosphate to form struvite crystals and uroliths. In addition, foods that have increased amounts of protein also tend to have increased phosphorus, which is a component of struvite uroliths. The recommended amount of dietary protein for struvite dissolution and prevention ranges from 30 to 45% DM protein.

The risk of calcium oxalate urolithiasis in people and dogs generally is considered to increase with ingestion of foods that are high in protein. During the last century, the predominant urolith type in people in the U.S. has shifted from struvite to calcium oxalate (Goldfarb, 1994). Cross-cultural studies have shown a shift from struvite to calcium oxalate uroliths with increasing industrialization (Samuel and Kasidas, 1995). The reason for the increased incidence of calcium oxalate in these human populations is unknown. However, dietary habits are thought to play a major role. Nutritional epidemiologic studies have emphasized the role of increased dietary intake of animal protein. This link seems plausible because the amount of animal protein in the diet correlates with industrialization. Dietary protein increases calcium, uric acid and possibly oxalate excretion and decreases urinary pH. Animal proteins are rich in sulfur-containing amino acids, which are metabolized to sulfate and thus may reduce urinary pH and increase urinary calcium and uric acid concentrations. High dietary protein intake reportedly increases urinary calcium excretion in dogs. The 24-hour urinary calcium excretion almost doubled when dogs were fed a food containing 31% DM protein compared with calcium excretion for dogs fed a food containing 10% DM protein (Bartges et al, 1995). The type of protein, duration of protein intake and phosphorus intake influence the effect of protein on calcium.

At present, available evidence does not support that excessive dietary protein is associated with calcium oxalate uroliths in cats. Healthy cats eating a high-protein food (13.7 g/100 kcal; 55% DM protein for a food with 4 kcal metabolizable energy [ME]/g DM) had increased water intake, urine volume and urinary pH; however, they did not have increased urinary calcium excretion (Funaba et al, 1996). In a case-controlled study of nutritional factors associated with urolithiasis, cats fed foods containing more than 7.98 g of protein/100 kcal (32% DM protein for a food with 4 kcal ME/g DM) were less likely to form calcium oxalate uroliths than cats fed low-protein foods (5.15 to 7.98 g/100 kcal; 21 to 32% DM protein for a food with 4 kcal ME/g DM) (Lekcharoensuk et al, 2001a). It is possible that increased urine volume associated with increased protein intake plays a role in decreasing risk of urolith formation. On the basis of current information, cats at risk for calcium oxalate uroliths should be fed foods with at least 32% DM protein. The protein content of foods intended for prevention of both struvite and calcium oxalate should be between 32 and 45% DM.

Sodium

Increasing the salt (i.e., sodium chloride) content of food is an effective method for increasing water intake and causing subsequent urine dilution in healthy cats (Hawthorne and Markwell, 2004; Luckshander et al, 2004). However, most factors that promote natriuresis tend to increase urinary calcium excretion, which could increase risk for calcium oxalate uroliths. Calcium and sodium are reabsorbed at common sites in the renal tubules. Hypercalciuric people who form calcium-containing uroliths appear to have a proportionally greater increase in urinary calcium excretion than non-urolith formers. Increasing dietary sodium intake from 140 to 310 mmol/day increased urinary calcium excretion by 34% and decreased urinary citrate by 10% (Kok et al, 1990). However, urinary calcium and sodium excretion was not correlated in healthy people with low dietary calcium intake (Dawson-Hughes et al, 1996).

Effects of increased sodium intake on urinary excretion of calcium or urinary calcium oxalate saturation in cats with calcium oxalate uroliths have not been reported. Increased urinary excretion of calcium was identified in cats with mild, naturally occurring chronic kidney disease consuming a food with 1.2% DM sodium compared with consumption of a food containing 0.4% DM sodium (Kirk et al, 2006). Additional study of effects of increased sodium intake on urinary calcium excretion in cats with kidney disease is indicated because nephroliths and ureteroliths, which are most often calcium oxalate, are being diagnosed more often in cats with chronic kidney disease (Ross et al, 2005, 2007).

In healthy cats fed a high-salt food, urine calcium concentration and calcium oxalate saturation were not increased, although there was a significant increase in 24-hour urine calcium excretion (Biourge et al, 2001). This was likely due to dilution of calcium and other substances in urine associated with increased urine volume. In another study of healthy cats, increased dietary sodium was associated with increased water intake and urine volume and significantly decreased values for calcium oxalate urine saturation (Hawthorne and Markwell, 2004).

In an epidemiologic study, feeding foods containing less sodium (0.48 to 0.77 mg sodium/kcal; 0.19 to 0.31% DM, for a food with 4 kcal ME/g DM) was associated with calcium oxalate uroliths in cats (Lekcharoensuk et al, 2001a). Despite this finding, feeding a veterinary therapeutic food containing 0.67 mg sodium/kcal (0.27% DM for a food with 4 kcal ME/g DM) to calcium oxalate urolith-forming cats was associated with a significant decrease in urine calcium excretion and calcium oxalate saturation compared with eating their regular food (Lulich et al, 2004). The recommended range for dietary sodium intake in cats at risk for calcium oxalate uroliths is 0.3 to 0.6% DM sodium.

Varying levels of sodium have been used in foods[f,g] that have been shown to be effective for struvite dissolution in feline patients (Osborne et al, 1990; Houston et al, 2004). In lieu of other data, based on the sodium levels in these foods, a recommended range for sodium content for foods for struvite dissolution could be developed by simply bracketing the levels in these foods (e.g., 0.37 to 1.27% DM sodium). However, research indicates that urinary calcium excretion increases when healthy cats are fed a high-salt food (Biourge et al, 2001). Also, as mentioned above, cats prone to the development of calcium oxalate urolithiasis benefit from avoiding increased sodium intake (Lulich et al, 2004). Thus, to avoid excess calcium excretion and the possibility of formation of calcium oxalate crystals while feeding these types of foods, a sodium range of 0.3 to 0.6% DM is recommended in foods intended for struvite dissolution.

Cats fed foods containing 1.43 to 3.7 mg of sodium/kcal (0.57 to 1.48% DM, for a food with 4 kcal ME/g DM) were 4.1 times as likely to develop struvite uroliths as cats consuming foods with less sodium (0.48 to 0.77 mg/kcal; 0.19 to 0.31% DM, for a food with 4 kcal ME/g DM) (Lekcharoensuk et al, 2001a). In this epidemiologic study there was a significant correlation between high sodium and high phosphorus content in foods. It is possible that increased risk for struvite uroliths in cats eating high-sodium foods is related to the type of sodium salt (e.g., monosodium phosphate, sodium tripolyphosphate) used in foods. However, additional study is needed to confirm this. There are no reported studies evaluating effects of increased sodium intake in cats with naturally occurring struvite uroliths. The recommended range of dietary sodium intake for prevention of struvite disease in cats is 0.3 to 0.6% DM.

In order to cause production of dilute urine, food must contain more than 1% DM sodium. Many foods formulated for cats with lower urinary tract diseases contain between 0.3 and 0.6% DM sodium, whereas, some contain 1 to 1.4% DM sodium. The minimum recommended allowance of sodium for adult cats is 0.068% DM (NRC, 2006). According to the most recent information published by the National Research Council (NRC), it is difficult to suggest a safe upper limit of sodium for healthy adult cats (NRC, 2006). The NRC has concluded that as long as unlimited amounts of water are available, cats probably can tolerate reasonably high concentrations of dietary sodium; the safe upper limit for adult cats has been defined as greater than 1.5% DM. However, the safe upper limit of sodium for cats with chronic kidney disease, lower urinary tract disorders and other conditions (e.g., hypertension) is unknown. One study revealed that six cats with early kidney disease had significant increases of serum creatinine, urea nitrogen and phosphorus when consuming a food with 1.2% DM sodium for three months vs. when fed a food with 0.4% DM sodium (Kirk et al, 2006). Additional evaluation of effects of increased sodium intake is needed because most studies have either been of short duration (<6 months) or were performed in healthy cats. Pending availability of additional data (e.g., effects of high sodium intake in cats with calcium oxalate uroliths), orally administered sodium chloride should be used cautiously and with careful monitoring because of the potential for increased risk of calcium oxalate urolith formation in some patients (Bartges and Kirk, 2006).

Urinary pH

The kidneys eliminate acid that is produced as a result of normal metabolism, including digestion of food. Therefore, to

Box 46-4. Determining the Effect of Food on Urinary pH.

Several important effects of food on acid-base balance can be described by the anion-cation balance (ACB). Calculation of a food's ACB has been evaluated as a practical method for predicting the effect of a food on urinary pH. In this method, the ACB is calculated from the concentrations of alkaline and acid compounds in the food, expressed as mmol/kg dry matter, using the formula:
ACB = 49.9 (Calcium) + 82.3 (Magnesium) + 43.5 (Sodium) + 25.6 (Potassium) – 64.6 (Phosphorus) – 13.4 (Methionine) – 16.6 (Cysteine) – 28.2 (Chloride). Factors take into account atomic/molecular weight and valence (2 for phosphorus).

This method was evaluated in a study involving 10 commercial foods (moist and dry) and several additives. Feeding trials involved four to six cats per trial. Cats were fed the foods for two days and urine was collected for at least five days. During the eight hours after feeding, urinary pH was measured immediately after urination and urine excreted during the remainder of the day was tested the following morning. A highly significant correlation was seen between ACB of the food and the mean urinary pH. In the amounts used in this study, the addition of calcium carbonate and calcium lactate significantly increased urinary pH; dibasic calcium phosphate and ascorbic acid had no effect; and calcium chloride, ammonium chloride and phosphoric acid decreased urinary pH.

Another study was conducted recently to determine if urinary pH could be predicted using the nutrient components of feline foods. One-hundred-fifty foods (90 dry, 60 wet) were fed to groups of 10 adult cats to determine urinary pH of cats fed each food. Each food was fed for seven days and pH was determined on freshly voided urine on Days 5 to 7 of the study. Using stepwise regression, it was determined which cations, anions and sulfur-containing amino acids were of importance for predicting urinary pH. Separate formulas had to be used for dry and wet foods to maintain accuracy.

Although calculation of ACB may roughly estimate urinary pH and formulas can be used to predict urinary pH based on nutrient content of food, the most accepted method of comparing foods is to feed the food to a group of cats and compare urinary pH values. However, although most reputable cat food manufacturers provide urinary pH data for their products, no standard urinary pH testing protocol has been developed. Consequently, it is important to know the protocol used to measure urinary pH before comparing results from different companies or laboratories.

The Bibliography for **Box 46-4** can be found at www.markmorris.org.

define "normal" urinary pH, it is necessary to consider the "normal" or habitual diet. On a volume basis, the gastric content of feral cats is approximately 90% small mammals (e.g., mice, rats) (Coman and Brunner, 1972). In one study, the average urinary pH was approximately 6.3 when cats were fed a diet of rat carcasses (Vondruska, 1987). In another study, mean urinary pH was reported to be 5.97 for feral female cats and 6.37 for feral male cats eating a natural diet (Cottam et al, 2002).

The kidneys provide long-term defense against acid and alkali deviations; this process occurs continuously as endogenous acids are generated. The kidneys must conserve bicarbonate in the glomerular filtrate and regenerate bicarbonate degraded by the reaction with metabolic acids to maintain normal plasma bicarbonate levels. The kidneys can increase the amount of net acid excretion in urine and generate bicarbonate in response to exogenous acid loads. Normally, the kidneys synthesize urinary ammonia (NH_3) and thus ammonium (NH_4^+) almost exclusively. With chronic metabolic acidosis, more NH_3 is produced and urinary NH_4^+ ion concentration is increased. The kidneys excrete hydrogen ions (H^+) in the form of titratable acid (e.g., phosphoric acid) and NH_4^+ ions. Reduction of urinary pH greatly increases the ratio of NH_4^+ to NH_3. Acidifying foods, therefore, increase urinary concentration of NH_4^+ ions, one component of struvite. Although decreasing urinary pH theoretically increases urinary NH_4^+ concentration, the same change in urinary pH decreases anionic phosphate levels in urine. Thus, as urine becomes more acidic, precipitation of struvite becomes less likely.

The effect of a food on urinary pH is the net effect of its constituent nutrients (**Box 46-4**). Dietary acid is derived from several nutrients (**Table 46-16**) (Halperin and Jungas, 1983).

Table 46-16. Urine acidifying and alkalinizing pet food ingredients.

Other acidifying ingredients
Ammonium chloride*
Calcium chloride
Calcium sulfate
dl-methionine
Phosphoric acid
Alkalinizing ingredients
Calcium carbonate
Potassium citrate
Magnesium oxide

*Not approved in the United States as a food additive.

Sulfuric acid is formed when sulfur-containing amino acid (e.g., methionine and cysteine) residues of proteins are oxidized to sulfate. In general, animal-source protein ingredients contain more sulfur-containing amino acid residues than do plant-source proteins. Phosphorus has strong effects on acid-base balance, depending on its chemical form. Inorganic phosphorus can be ingested as phosphoric acid, monobasic and dibasic or anionic phosphate. Phosphoric acid is used in cat foods to enhance palatability, either separately or as a component of topically applied animal digests. Phosphoric acid has a strong acidifying effect. Monobasic phosphate also is acidifying, whereas dibasic phosphate has little effect on urinary pH (Kienzle et al, 1991). Anionic phosphate is alkalizing.

Mineral salts vary in their effect on urinary pH and thus are potential acid or base sources. Oxides and carbonates are alka-

Table 46-17. Effect of urinary pH on urine saturation values in healthy cats (n = 6).*

Food	Urinary pH	CaOx RSS	Struvite RSS
$NaHCO_3$	6.81 ± 0.33[b]	0.78 ± 0.53[a]	7.98 ± 4.62[b]
Control	6.18 ± 0.26[a]	0.71 ± 0.28[a]	1.61 ± 1.11[a]
NH_4Cl	5.81 ± 0.14[a]	1.66 ± 0.58[b]	1.16 ± 0.25[a]

Key: $NaHCO_3$ = sodium bicarbonate, NH_4Cl = ammonium chloride, CaOx = calcium oxalate, RSS = relative supersaturation.

**High in calcium, therefore, may not be ideal for cats with calcium oxalate uroliths.

lizing. Differences in absorption of the cation and anion portion of a salt are important. Intestinal absorption of calcium and magnesium is relatively low. However, absorption of accompanying anions can be high and influences urinary pH. Nonmetabolizable anions (e.g., chloride, phosphate and sulfate) absorbed in excess of their accompanying cations are acidifying. For example, ammonium chloride, calcium chloride and calcium sulfate decrease urinary pH, and magnesium oxide and calcium carbonate increase urinary pH.

Urinary pH plays a critical role in managing cats with struvite disease but appears less important in cats with calcium oxalate uroliths. Struvite is highly soluble and is, therefore, less likely to precipitate in acidic urine (pH <6.5). Alterations in urinary pH have a proportionally greater effect on changing struvite activity product than changes in crystalloid (e.g., magnesium) concentrations. Decreasing urinary pH, therefore, is the most reliable means of producing urine undersaturated for struvite. Although acidifying foods have been associated with occurrence of calcium oxalate uroliths in cats, changes in urinary pH values over the physiologic range appear to have little effect on solubility of calcium oxalate (**Figure 46-17**) (Verplaetse et al, 1985; Yu and Gross, 2007; Stevenson et al, 2000). One study showed that pH changes between 4 and 11 had minimal effect on calcium oxalate solubility (Verplaetse et al, 1985). In a study of healthy cats fed three foods to produce different urinary pH values, reducing urinary pH from 6.81 to 6.18 had no significant effect on urine saturation for calcium oxalate (0.78 vs. 0.71) but significantly decreased struvite saturation (**Table 46-17**) (Stevenson et al, 2000).

The recommended urinary pH range for dissolving struvite uroliths is 5.8 to 6.2. To decrease risk for recurrence of struvite uroliths or urethral plugs, urinary pH should be 6.0 to 6.4; however, to decrease risk for recurrence of calcium oxalate uroliths, urinary pH should be at least 6.2. Thus, foods for prevention of both struvite and calcium oxalate urolithiasis should produce a urinary pH between 6.2 to 6.4.

Fatty Acids

Urinary bladder inflammation is characteristic of most lower urinary tract disorders including FIC and urolithiasis. Long-chain omega-3 (n-3) fatty acids such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) have potent antiinflammatory properties. These dietary fatty acids are absorbed and incorporated into cell membranes, including those of the urinary bladder, where they may alter production of inflammatory mediators. Antiinflammatory effects of omega-3 fatty acids such as EPA have been demonstrated in dogs with osteoarthritis and patients with dermatitis. Effects of omega-3 fatty acids have not been evaluated in cats with various lower urinary tract disorders; however, they appear to have beneficial urinary effects in studies of other species. Administration of EPA to rats prevented experimentally induced nephrocalcinosis and significantly decreased urinary calcium excretion compared with a placebo (Buck et al, 1991). In a second part of the study, 12 human patients with recurrent calcium oxalate uroliths and hypercalciuria had signifi-

cantly decreased urinary calcium and oxalate excretion when treated with EPA for eight weeks. In another study, administration of EPA for three months to 88 people with recurrent urinary stones, primarily calcium oxalate, was associated with significantly decreased urinary calcium in those with hypercalciuria (Yasui et al, 2001).

The recommended range of dietary total omega-3 fatty acids (i.e., DHA and/or EPA) for managing inflammation associated with lower urinary tract diseases is 0.35 to 1.0% DM. This range was extrapolated from levels associated with antiinflammatory effects in other species. Additional study is needed to better define the therapeutic range of omega-3 fatty acids for managing patients with FIC and calcium oxalate uroliths.

Other Nutritional Factors

Antioxidants

Vitamin E has antioxidant properties that have been shown to decrease oxidative stress and damage caused by free radicals. Because oxidative stress is often associated with inflammation, antioxidants may help create an unfavorable environment for the development of uroliths. However, this has not been evaluated in cats with naturally occurring urolithiasis.

Vitamin C is also an antioxidant. However, a portion of urinary oxalate is derived from endogenous metabolism of vitamin C. In a controlled study of healthy cats fed differing amounts of vitamin C ranging from 40 to 193 mg vitamin C/kg of food for four weeks, there was no significant change in urinary oxalate excretion (Yu and Gross, 2005). Effects of vitamin C supplementation have not been studied in cats with calcium oxalate uroliths. Because cats do not have a dietary requirement for vitamin C, supplementation should be avoided in cats at risk for calcium oxalate uroliths (Bartges and Kirk, 2006). One source of vitamin C that should be avoided is cranberry concentrate tablets.

Oxalate

Excessive intake of oxalate is unlikely in dogs and cats eating most commercial foods but it could occur in pets receiving excessive amounts of certain human foods as treats. Foods that contain relatively high amounts of oxalate (e.g., spinach, carrots, liver, sardines) should be avoided in patients with a history of calcium oxalate uroliths. **Table 46-18** provides more information about the oxalate content in selected human foods.

Potassium

Transient negative potassium balance has been reported to occur in adult cats receiving long-term dietary acidification (i.e., for struvite urolith prevention) with phosphoric acid and NH_4Cl; potassium balance returned to normal by the end of both studies (Fettman et al, 1992; Ching et al, 1990). In an epidemiologic study, cats fed foods with higher amounts of potassium (2.17 to 3.20 mg/kcal; 0.87 to 1.28% DM for a food with 4 kcal ME/g DM) had decreased risk of calcium oxalate uroliths compared with cats that were eating foods with less potassium (0.95 to 1.60 mg/kcal; 0.35 to 0.64% DM for a food with 4 kcal ME/g DM) (Lekcharoensuk et al, 2001a). Additional study is needed to determine if potassium supplementation benefits cats with calcium oxalate uroliths. Based on current information, dietary potassium intake should exceed 0.65% DM in cats at risk for struvite disease and calcium oxalate uroliths. Most commercial foods are replete with potassium.

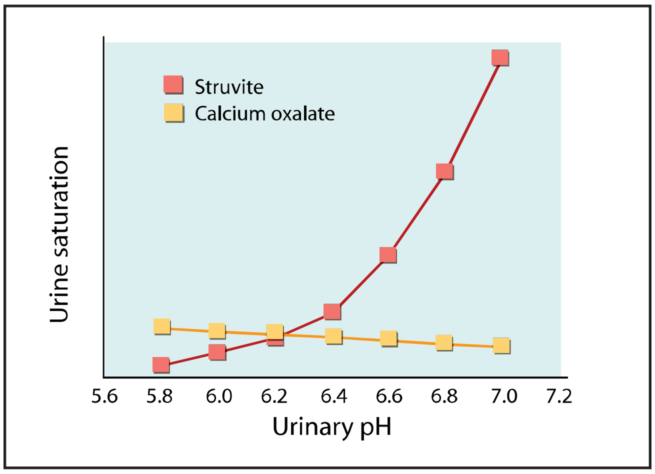

Figure 46-17. This graph demonstrates the relationship between urinary pH and urine saturation values for struvite and calcium oxalate. Data were collected from 21 adult cats (10 healthy and 11 urolith-forming cats) during consumption of a food (Hill's Prescription Diet c/d Multicare Feline) formulated to manage both struvite and calcium oxalate uroliths. Mineral type was not available for uroliths in most cats; however, calcium oxalate was presumed most likely due to location (eight cats had nephroliths), radiographic appearance and results of quantitative analysis for uroliths that were removed. Urine constituents (e.g., calcium oxalate, magnesium, phosphate) and pH were measured for each cat and used to calculate values for relative supersaturation (RSS). This was followed by a computer-modeling procedure to predict effect that changing only urinary pH would have on RSS values. Results were similar for both healthy and urolith-forming cats; therefore, all data are shown in one graph. Note that as urinary pH increases, urine saturation for struvite increases; however, as urinary pH decreases over the physiologic range, there is only a slight change in calcium oxalate saturation. In this model, reducing urinary pH from 7.4 to 6.4 decreased struvite saturation by 122 units but only increased calcium oxalate saturation by 0.9 units. (Adapted from Yu S, Gross KL. Dietary management of the three most common lower urinary tract diseases in cats. In: Proceedings. Hill's Symposium on Lower Urinary Tract Disease. Educational Concepts, 2007: 53-57.)

Vitamin B_6 (Pyridoxine)

Increases in urinary oxalic acid excretion have been observed in kittens fed pyridoxine-deficient foods. However, no studies have evaluated effects of vitamin B_6 in cats with calcium oxalate uroliths (Bai et al, 1989, 1991). No evidence suggests that supplementing vitamin B_6 beyond nutritional requirements benefits cats with calcium oxalate urolithiasis. Because most commercially available pet foods are well supplemented with vitamin B_6, it seems unlikely that additional supplementation would be helpful unless the primary food is homemade.

Vitamin D

Increased vitamin D intake should be avoided because it can lead to increased intestinal absorption of calcium with subse-

quent hypercalciuria and increased risk for oxalate uroliths. The minimum recommended allowance for vitamin D for adult cats is 280 IU/kg food (DM; for a food with 4 kcal ME/g DM) (NRC, 2006). However, cats at risk for calcium oxalate urolithiasis and those with hypercalcemia associated with calcium oxalate urolithiasis should be fed foods that do not exceed 2,000 IU/kg of food. Dietary supplements containing vitamin D should not be fed to at-risk cats.

Fiber

The role of dietary fiber has not been carefully evaluated in cats with lower urinary tract disorders. In an epidemiologic study of cats with uroliths, those fed high-fiber foods (0.71 to 11.57 g/100 kcal) were 2.12 times more likely to develop struvite uroliths than cats fed low-fiber foods (0.06 to 0.30 g/100 kcal) (Lekcharoensuk et al, 2001a). In the same study there was no association between dietary fiber and development of calcium oxalate uroliths. Dietary fiber may bind calcium in the small intestine, preventing its absorption. There are anecdotal reports that feeding foods with increased fiber helps control hypercalcemia in cats with concomitant calcium oxalate uroliths (McClain et al, 1999).

FEEDING PLANS

Successful management of cats with various lower urinary tract diseases requires a multifaceted approach and effective communication between health care team members and owners. Nutritional management plays a key role in the treatment of patients with FIC, struvite disease (uroliths and urethral plugs) and calcium oxalate uroliths. Environmental enrichment (e.g., stress reduction, litter box management) also should be implemented in patients with FIC and may be helpful for cats with other lower urinary tract disorders. For cats with persistent clinical signs, especially periuria, behavioral modification may also be needed to correcting the underlying medical disorder. Finally, other treatments such as pain management may be needed for some cats, especially during acute episodes.

Feeding plans for cats with various lower urinary tract diseases continue the iterative process and include the following steps: 1) assess and select the food, 2) assess and determine the feeding method and 3) reassess and modify the feeding plan, as

Table 46-21. Summary of evidence for treatments used to manage cats with idiopathic cystitis, struvite uroliths or urethral plugs and calcium oxalate uroliths.*

Feline idiopathic cystitis
Grade III
- Environmental enrichment/stress reduction
- Feeding moist food
- Long-term treatment with amitriptyline (6 to 9 months) for severe cases

Grade IV
- Increased salt intake to stimulate urine dilution
- Additional methods to stimulate water intake
- Analgesics and nonsteroidal antiinflammatory drugs during acute episodes
- Feline facial pheromone
- Glycosaminoglycans (pentosan polysulfate, glucosamine/chondroitin sulfate)
- Propantheline during acute episodes

Dissolution of struvite uroliths
Grade III
- Hill's Prescription Diet s/d Feline
- Medi-Cal Dissolution Formula

Grade IV
- Other therapeutic foods formulated to dissolve uroliths

Prevention of struvite urolith or urethral plug recurrence
Grade III
- Hill's Prescription Diet s/d (for urethral plug prevention)

Grade IV
- Other therapeutic foods formulated to prevent struvite disease

Decreasing risk of calcium oxalate recurrence**
Grade III
- Feeding moist food
- Hill's Prescription Diet x/d Feline (currently available as c/d Multicare Feline)

Grade IV
Other therapeutic foods formulated to prevent calcium oxalate
- Potassium citrate
- Thiazide diuretics
- Vitamin B_6
- Using other methods (in addition to moist food) to increase water intake

**Moist foods are best because increased water intake is considered important in the management of feline idiopathic cystitis.

necessary. Four feeding plans are reviewed below, including treatment and prevention of FIC, dissolution of struvite uroliths, prevention of struvite urolithiasis and urethral plugs and managing cats with calcium oxalate urolithiasis.

Regarding the food assessment/selection step: more recently, several foods have been developed that are intended to simultaneously manage the combination of risk factors associated with FIC-, struvite- and calcium oxalate-based FLUTD. These foods are listed in **Table 46-19** and are compared to the composite key nutritional factors for these three forms of lower urinary tract disease. The use of this type of food is intended to simplify and improve the effectiveness of FLUTD prevention strategies. The following sections provide guidelines for successful implementation of feeding plan recommendations and other treatments that may improve outcome and enhance quality of life for cats and their owners. In addition to considering key nutritional factors, the quality of evidence supporting different treatments and foods should be evaluated (Roudebush et al, 2004; Forrester and Roudebush, 2007). **Tables 46-20** and **46-21** provide more information about evidence for treatments of cats with FLUTD.

Feline Idiopathic Cystitis

FIC is characterized by recurrent episodes of lower urinary tract signs that usually resolve within three to five days. Because of the nature of this disorder, complete elimination of episodes is unlikely. Therefore, goals of treatment are to improve quality of life by decreasing frequency of episodes and their severity. Environmental enrichment (e.g., stress reduction, litter box management) should also be implemented in patients with FIC. In cats with persistent clinical signs, especially periuria, behavioral modification may be needed in addition to correcting the underlying medical disorder. Other treatments such as pain management may be needed for some cats, especially during acute episodes. **Boxes 46-5**, **46-6**, and **46-7** include information about environmental enrichment, behavioral modification and pain management.

Assess and Select the Food

Moist foods are recommended for patients with FIC. Feeding moist food has been associated with increased daily water intake and urine volume in cats compared with feeding dry food (**Table 46-14**) (Burger and Smith, 1987; Gaskell, 1989). Beneficial effects have been observed in patients with FIC when urine specific gravity decreased from values around 1.050

Box 46-5. Ancillary Management for Patients with Feline Idiopathic Cystitis: Environmental Enrichment.

In addition to nutritional management, currently recommended treatment for patients with feline idiopathic cystitis (FIC) includes environmental enrichment, stress reduction and appropriate litter box maintenance. Recently, a prospective, uncontrolled study evaluated the effects of multimodal environmental modification in 46 client-owned cats with FIC. Significant reductions in lower urinary tract signs, fearfulness and nervousness were seen after treatment for 10 months, compared with the signs noted before using environmental enrichment.

Environmental enrichment includes providing opportunities for play/resting (e.g., horizontal and vertical surfaces for scratching, hiding places and climbing platforms). Food and water bowls should be clean and kept in safe places (e.g., not next to noisy appliances). Litter boxes should be clean and kept in locations that do not increase stress. An adequate number of litter boxes (generally defined as one more than the number of cats in the home) should be available. Most cats prefer clumping, unscented litter but individual preferences may differ for some cats and different strategies can be used to determine a cat's particular preference. More detailed and helpful information about environmental enrichment and litter box management is available elsewhere.

BEHAVIORAL MANAGEMENT

Even after successful implementation of strategies described above, some patients with FIC (or other lower urinary tract disorders) may continue to urinate in inappropriate locations. This undesirable behavioral pattern may be maintained for several reasons. Classic conditioning may play a role in persistent periuria. The litter box is associated with pain and discomfort that occurred when the cat urinated in the box previously; therefore, the cat might associate this experience with the litter box and avoid using it in the future. In this situation, it may help to change the location or physical characteristics of the litter box. It also is possible for cats to develop a litter box aversion secondary to lack of cleanliness, because the litter box may be used more frequently during episodes of FIC. If this happens, it may help to provide additional litter boxes and/or increase frequency of cleaning the litter box or changing litter. If a cat develops a litter box aversion secondary to FIC or experiences an urgency that causes elimination elsewhere, the possibility exists for development of a secondary location or substrate preference. In this situation, the litter box is not necessarily the problem; however, the cat may discover a better toileting option (e.g., a substrate that is softer, more absorbent, more accessible or cleaned more readily). To resolve this problem, the preferred inappropriate site should be made less attractive or unavailable while the litter box is improved to meet the preferences of the cat. Finally, the pain associated with an episode of FIC may result in increased irritability and subsequent social strife between previously friendly cats in the household. When signs of FIC resolve, cats may not return to their previously friendly relationship. In serious cases, full segregation and gradual reintroduction using desensitization and counter-conditioning may be necessary. Cats with persistent periuria can be very frustrating to manage and may be relinquished to a shelter if not handled appropriately. Therefore, consulting with a veterinary behaviorist (sooner rather than later) should be considered to increase chances of improving quality of life for the cat and the owner. **Boxes 46-6** and **46-7** provide more information about behavioral management of cats with inappropriate urination.

PAIN MANAGEMENT

Analgesics are indicated to manage patient discomfort during acute episodes of FIC. Drugs that have been used include buprenorphine[a] (0.03 mg/kg body weight administered topically via buccal mucosa every six to eight hours), butorphanol[b] (0.5 to 1 mg/kg body weight orally every six to eight hours) and meloxicam[c] (0.1 mg/kg body weight orally once daily for three to four days). Although other analgesics and nonsteroidal antiinflammatory agents may be appropriate, selection is often based on clinician preference or experience and whether the patient has concomitant conditions (e.g., kidney disease) that might preclude their use. No clinical studies have evaluated opioid analgesics (e.g., butorphanol, buprenorphine) or nonsteroidal antiinflammatory agents in patients with FIC.

FELINE FACIAL PHEROMONE

Synthetic feline facial pheromone therapy has been recommended to decrease signs of stress in patients with FIC. In a double-blind, placebo-controlled clinical study of 20 hospitalized cats (13 with lower urinary tract disease and seven apparently healthy), exposure to feline facial pheromone[d] was associated with significant increases in grooming, interest in food and food intake; these results suggested an anxiolytic effect in some cats. Another study evaluated effects of feline facial pheromone in 12 patients with FIC. Although no significant difference was seen between treatment of the environment with placebo and feline facial pheromone for two months, a trend was identified for cats exposed to facial pheromone. Exposed cats had fewer days with clinical signs of cystitis, a reduced number of episodes and reduced negative behavioral traits (e.g., less aggression and fear). Further study is needed; however, it seems reasonable to consider treatment with facial pheromones in cats with signs of stress or when clinical signs persist after implementing environmental enrichment and methods to increase water intake.

GLYCOSAMINOGLYCANS

Glycosaminoglycan (GAG) replacers such as pentosan polysulfate have been used in people with interstitial cystitis and have been recommended for patients with FIC. Anecdotally, these agents have

to values ranging from 1.032 to 1.041 (Markwell et al, 1999; Gunn-Moore and Shenoy, 2004). It is not known if FIC predisposes to urolith formation, but the presence of inflammatory cells and other products of inflammation could conceivably pose such a risk. Foods that are most similar to the key nutritional factor target ranges and/or have the best evidence for managing these uroliths should be considered for cats with FIC. **Tables 46-19** and **46-22** provide key nutritional factor information about selected veterinary therapeutic foods for managing patients with FIC compared with recommended levels of key nutritional factors. When possible, moist foods should be selected over dry foods.

been mentioned as useful. However, only one GAG has been critically evaluated. In a randomized, double-blinded, controlled clinical study, administration of glucosamine hydrochloride[e] (125 mg orally once daily) was not associated with any difference in clinical signs compared with cats that received placebo. If signs of FIC persist despite other treatments, GAGs (such as pentosan polysulfate[f] [8 mg/kg body weight orally q12h] or a combination of glucosamine and chondroitin sulfate[g] [250 mg/200 mg orally q24h]) may be attempted.

AMITRIPTYLINE

Amitriptyline[h] is a tricyclic antidepressant with anticholinergic, antihistaminic, sympatholytic, analgesic and antiinflammatory properties that has been used in treating people with interstitial cystitis and cats with FIC. In an uncontrolled study of cats with severe, recurrent FIC that failed to respond to other treatments, administration of amitriptyline for 12 months was associated with decreased clinical signs in nine (60%) of 15 cats during the last six months of treatment. A randomized, controlled clinical trial of amitriptyline treatment for seven days revealed no significant difference in rate of recovery from pollakiuria or hematuria; overall, clinical signs recurred significantly faster and more frequently in cats that had been treated with amitriptyline compared with control cats. In a similar study, amitriptyline combined with amoxicillin was no more effective than placebo and amoxicillin when given to cats with FIC for seven days. Based on current information, amitriptyline does not appear to be beneficial for short-term management of cats with FIC. It is possible that longer use (i.e., several months) may be helpful; however, this has not yet been demonstrated in a controlled, long-term clinical study.

Assess and Determine the Feeding Method

Gradual transition to moist food and recommending other strategies to increase water intake should be part of initial management of patients with FIC. Cat owners may be hesitant to switch from dry to moist food and some believe their cat will not eat moist food. However, switching to moist food is possible in most situations if the change is made gradually; for some cats this many require a period of several weeks. Failure to make a gradual transition may result in refusal to eat the moist food or increased stress, which may cause recurrence of clinical signs. Therefore, moist food should be offered initially as a food option in a second dish next to the usual food (two-pan approach) (Westropp and Buffington, 2004; Buffington, 2007). If the cat consumes the moist food, the amount of moist food can be increased gradually while decreasing the amount of dry food correspondingly. **Table 46-23** lists tips for increasing water consumption.

Increasing frequency of feeding (i.e., dividing the daily amount of food into several meals) may increase daily water intake in cats. In a study of healthy cats with free access to water, feeding two or three meals per day was associated with a significant increase in total water intake compared with feeding a single meal (Kirschvink et al, 2005).

Reassessment

Clinicians should use their best judgment regarding the most appropriate times for reevaluating patients with FIC. Because of stress associated with hospital visits, it may be preferable to conduct evaluations by talking with owners more often than examining the patient. This allows for discussing effectiveness of current treatments and recommendations for changes if needed. If there are changes in the cat's clinical findings (e.g., increased severity or frequency of episodes) despite appropriate treatment, additional patient evaluation including urinalysis, urine culture and diagnostic imaging is indicated to detect other disorders (e.g., uroliths, UTI).

Feeding Plan for Struvite Urolith Dissolution

Treatment options for cats with struvite uroliths include dissolution by nutritional management and physical removal of uroliths (e.g., cystotomy, voiding urohydropropulsion, catheter retrieval, laser lithotripsy). Treatment selection depends on clinician experience, expertise and preference, availability of necessary equipment, patient factors and client preferences. Considering all factors, it is generally preferred to select the least invasive treatment that has the most evidence for effectiveness.

Two studies reported effects of feeding a dissolution food to cats with struvite uroliths (Osborne et al, 1990; Houston et al, 2004). In one study, 25 cats (13 males, 12 females) with 28 occurrences of struvite uroliths were fed a struvite dissolution food[f] (Osborne et al, 1990). Among cats in the study, there were 20 occurrences of sterile uroliths and eight with UTI (five urease-positive infections, three urease-negative infections). Mean time for sterile struvite urolith dissolution was 36 days (range, 14 to 141 days), while the average time for dissolution of uroliths associated with UTI was 44 days (range, 14 to 92 days). Clinical signs (gross hematuria and dysuria/pollakiuria) were present in 90% or more of urolith occurrences before nutritional management and were absent by the time of first reevaluation in two weeks. None of the cats developed urethral obstruction but perineal urethrostomy had been performed

Box 46-6. Behavioral Screen for Cats with Inappropriate Urination.*

All cats that urinate outside the litter box or in inappropriate places should receive a medical evaluation to identify and address underlying medical disease(s). In some cases, a primary medical reason for inappropriate urination will be identified, treatment implemented and the problem resolved. However, in other cases there will be no primary medical problem identified or even after resolution/control of an identified medical issue, inappropriate urination continues. In the latter case, the medical problem may have been the initiating cause but behavioral issues maintain inappropriate urination, despite successful control/resolution of primary medical problems. For cats with continued inappropriate urination despite diagnosis and management of all primary medical issues, the following questions should be considered:

Question**	Answer
1. Does your cat urinate on vertical surfaces outside the litter box?	☐YES ☐NO
2. Does your cat urinate on horizontal surfaces outside the litter box?	☐YES ☐NO
3. Does your cat seek out certain targets for urination?	☐YES ☐NO
4. Do these targets have a common quality (e.g. all soft, absorbent materials, certain room, always slick surfaces)?	☐YES ☐NO
5. Is the quantity of urine deposited very small?	☐YES ☐NO
6. Does your cat defecate outside the litter box?	☐YES ☐NO
7. Does your cat ever use the litter box?	☐YES ☐NO
8. Does your cat dig in its litter when it uses the litter box?	☐YES ☐NO
9. Is there more than one cat in the household?	☐YES ☐NO
10. Does your cat ever fight or appear frightened of other pets or people in the household?	☐YES ☐NO
11. Are the litter boxes all in the same site/room/area/floor of the home?	☐YES ☐NO

Total number of litter boxes in the house . . . . ________

Indicate number of boxes with each characteristic:

**"YES" answers for Questions 1 and 5 may indicate urine marking.

previously in 10 of the male cats. In another study, 32 cats (10 males, 22 females) with struvite uroliths were fed either a dry or moist version of a dissolution food[g] (Houston et al, 2004). Mean time for dissolution in cats eating moist food (3.73 weeks) was not significantly different from those eating dry food (4.82 weeks) (p = 0.066). Clinical signs resolved in an average of 19 days after beginning nutritional management. No occurrences of urethral obstruction were reported. Approximately 30% of cats had radiographic evidence of urolith disappearance after two weeks of feeding the dissolution food. Time to resolution of clinical signs or urolith dissolution did not differ significantly with the number of uroliths.

Box 46-7. Behavioral Management for Cats with Inappropriate Urination.*

Cats that urinate and/or defecate outside the litter box can do so for a variety of reasons including disease, communication (e.g., marking) and toileting preferences/aversions. Sometimes the medical problem can be an initiating factor for toileting problems. For example, medically triggered urgency to urinate causes the cat to select a convenient location like the bed; but even with resolution of the medical problem, the new behavior persists. These cats develop a new preference for toileting. (e.g., the bed is convenient, nicely absorbent and is cleaned readily) or have such negative associations with the litter box (e.g., painful urination when they were ill) that they persist in using a new, alternative, inappropriate site. Issues that should be addressed in cases of inappropriate elimination are listed below.

Resources	Recommendations	Explanations/consequences
Number of litter boxes	Number of litter boxes = number of cats +1	Too few litter boxes may result in problems that cause a cat to seek alternative toileting sites. These problems may include: volume of excrement in the litter box; box occupied by another cat; box being guarded by another cat.
Location of litter boxes	Should be spread throughout environment in easily accessible locations	Clustering litter boxes in one location may create access problems. These problems may include: guarding by another cat and physical challenges (e.g., stairs/distance) with getting to the litter box location.
Litter box style	Large	Boxes that are too small may be uncomfortable for cats to use, causing them to seek out other sites.
	Uncovered	Boxes that are covered may trap odors, creating an unpleasant environment and causing the cat to seek other toileting sites.
Litter	Clumping (sand-like) Unscented	Although individual preferences exist, the majority of cats prefer unscented clumping (finely particulate matter–similar to sand) litter.
Litter box hygiene	Daily litter box scooping Complete litter box cleaning/change every 1 to 4 weeks	Cats tend to be fastidious and prefer clean toileting locations. Frequency of full box cleaning (wash/new litter) will depend on litter type; clumping type litters that allow owners to remove urine may require less frequent changes.
Scratching posts/pads	Multiple, sturdy, tall, prominently located	Scratching is a form of marking behavior. Encouraging scratch marking on appropriate targets may reduce the likelihood of other forms of marking and prevent destruction of household items.
Resting perches	Multiple, single cat sized, elevated, upholstered surfaces	Creative use of vertical space in the home can reduce inter-cat tension/aggression. Cats tend to prefer upholstered surfaces over slick surfaces but individual preferences may exist.
Feeding/water stations	Number of stations = number of cats	Providing adequate resources spread throughout the environment allows cats to self-segregate; this may help to reduce social tension in multi-cat households.
Play/social interaction	At least 2 to 3 daily short sessions (5 to 10 minutes)	Cat age and personality may affect type and duration of interaction but it is important to recognize that domesticated cats are social and will often benefit from play/interaction. Indoor-only cats can especially benefit from owner-initiated activity such as play with toys for overall stress reduction and exercise. Play activity also enhances the family-pet bond and is useful for overweight cats.

*Adapted from Neilson JC. FLUTD: When should you call the behaviorist? In: Proceedings. Hill's Symposium on Feline Lower Urinary Tract Disease, 2007: 20-28 (www.hillsvet.com/conferenceproceedings).

Despite evidence for effectiveness of nutritional management for dissolving struvite uroliths, many veterinarians still prefer to surgically remove uroliths because of perceptions that surgical management is more effective, is less expensive overall when considering monitoring and aftercare, controls clinical signs quicker and will not be associated with urethral obstruction as uroliths decrease in size, especially in male cats. Although surgical removal of uroliths has not been critically evaluated in cats, a retrospective study of 37 dogs and 29 cats with urinary bladder uroliths revealed that four cats (14%) and eight dogs (22%) had incomplete removal of uroliths by cystotomy in a veterinary teaching hospital (Lulich et al, 1993a; Lulich and Osborne, 2007).

Assess and Select the Food

Table 46-24 provides nutrient information about foods compared with recommended levels of key nutritional factors for dissolution of struvite uroliths. Generally the food that most closely matches the recommendations should be selected; however, only two foods[f,g] have published clinical evidence of effectiveness. Treatment with a struvite dissolution food is contraindicated in growing kittens, reproducing queens and

Table 46-23. Tips for increasing water consumption in cats.

Food
Feed moist food
Add small amount of water to moist food
Add warm water to dry food
Divide daily food amount into several smaller meals
Add flavor enhancers to food
- Low-sodium chicken or beef broth
- Clam juice
- Tuna juice (low sodium)

Water
Use fresh, clean water at all times (change at least once daily)
Try water from different sources
- Tap water
- Filtered water
- Bottled water
- Distilled water

Place ice cubes in water or provide cold water
Offer frozen cubes of water mixed with low-sodium tuna juice, etc.

Containers
Use non-reflective bowls for food and water
Use wide bowl so whiskers do not touch sides
Ensure ideal location of water and food bowls
- Quiet, draft-free environment (avoid noisy appliances, near vents)
- In areas where cats can escape if needed
- Not in same area as litter boxes
- On different levels of multi-floor house

Provide access to other sources of water
- Water fountains with circulating water
- Dripping faucet

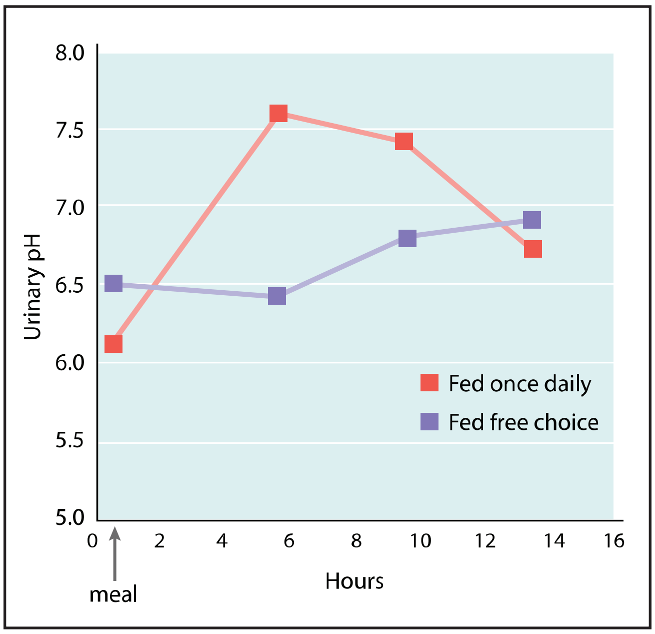

Figure 46-18. Mean urinary pH of cats fed a commercial food either free choice (i.e., ad libitum) or once daily. Note how once daily feeding results in a significant increase in urinary pH (i.e., postprandial alkaline tide). (Adapted from Taton DF, Hamar D, Lewis LD. Evaluation of ammonium chloride as a urinary acidifier in the cat. Journal of the American Veterinary Medical Association 1984; 184: 433-436.)

patients with metabolic acidosis or hypokalemia. In addition, struvite dissolution foods with increased amounts of sodium may not be ideal for patients with concomitant conditions including chronic kidney disease, hypertension or congestive heart failure.

Assess and Determine the Feeding Method

Cats with suspected struvite uroliths (usually <7 years of age, often with alkaline urinary pH, struvite crystalluria and/or radiopaque uroliths) can usually be transitioned to a dissolution food over a seven-day period. The method of feeding influences urinary pH values throughout the day and therefore may affect the success of the struvite dissolution protocol. When fed free choice, most cats will eat small amounts every few hours, resulting in a smaller but more prolonged alkaline tide than with meal feeding (**Figure 46-18**) (Taton et al, 1984). The smaller alkaline urinary pH excursions observed with free-choice feeding may improve dissolution of struvite uroliths and thus may be the preferred method of feeding. However, this has not been confirmed. Also, dry foods are most likely to be fed free-choice; nevertheless, feeding moist food is preferred for dissolution of struvite uroliths and managing most other types of uroliths and FIC.

If a UTI has been diagnosed, an appropriate antimicrobial drug should be administered for two to four weeks beyond removal or radiographic disappearance of uroliths. Although most cats do not have UTI, infection with urease-producing organisms may cause struvite uroliths in some cases and other bacteria may cause UTI secondary to uroliths in others.

Reassessment

During the time a dissolution food is being fed, cats should be reevaluated every two to four weeks. A thorough nutritional history should be collected, including amounts of all foods and supplements given; this is especially helpful when uroliths do not decrease in size as expected. Urinalysis is indicated to evaluate urinary pH and examine urine sediment for presence of abnormalities (e.g., crystalluria, pyuria). When interpreting pH of a spot or random urine sample, consider when the sample was collected relative to the time of eating. Samples obtained early in the morning, before food is offered, tend to be more acidic, whereas samples obtained within several hours of eating tend to be more alkaline (because of the postprandial alkaline tide). When evaluating effects of a food change on urinary pH, standardize the time of collection relative to the time of eating. For most accurate results, urinary pH should be measured using a pH meter. Urine culture should be done in cats with UTI to confirm the absence of infection during treatment with antimicrobial drugs and one week after completion of treatment to confirm eradication of UTI. Abdominal radiographs should be taken to evaluate number and size of uroliths compared with previous results. Nutritional management should be continued for one month beyond radiographic evidence of urolith(s) dissolution. If uroliths do not dissolve completely or decrease in size after two months of feeding a dissolution food exclusively, a different treatment (urolith removal) should be considered.

Figure 46-19 is an algorithm to assist in managing patients with struvite urolithiasis (Lulich, 2007a).

The rate of urolith recurrence has not been critically evaluated in cats. However, a recently published abstract described the rate of urolith recurrence in cats that had uroliths submitted for quantitative analysis at the Minnesota Urolith Center in 1998 (Albasan et al, 2006). Recurrence (defined as subsequent urolith submission) was detected in 2.7% of 1,821 cats with struvite uroliths; 0.2% of cats had a second recurrence. Mean time to initial recurrence was 27 months. Urolith recurrence was 1.6 times higher in females than males. Because some uroliths associated with recurrent episodes were likely not submitted for analysis, the actual recurrence rate for struvite uroliths was likely higher.

Box 46-8. Regulatory Claims Related to Feline Urinary Foods in the United States, Canada and the European Union.

The United States Food and Drug Administration, Center for Veterinary Medicine (FDA-CVM) has issued guidelines for pet-food companies to establish the following claims: "reduces urinary pH," "low magnesium" and "improves urinary tract health." The FDA-CVM suggests that submissions requesting permission to make "reduces urinary pH" or "improves urinary tract health" claims include supportive utility data demonstrating efficacy (i.e., the ability of the food to produce appropriately acidic urine compared with a non-acidifying control food) and safety data.

Foods with label claims such as "helps maintain urinary tract health" are low in magnesium and produce appropriately acidic urine. The FDA-CVM has promulgated guidelines for protocols to support urinary tract health claims. The guidelines focus on prevention of struvite urinary precipitates, but do not address the question of calcium oxalate precipitate formation.

Guidelines suggest safety studies for a minimum of six months. These studies should include physical examinations and the following observations: food consumption, body weight measurements, urinalyses (including sediment examinations), serum biochemistry and blood gas analyses and mineral (calcium, phosphorus, magnesium and potassium) balance studies. Foods claiming to promote urinary tract health and reduce urinary pH must be nutritionally complete and balanced, as demonstrated by the Association of American Feed Control Officials (AAFCO) feeding protocols. It is noteworthy that the "improves urinary tract health" claim focuses on documentation of safety, urine acidification and restricted dietary intake of magnesium and does not in any way address the issue of calcium oxalate urolith formation.

The guideline for a low-magnesium claim is a magnesium level guaranteed less than 0.12% dry matter, using the maximum magnesium and maximum water guarantee. The magnesium must also be less than 25 mg/100 kcal, with energy content based on the AAFCO-approved calculation method or an actual digestibility study. Analysis of multiple batches is required. The FDA-CVM does not allow the claim of "low ash" on cat food labels. Current scientific information does not demonstrate that ash per se is related to the incidence of lower urinary tract disease. Ash content can only be included in the guaranteed analysis of the food.

The Canadian Veterinary Medical Association (CVMA) Pet Food Certification Program has established guidelines for nutrient standards for magnesium-restricted/pH-controlling cat foods. These foods must meet the following requirements:

Magnesium levels must be no more than 0.1% and no less than 0.05%, dry matter basis.

Magnesium levels per 100 kilocalories (kcal) of metabolizable energy (ME) shall be no more than 20 milligrams.

The average resting urinary pH shall be 6.5 or less, and the average postprandial peak pH shall not exceed 7.0.

In July 1995, labeling of veterinary therapeutic foods in Europe (termed "dietetic pet foods") became strictly regulated (Chapter 9). European regulations require only certain indications for therapeutic foods, termed "Particular Nutritional Purposes." Indications permitted for feline lower urinary tract disease include: 1) dissolution of struvite uroliths, 2) reduction of struvite urolith recurrence, 3) reduction of oxalate urolith formation, 4) reduction of urate urolith formation and 5) reduction of cystine urolith formation. Essential nutritional characteristics of the corresponding foods and specific label declarations must be met.

The Bibliography for **Box 46-8** can be found at www.markmorris.org.

After dissolution or removal of struvite uroliths, further nutritional management is indicated to prevent recurrence. (See Feeding Plan for Prevention of Struvite Urolithiasis and Urethral Plugs.) If UTI with urease-producing bacteria was the cause of uroliths, controlling infections may prevent urolith recurrence; however, most uroliths in cats are either sterile or cause secondary infections. It is unknown how long struvite preventive foods should be fed. Struvite disease is more common in young- to middle-aged cats; however, as cats age, the risk of calcium oxalate urolithiasis increases. Cats eating struvite preventive foods should be monitored periodically for crystalluria and urinary pH values. If no episodes of struvite uroliths occur for several years, consider recommending a high-quality wellness food that avoids excessive magnesium and phosphorus, as cats get older. Cats should still be monitored periodically for occurrence of alkaline urinary pH, struvite crystalluria and urolith recurrence.

Struvite uroliths may recur months to years after removal or dissolution, particularly if preventive measures are not implemented (Osborne et al, 1990). Interpretation of recurrence of uroliths (of any mineral type) and interval until recurrence should be based on answering a number of questions (Lulich et al, 1993). 1) *Were all uroliths removed from the urinary tract at the time of surgery or other procedure?* Recurrence of uroliths following surgery is commonly attributed to failure of medical therapy to prevent urolith formation. However, this hypothesis is based on the premise that all stones were completely removed from the urinary tract before beginning preventive measures. Incomplete surgical removal of uroliths probably occurs more frequently than recognized, even when performed by experienced surgeons (Lulich et al, 1993a; Lulich and Osborne, 2007). 2) *Did nonabsorbable suture materials left exposed in the lumen of the urinary bladder during surgery provide a nidus for precipitation of crystalline material?* In 2005, the Minnesota Urolith Center analyzed uroliths from more than 32,000 dogs; nonmineral, foreign material was identified in uroliths from 96 dogs and 86 of these submissions contained a nidus of suture material (Lulich and Osborne, 2007). Uroliths from an additional 235 dogs contained a hollow cylindrical track consistent with formation around suture material. On the basis of these findings, approximately 1% of canine uroliths would be best prevented by more appropriate selection and placement of sutures. Similar data for cats have not been reported; however, it seems reasonable that inappropriate surgical techniques also

could predispose to development of feline uroliths. 3) *What diagnostic methods were used to detect recurrence?* 4) *How often was the patient evaluated for recurrence?* 5) *Were recommendations to decrease likelihood of recurrence given and was the owner able to follow them?* 6) *Has infection with a urease-producing microorganism persisted or recurred?* Most uroliths in cats are not associated

*Nutrients expressed on a dry matter basis unless otherwise stated.
**In general, moist foods should be fed to cats with FLUTD.

Table 46-27. Stepwise approach for management of calcium oxalate urolithiasis in cats.*

1. Obtain baseline data (post-removal radiographs, complete urinalysis, serum concentrations of calcium, urea nitrogen and creatinine) to evaluate effectiveness of removal procedure, renal function and calcium homeostasis.
2. If the patient is hypercalcemic, correct underlying cause. If no cause is identified (i.e., idiopathic hypercalcemia exists) consider high-fiber foods and potassium citrate to decrease urine acidity.
3. If the patient is normocalcemic, consider foods with reduced oxalate, sodium and protein that do not promote formation of overly acidic urine (pH <6.2). Ideally foods should contain additional water and citrate and have adequate phosphorus and magnesium. Avoid excess vitamins C and D.
4. Reevaluate patient in two to four weeks to verify compliance with nutritional recommendations (urine specific gravity and pH) and amelioration of crystalluria (urine sediment examination). For most accurate results, urinary pH should be measured using a pH meter.
5. If calcium oxalate crystals or concentrated urine (specific gravity >1.030) persist, consider moist foods or additional water added to current food. If calcium oxalate crystals or aciduria persist (urinary pH <6.2), consider additional potassium citrate.
6. Reevaluate patient in two to four weeks to verify compliance with nutritional recommendation (urine specific gravity and pH) and amelioration of crystalluria (urine sediment examination). If calcium oxalate crystalluria persists, and patient is consuming a homemade food, consider vitamin B_6 supplementation (2 to 4 mg/kg every 24 hours).
7. After three to six months, reevaluate patient to verify compliance with nutritional recommendations, amelioration of crystalluria and lack of urolith recurrence (abdominal radiography). If no uroliths are present, continue present therapy and reevaluate in three to six months. If uroliths have recurred, consider nonsurgical urolith removal. Consider using voiding urohydropropulsion in females or male cats with a previously performed perineal urethrostomy. If unsuccessful, surgery can be considered if clinical signs referable to urocystolithiasis persist. If clinical signs are not present, continue therapy to minimize urolith growth.

with UTI; however, some cats will develop struvite uroliths associated with urease-producing organisms. 7) *Has an underlying anatomic defect gone uncorrected?*

Feeding Plan for Prevention of Struvite Urolithiasis and Urethral Plugs

Generally, appropriate nutritional management is the most important consideration for prevention of recurrence of struvite uroliths and urethral plugs.

Assess and Select the Food

Foods that are most similar to the key nutritional factor target ranges and/or have the best evidence for managing the patient's disorder should be selected. Information about content of many nutrients (e.g., magnesium, calcium, phosphorus and sodium) and target urinary pH ranges are not required on pet food labels. **Tables 46-19** and **46-25** provide lists of selected veterinary therapeutic foods marketed for prevention of struvite urolithiasis (and urethral plugs) and compare their key nutritional factor content to the recommended levels of key nutritional factors. The foods listed in **Table 46-19**, in addition to struvite-associated disease, are intended to co-manage FIC- and calcium oxalate-based FLUTD. These foods are compared to composite key nutritional factors for the aforementioned types of lower urinary tract disease. For foods under consideration that are not listed in **Tables 46-19** and **46-25**, contact the manufacturer or review published information to determine key nutritional factor content. For cats that have urethral plugs composed only of matrix or other substances (e.g., epithelial cells or mucus), feeding the moist form of the selected food is recommended.

Regarding urethral plugs, a struvite dissolution food (**Table 46-24**) may be appropriate for initial management (i.e., one to three months) after relieving obstruction. (See Feeding Plan for Struvite Urolith Dissolution, above.) However, such a food should not be fed long term because of risks associated with prolonged, excessive urinary acidification (urinary pH <6.0).

Several commercially available foods have claims for struvite prevention; however, only one has been evaluated in cats with urethral plugs. In a randomized, prospective study of cats with urethral plugs, effectiveness of feeding this food was compared with perineal urethrostomy alone and perineal urethrostomy plus the calculolytic food[f] (Osborne et al, 1991). During the one-year study, urethral obstruction was not observed in any group. This study did not include an untreated control group; however, recurrence rates for urethral obstruction in two other studies were 35 and 36% (Bovee et al, 1979; Gerber et al, 2007). Bacterial UTI occurred in 40 to 50% of cats that had perineal urethrostomies, but was not observed in cats managed by the calculolytic food alone. Several foods formulated for struvite prevention have been evaluated by measuring values for struvite saturation in healthy cats (Bartges et al, 1998; Abood et al, 2000; Devois et al, 2000; Xu et al, 2006).

Urinary tract health claims on pet food labels may be of some help in evaluating foods (**Box 46-8**). In the U.S., a food with a "low magnesium" claim contains a maximum of 0.12% DM magnesium or 25 mg magnesium/100 kcal ME.

Depending on the amount fed, treats and other supplements can significantly alter the key nutritional factor profile of the desired dietary regimen and may decrease the effectiveness of appropriately formulated therapeutic foods. Some commercial cat treats or foods, and processed human foods may have very high levels of magnesium or phosphorus and their effect on urinary pH is hard to predict. Most pet owners give their pets treats or supplement their pets' primary food with other foods, either another cat food or human food. Therefore, it is important for veterinary health care team members to educate owners about the importance of compliance to the successful outcome. This is especially true for cats that are at risk for urethral obstruction. Owners aware of the risks may be more willing to avoid feeding other foods or products and encourage their cats only to eat the recommended therapeutic food.

Assess and Determine the Feeding Method

Cats should be transitioned gradually to a food formulated to decrease occurrence of struvite crystalluria. The method of feeding influences urinary pH values throughout the day and therefore may affect success of the dietary management protocol. Ingestion of food stimulates secretion of acid by gastric parietal cells with subsequent secretion of bicarbonate into the blood in exchange for chloride ions. This alkali load transiently increases urinary bicarbonate and pH (i.e., postprandial alkaline tide) unless offset by absorption of acidifying ingredients. When offered food free choice, most cats will eat small amounts every few hours, resulting in a smaller but more prolonged alkaline tide than with meal feeding (**Figure 46-18**) (Taton et al, 1984). The smaller alkaline urinary pH excursions observed with free-choice feeding may reduce the likelihood of struvite precipitate formation, and thus may be the preferred method of feeding to prevent struvite associated disease; however, this has not be confirmed in clinical studies. Free-choice feeding may be associated with obesity; however, which in turn is a risk factor for lower urinary tract diseases in general. In addition, free-choice feeding is most likely to be done using dry food, and moist food is preferred for managing urolithiasis and FIC.

Based on information currently available, meal-feeding moist food would seem to be best for most cats with struvite disease because of increased water intake and reduced concentration of crystal-forming elements. However, less evidence supports this benefit compared with cats that have calcium oxalate uroliths. If meal feeding is associated with increased urinary pH throughout the day and significant struvite crystalluria or recurrent uroliths or urethral plugs, another feeding method should be considered (e.g., feeding dry food or feeding multiple small meals of moist food).

Reassessment

Cats eating struvite preventive foods should be monitored periodically for evidence of crystalluria and urinary pH values. If no episodes of struvite uroliths occur for several years, it would be appropriate to consider switching to a high-quality wellness food that maintains an appropriate urinary pH and avoids excessive magnesium and phosphorus.

Feeding Plan for Calcium Oxalate Urolithiasis

Calcium oxalate uroliths are not amenable to medical dissolution and must be removed by surgery, voiding urohydropropulsion, lithotripsy or other techniques. An alternative to cystotomy is voiding urohydropropulsion if urocystoliths are small enough to pass through the urethra (Lulich et al, 1993). Voiding urohydropropulsion is generally more successful in queens than in tomcats because the urethra is larger in females than in males. Voiding urohydropropulsion is usually ineffective in cats with uroliths lodged in the urethra. After urolith removal, medical protocols to minimize recurrence should be implemented. Goals of nutritional management include decreasing urine calcium and oxalate concentrations, promoting high concentrations of urolith inhibitors, decreasing urine acidity and decreasing urine specific gravity (i.e., urine dilution).

Assess and Select the Food

Several commercially available therapeutic foods are marketed for prevention of calcium oxalate uroliths in cats. No foods have been studied to determine if they prevent urolith recurrence and only one food[e] has been evaluated in cats with naturally occurring calcium oxalate uroliths (Lulich et al, 2004). In a study of 10 cats with confirmed calcium oxalate uroliths, urinary calcium oxalate saturation was measured before beginning the study and after feeding the therapeutic food. Using a crossover design, half of the cats were randomly assigned to continue their regular food and the other half were assigned to eat the therapeutic food. After eight weeks, the foods were switched and fed for another eight weeks. Urinary calcium oxalate saturation values (i.e., activity product ratios and relative supersaturation values) were determined and compared between groups (regular vs. therapeutic food). Results revealed that hypercalciuria was a consistent abnormality in urolith-forming cats and urinary calcium oxalate saturation was significantly lower in cats fed the therapeutic food compared with regular food. This

study concluded that feeding the therapeutic food decreased the risk of urolith recurrence.

Tables 46-19 and **46-26** list selected veterinary therapeutic foods marketed for prevention of calcium oxalate urolithiasis and compare their key nutritional factor content to the recommended levels. The foods listed in **Table 46-19** are also intended to co-manage FIC- and struvite-based FLUTD. These foods are compared to composite key nutritional factors for all three of these types of lower urinary tract disease. For foods under consideration that are not listed, contact the manufacturer or review published information to determine levels of key nutritional factors. Foods that are most similar to the key nutritional factor target ranges and/or have published evidence of efficacy for managing calcium oxalate urolithiasis should be selected. Owners of cats that form calcium oxalate crystals and uroliths should be cautioned about grocery brand foods with urinary tract health claims because these foods are formulated for healthy cats to avoid struvite crystals and uroliths. Feeding such foods may actually increase the risk of developing calcium oxalate uroliths. The standard of care for decreasing risk of calcium oxalate urolith recurrence is to feed moist food and encourage water intake (**Table 46-23**). In addition, owners should be advised to avoid giving treats with increased amounts of calcium or oxalate (**Tables 46-15** and **46-18**). These foods/products may increase urinary excretion of calcium and oxalate, which increases the risk for development of uroliths.

Therefore, veterinary health care team members need to educate owners about the importance of nutritional management in the treatment of cats with calcium oxalate disease, especially cats at risk of urethral obstruction. Increasing owners' awareness may lead to better compliance.

Assess and Determine the Feeding Method

Based on information currently available, meal feeding moist food is appropriate to manage cats with calcium oxalate uroliths. Moist foods increase water intake and reduce concentrations of crystal-forming elements. The method of feeding influences urinary pH throughout the day and therefore may affect success of managing cats with calcium oxalate urolithiasis. Although calcium oxalate crystalluria is not as pH dependent as is struvite crystalluria formation, management of urinary pH is still important. As discussed above, ingestion of food stimulates a postprandial alkaline tide, unless offset by acidifying ingredients in the food. When offered food free choice, most cats will eat small amounts every few hours, resulting in a smaller but more prolonged alkaline tide than with meal feeding (**Figure 46-18**) (Taton et al, 1984). Thus, it has been suggested meal feeding, rather than feeding multiple small meals per day (as in free-choice feeding), might lower the risk of calcium oxalate urolith formation because of the production of a more alkaline urinary pH (Bartges and Kirk, 2006).

Reassessment

Of cats with calcium oxalate uroliths submitted to the Minnesota Urolith Center in 1998 (n = 2,393), 169 (7.1%) had a recurrence (i.e., subsequent urolith submission), 15 (0.6%) had a second recurrence and two (0.1%) had a third recurrence (Albasan et al, 2006). Mean recurrence times were 23, 38 and 48 months, respectively. Urolith recurrence rate was not different between males and females. It is likely that uroliths from some cats with recurrences were not submitted for subsequent evaluation; therefore, the actual recurrence rate was probably higher. Further study is needed to better define recurrence rates for calcium oxalate uroliths in cats.

All cats should be monitored for recurrence, including urinalysis every three months to detect calcium oxalate crystalluria and diagnostic imaging every six months to detect uroliths. Serum calcium concentration should be monitored in cats with hypercalcemia. If uroliths recur, less-invasive procedures (e.g., voiding urohydropropulsion) are more likely to be effective when uroliths are smaller. **Table 46-27** summarizes the steps for managing cats with calcium oxalate urolithiasis. **Box 46-9** reviews other treatments for calcium oxalate urolithiasis

CONCLUSION

The most common forms of FLUTD include FIC, struvite disease (uroliths and urethral plugs) and calcium oxalate uroliths. Trends in occurrence of urolith types have changed in the past 25 years. Many risk factors have been identified for FLUTD, in general; however, additional study is needed to determine pathogenesis and show a cause-and-effect relationship. Although many treatments have been recommended for FIC, only a few have been evaluated by controlled, randomized clinical trials in cats with naturally occurring disease. When evaluating treatment, consider those options that have the highest level of evidence for effectiveness (**Tables 46-20** and **46-21**) (Roudebush et al, 2004; Forrester and Roudebush, 2007). Feeding moist food and recommending other methods to increase water intake are appropriate for the most common forms of FLUTD including FIC, urolithiasis and urethral plugs. In addition, implementing environmental enrichment and stress reduction is indicated for patients with FIC. Feeding a therapeutic food for one to two months is a very effective method for dissolving struvite uroliths in cats. Foods formulated to prevent recurrence of struvite uroliths or urethral plugs are indicated after urolith dissolution or removal of urethral plugs. Treatment for calcium oxalate uroliths involves urolith removal, followed by feeding moist food formulated to decrease risk of urolith recurrence. Cats with lower urinary tract disorders should be monitored periodically by performing urinalyses and diagnostic imaging to detect recurrence of their original disease, development of a different lower urinary tract disorder or occurrence of adverse events associated with therapeutic interventions. The therapeutic regimen can then be modified as needed.

Box 46-9. Additional Treatments for Calcium Oxalate Urolithiasis.

VITAMIN B_6

Deficiency of vitamin B_6 has been associated with increased urinary oxalate excretion; however, it has not been shown to cause calcium oxalate uroliths. Additional vitamin B_6 is unlikely to benefit cats eating most commercial foods; however, if a cat with calcium oxalate uroliths is being fed a homemade food, it would be appropriate to supplement with vitamin B_6 (2 to 4 mg/kg body weight orally once daily).

THIAZIDE DIURETICS

Thiazide diuretics are known to cause renal tubular reabsorption of calcium, resulting in decreased urine calcium excretion, which may decrease likelihood of calcium oxalate urolith recurrence. Thiazide diuretics have been used for treatment of calcium oxalate urolithiasis in people but no studies have been reported in cats with calcium oxalate uroliths. In a blinded, placebo-controlled crossover study performed with healthy cats, administration of hydrochlorothiazide suspension (1 mg/kg orally q12h) was associated with significantly decreased urinary saturation of calcium oxalate compared with placebo. For cats with recurrent calcium oxalate uroliths despite feeding a therapeutic food and increasing water intake, thiazide diuretics may be considered. Thiazide diuretics should not be used in cats with hypercalcemia.

POTASSIUM CITRATE

Increased urinary citrate may form soluble complexes with calcium, making it unavailable to form calcium oxalate uroliths. Citrate inhibits calcium oxalate crystal formation by promoting formation of alkaline urine and by forming complexes with calcium (**Figure 1**). When citrate complexes with calcium, ionic calcium concentration and urine saturation with calcium oxalate are reduced.

Hypocitraturia is reported to occur in 19 to 63% of human patients with calcium oxalate urolithiasis; however, frequency of hypocitraturia in cats with calcium oxalate urolithiasis is unknown. Changes in acid-base status influence renal handling of citrate. Metabolic acidosis virtually eliminates urinary citrate excretion by promoting citrate oxidation. Acidosis favors influx of citrate into renal mitochondria and inhibits efflux of citrate from mitochondria. Tubular and peritubular citrate uptake increases when cytosolic citrate concentration decreases. Increased reabsorption of citrate reduces urinary citrate excretion. The citrate in urine is the small quantity that escapes reabsorption. In metabolic alkalosis, urinary citrate increases because mitochondrial uptake and thus oxidation of citrate is reduced, cytosolic citrate concentration increases, reabsorption decreases and urinary excretion of citrate increases.

Thus, depending in part on the acid-base status of the patient, dietary citrate may have little effect on urinary citrate. Feeding up to 100 mg of citric acid/kg body weight to cats has been shown to have little effect on urine citrate concentrations. Effects of potassium citrate alone on urinary calcium oxalate saturation or urolith recurrence have not been evaluated in healthy cats or cats with calcium oxalate uroliths. One therapeutic food[a] containing potassium citrate was associated with decreased urinary calcium oxalate saturation in cats with calcium oxalate uroliths. Potassium citrate (50 to 75 mg/kg body weight orally q12h with food) should be considered in cats that have recurrent calcium oxalate uroliths despite using other measures (e.g., feeding moist food or therapeutic food, increased water intake).

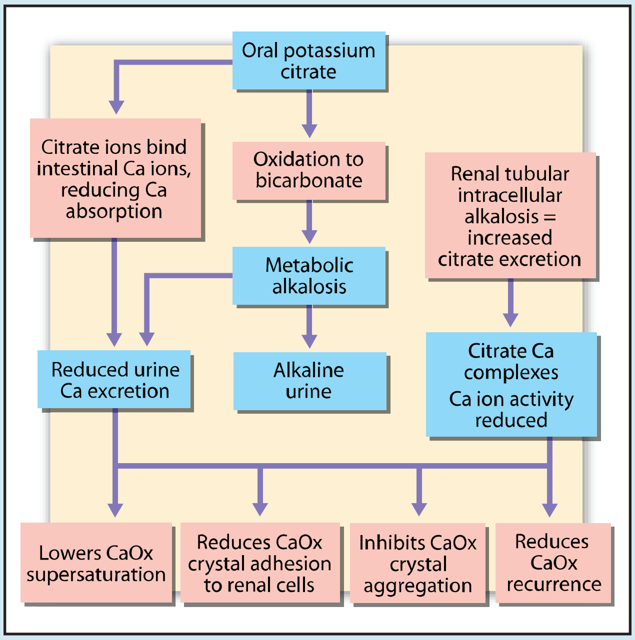

Figure 1. Schematic depicting the role of citrate in binding intestinal calcium (Ca) ions and reducing calcium absorption, promoting formation of alkaline urine and preventing calcium oxalate (CaOx) urolith formation.

Chapter 47

Periodontal Disease

Ellen I. Logan
Robert B. Wiggs
Dale Scherl
Paul Cleland

"Because periodontal disease is the most common problem affecting dogs and cats of all age groups, programs to prevent periodontal disease should be considered among the most important prophylactic services we can offer."
Gregg A. Dupont

INTRODUCTION

Primary oral diseases can be subdivided into conditions affecting the tooth, the periodontium or other oral tissues (**Table 47-1**). Diseases that affect tooth structure (**Figure 47-1**) may result in lesions of the periodontal apparatus, oral mucosa or both. Diseases affecting the periodontium may result in exfoliation of teeth. Additionally, primary diseases of other organs may cause oral lesions and are important considerations in formulating differential diagnoses. Furthermore, oral disease can contribute to diseases of other organs and body systems.

Periodontal disease is the principal cause of tooth loss in dogs and cats. Food can influence periodontal disease through control of plaque and thus is the primary focus of this chapter. Oral health is achieved through professional care and effective homecare; however, compliance is a significant issue in veterinary dentistry (**Box 47-1**). Traditional methods of plaque control such as toothbrushing may be difficult for clients to accomplish. Therefore use of an effective dental food can be an appropriate and effective means of daily plaque control and oral health maintenance for dogs and cats.

The steps in promoting oral health in dogs and cats include: 1) controlling plaque, the cause of periodontal disease, 2) assessing the level of plaque control necessary to prevent gingivitis in each patient, 3) determining each pet owner's ability to control substrate accumulation and selecting methods most likely to ensure compliance, 4) feeding a food with an appropriate texture and nutritional profile and 5) recognizing that oral health may affect systemic health; therefore, a healthy oral cavity may affect longevity and quality of life.

CLINICAL IMPORTANCE

Prevalence of Periodontal Disease

Periodontal disease is the most common disease of adult dogs and cats. As early as 1899, Eugene Talbot described "interstitial gingivitis or so-called pyorrhoea alveolaris" found in dogs at necropsy (1899). In 1939, Wright noted that "the incidence of

Table 47-1. Conditions affecting the oral cavity.

Pulpitis	Periodontitis
	Ulcers

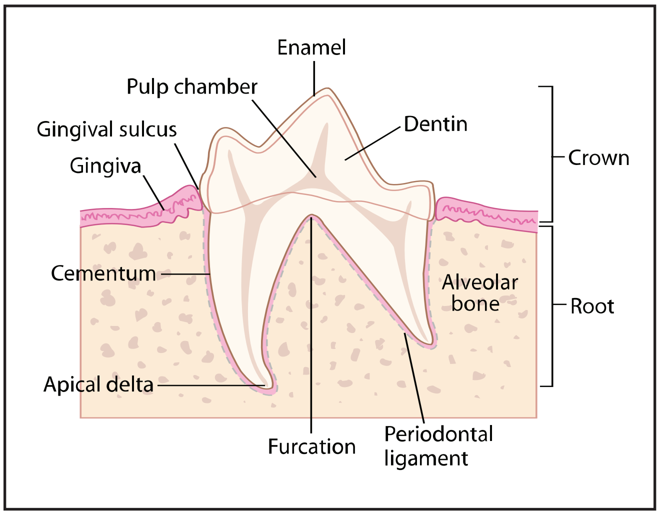

Figure 47-1. Normal tooth and periodontal anatomy.

disease of the teeth in the dog is so high that dental surgery occupies a prominent place in the work of the veterinarian engaged in small-animal practice. The most common affection necessitating surgical interference is paradontal disease" (1939).

Periodontal disease has been observed in dogs and cats of varying breed, gender and age. Surveys from several countries report prevalence rates of periodontal disease that range from 60 to more than 80% of dogs and cats examined (Gray, 1923; Bell, 1965; Rosenberg et al, 1966; Saxe et al, 1967; Gad, 1968; Hamp et al, 1975; Hamp and Lindberg, 1971; Sorensen et al, 1980; Page and Schroeder, 1979; Golden et al, 1982; Reichart et al, 1984; Isogai et al, 1989; Harvey, 1992; Hoffman and Gaengler, 1996).

Data from the National Companion Animal Study representing 54 veterinary practices across the United States confirmed that oral disease was the most frequent diagnosis in all age categories of 39,556 dogs and 13,924 cats (Lund et al, 1999).

PATIENT ASSESSMENT

History

A complete history is important to diagnosis and treatment planning and is an integral tool for developing a complete health maintenance program for pets. An adequate health history must include: 1) information about previous medical and surgical procedures, 2) current preventive measures such as vaccination status and heartworm medication administration, 3) the pet's general environment, including confinement, 4) information about other household pets and 5) who in the household is responsible for primary care.

Inquiries specific to nutrition and oral care should include past and present information about: 1) oral hygiene and level of compliance, 2) presence of any signs that may be related to oral dysfunction, 3) chewing behavior, 4) access to rocks and other materials that may cause occlusal trauma, 5) access to dental treats and toys, 6) eating behavior and 7) foods eaten, with special attention given to texture and other factors.

Box 47-1. Compliance and Dental Homecare.

Oral health is achieved through an effective periodontal management program that includes professional care and client-provided homecare. Appropriate homecare recommendations consider the client and patient preferences and specifically address the degree of oral pathologic change present and client and patient compliance.

Compliance is critical to effective homecare. Clients must be willing and able to perform the recommended hygiene and the patient must accept oral hygiene procedures. Noncompliance may result from lack of an effective recommendation by the veterinary health care team. A comprehensive study of compliance demonstrated that appropriate periodontal therapy was not provided for approximately 15.5 million dogs and cats with recorded periodontal disease scores of 2, 3 or 4. No recommendation for periodontal management was given in 66% of cases with a recorded periodontal disease score of 1. In the same study, 19% of patients lacked any notation of periodontal examination or score in health records.

Even with client education and good pet compliance, some owners are unable to provide routine and effective plaque control. Compliance failure may be due to: 1) lack of skill, 2) lack of perceived benefit, 3) unpleasantness of procedure, 4) lack of noticeable impact and 5) lifestyle constraints. Emphasizing the benefits, including improved oral and systemic health, less breath odor, cost effectiveness and strengthening of the owner-pet bond, may increase compliance.

The most important part of periodontal therapy is how well a patient maintains oral health. Long-term success depends on the degree of plaque control the client is capable of providing between professional visits.

Physical Examination

Initial Oral Examination

Examination of the skull and oral cavity should be a regular part of every physical examination. An extraoral examination should be done before opening the mouth to inspect the skull and facial areas for any abnormalities, such as muscle atrophy, swelling, draining tracts and ocular or nasal discharge. Extraoral examination should also include inspection for facial symmetry,

palpation of the temporomandibular joints, regional lymph nodes and salivary glands and thorough inspection of the skin and lips. Extraoral abnormalities related to oral dysfunction may include mucopurulent discharge from the eyes or nostrils, soft or hard swellings, crepitus, salivation and an inability to open or close the mouth (Marretta, 1987, 1992; Kapatkin et al, 1991; Ramsey et al, 1996).

After the extraoral examination, the lips should be gently parted or retracted to allow inspection of the oral mucosa. Patients experiencing severe oral pain may not tolerate even a cursory oral examination without sedation. The facial surfaces of the teeth and gingivae (**Figure 47-2**) should be examined for substrate accumulation (i.e., plaque, calculus and stain [See Etiopathogenesis.]), inflammation, trauma and capillary refill time. Tooth position and occlusion should be evaluated. The lingual surfaces of the teeth and gingivae should be inspected, as well as the palates, tongue (ventral and dorsal), frenulum, oropharyngeal area and tonsils.

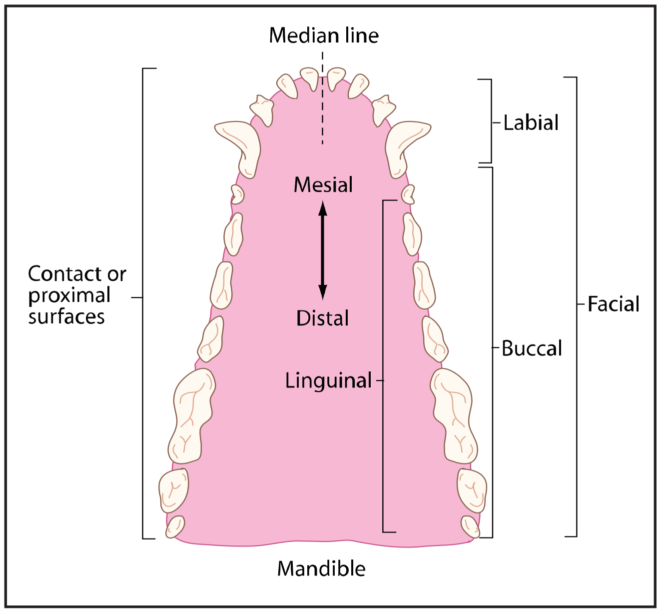

Figure 47-2. Directional nomenclature used to describe anatomic position of tooth surfaces. (Adapted from Wiggs RB. Canine oral anatomy and physiology. Compendium on Continuing Education for the Practicing Veterinarian 1989; 11: 1476.)

Comprehensive Oral Examination

A definitive oral examination must be done with the patient heavily sedated or anesthetized, and is often done immediately before periodontal therapy. The general examination should be used as a starting point in client communication with the understanding that the definitive oral examination may uncover other lesions that require treatment.

The examination should begin with a thorough inspection of all oral tissues. An overall assessment of oral health should consider the amount and location of substrate accumulation. Substrate location and accumulation provide valuable information about the frequency and effectiveness of oral hygiene (Woodall, 1990). Common substrate and periodontal indices used to measure oral health have been described (Logan et al, 1992; Logan and Boyce, 1994) and were adopted by participants of the 1994 International Symposium on Veterinary Oral Care (Logan and Boyce, 1994; SVOC, 1994). Modifications and refinements to substrate indices have been published (Hennet, 1999; Harvey, 2002; Hennet et al, 2006). Furthermore, a recognized system (Veterinary Oral Health Council [VOHC]) exists for validating product claims.

The remainder of the periodontal indices (e.g., probe depth, attachment loss, furcation exposure and tooth mobility) are usually charted after prophylaxis or periodontal therapy to ensure accurate assessment after removal of subgingival debris that may impede measurement. Each tooth and its associated periodontium should be evaluated using a dental explorer-probe to examine the tooth for defects, lesions or both. The same instrument should be used to evaluate periodontal health by measuring the extent of gingival inflammation, attachment loss and alveolar bone loss. Any abnormalities in tooth or periodontal structures should be noted on the dental chart. Detailed dental charting allows for disease assessment and provides a record for future reference. The results should become part of the patient's permanent medical record.

Radiographic Examination

Oral radiography may be indicated to identify lesions that cannot be detected visually or manually, and to determine the extent of pathology. Root fractures, periapical abscesses, alveolar bone loss, acute resorption lesions and anatomic anomalies are difficult to assess without radiography. Additionally, oral radiographs are useful in selecting a definitive treatment plan and assessing the outcome of a dental procedure. Oral radiographic techniques have been well described elsewhere (Wiggs and Lobprise, 1997; Niemiec, 2005; Niemiec and Furman, 2004, 2004a; Niemiec et al, 2004, 2004a). In addition, digital radiography is becoming more common (DuPont and DeBowes, 2002).

Laboratory Studies

A complete blood count, serum biochemistry profile, bacterial culture, virus isolation, cytologic examination and biopsy may add useful information. Other diagnostic tests such as urinalyses and cardiac examinations may complement a standard panel as part of a preanesthetic profile. Patients with suspected renal or cardiac disease may be compromised by bacteremia associated with dental manipulations.

Risk Factors

All mammals are susceptible to periodontal disease. The primary etiologic agents associated with periodontal disease are bacterial plaque and bacterial by-products (Löe et al, 1965; Theilade et al, 1966; Socransky, 1979; Lindhe et al, 1973; Lindhe and Rylander, 1975). Bacterial plaque is also directly involved in the pathogenesis of enamel caries and may be a contributing factor in the development and progression of

Box 47-2. Digestible Carbohydrates and Their Role in Oral Health of Dogs and Cats.

The role of digestible (soluble) carbohydrates (sugars) in the development of dental caries has been well documented in people and rodents. Dental caries, however, occurs infrequently in dogs and cats. One study demonstrated that dogs do not develop carious lesions even after long periods of consuming carbohydrate-rich foods. Carlsson and Egelberg reported that the addition of sucrose to a soft food resulted in no difference in plaque accumulation and gingival inflammation in a group of 12 mongrel dogs. Human studies have demonstrated that larger amounts of plaque were formed when sucrose was the primary sugar consumed. Commercial and homemade pet foods typically contain large quantities of digestible carbohydrates, usually in the form of starch.

The Bibliography for **Box 47-2** can be found at www.markmorris.org.

tooth resorption and other oral inflammatory lesions. Any factor that enhances bacterial accumulation or affects the resistance of the periodontium may influence the disease process. Specific risk factors that contribute to the severity and progression of periodontal diseases include: 1) breed, 2) age, 3) immunocompetence, 4) nutrition and food characteristics, 5) chewing behavior and 6) systemic health (Wiggs, 1995).

Breed

Breed plays a major role in the development of dental disease. Small, toy and brachycephalic breeds are prone to malocclusive disorders including overcrowding and rotation of teeth, retained deciduous teeth and supernumerary teeth. Occlusal abnormalities provide plaque retentive areas and increase the difficulty of oral hygiene procedures. Brachycephalic breeds are also predisposed to mouth breathing, which tends to dry and irritate oral tissues (West-Hyde and Floyd, 1995). Periodontal disease, tooth resorption and gingivostomatitis have been reported to occur with relatively greater frequency in purebred cats, particularly Asian breeds such as Siamese and Abyssinians (Van Wessum et al, 1992). Ulcerative stomatitis has been documented to occur in family clusters of Maltese dogs (Harvey and Emily, 1993).

Age

Several surveys have reported that older pets have a greater frequency and an increased severity of dental disease. One report of a survey of owners of 1,350 dogs noted that calculus deposition, gingival inflammation, tooth mobility, furcation exposure, attachment loss and missing teeth all increased significantly with increasing age (Harvey et al, 1994). In an evaluation of 4,776 cats aged seven to 25 years and 8,692 dogs aged 10 to 25 years, oral disease was the most frequent diagnosis reported (Lund et al, 1999).

It has long been reported that periodontal disease in people increases in severity with increasing age. Recent data suggest that the severity may represent a lifetime disease accumulation and not necessarily be an age-specific condition (Page, 1984; Van der Velden, 1984; Johnson et al, 1989). There may be some age-related changes that could negatively affect oral health, such as decreased salivary flow and antioxidant capacity (Dodds et al, 2005; Aejmelaeus et al, 1997; Navazesh, 2002). It is not surprising that geriatric pets with little history of oral hygiene or veterinary oral care demonstrate an increased prevalence and severity of periodontal disease.

Immunocompetence

The host immune response protects against systemic infection from periodontal pathogens. An over exaggerated immune response can cause severe local periodontal destruction. An inadequate immune response may predispose pets to opportunistic or overwhelming systemic infection (Genco, 1992).

Nutrition and Food Characteristics

The dramatic difference in food form represented by commercial dog and cat foods as compared with the natural prey of wild canids and felids is often implicated as a significant cause of the degree of periodontal disease diagnosed in domestic dogs and cats (Gray, 1923; Colyer, 1990; Watson, 1994). Colyer examined 1,157 wild canid skulls and reported that periodontal disease as suggested by alveolar bone destruction was present in only 2% of specimens (1990). The subject of how well specific commercial food types promote oral health is discussed below.

Box 47-2 reviews a common concern of pet owners regarding food sugar content and dental caries and **Box 47-3** discusses the role of topical coatings of dry cat foods in feline tooth resorption. Although not associated with periodontal disease, these text boxes are included because the topics relate to food and dental diseases.

Etiopathogenesis

Tooth-Accumulated Materials

Several materials accumulate on tooth surfaces and participate in the pathophysiology of dental and periodontal disease. These substances are commonly referred to as tooth-accumulated materials or dental substrates and are categorized as: 1) acquired enamel pellicle, 2) microbial plaque, 3) materia alba/debris, 4) calculus and 5) stain. These substrates accumulate in a dynamic continuum, initiated by the adsorption of salivary constituents onto tooth surfaces (Fedi, 1985; Schwartz et al, 1971).

Saliva is a critical oral fluid primarily recognized for its digestive functions. However, saliva also bathes the oral cavity with a fluid rich in proteins (e.g., enzymes), glycoproteins, electrolytes, lipids, antioxidants, antimicrobial peptides (defensins), immunoglobulins, bicarbonate ions and mucins that provide an initial protective barrier to pathogenic invasion, lubricate and clean the oral cavity and aid in the transportation of solids (Lingström and Moynihan, 2003; Mizukawa et al, 1999). In people, diminished salivary function (xerostomia) is associated with increased prevalence of caries and periodontal disease, mucosal irritation, difficulties in chewing and swallowing and

impaired taste. Saliva initiates film formation on all oral surfaces (Scannapieco and Levine, 1990; Navazesh, 2002).

ENAMEL PELLICLE

Enamel pellicle is a thin film or cuticle. Early enamel pellicle is composed of proteins and glycoproteins deposited from saliva and gingival crevicular fluid. Early enamel pellicle protects and lubricates. However, as pellicle ages, existing constituents are modified and additional salivary, crevicular and bacterial components are incorporated. Enamel pellicle and its components provide a framework for initial bacterial colonization and also function in the maturation of dental plaque (Scannapieco and Levine, 1990; Rolla, 1983).

DENTAL PLAQUE

Pellicle deposition and subsequent bacterial colonization occur almost immediately after a dental prophylaxis. Studies have demonstrated that within minutes after polishing, approximately one million organisms are deposited per mm^2 of enamel surface (Lindhe, 1989). Aggregates of bacteria combine with salivary glycoproteins, extracellular polysaccharides and occasionally epithelial and inflammatory cells to form a soft adherent plaque that covers tooth surfaces. Dental plaque is not easily removed by normal tongue actions, water drinking or forced water spray, but can be affected by mechanical and chemical means.

Dental plaque has a specific composition and structure that changes with time (DuPont, 1997). Supragingival dental plaque forms above and along the free gingival margin; subgingival dental plaque is formed entirely within the gingival sulcus. Growth and maturation of supragingival plaque are necessary for subsequent colonization of subgingival surfaces by dental plaque (Kornman, 1986). Supragingival and subgingival plaque are distinct compositional masses that influence the inflammatory reaction of gingival tissues. Studies in people have demonstrated an organized progression of microbial colonization and growth that leads to the development of mature pathogenic dental plaque (Lindhe, 1989).

Canine and feline studies characterizing the microbial composition of supragingival and subgingival plaque have been reported. Supragingival plaque in dogs with clinically healthy gingivae is primarily composed of gram-positive aerobic organisms. As plaque matures, the bacterial composition shifts to a predominately gram-negative anaerobic flora (Courant et al, 1968; Soames and Davis, 1974; Wunder et al, 1976; Syed et al, 1980, 1981; Svanberg et al, 1982; Isogai et al, 1988; Mallonee et al, 1988; Hennet and Harvey, 1991, 1991a, 1991b; Boyce et al, 1995; Harvey et al, 1995). Several sources have detailed lists of specific bacteria associated with periodontal diseases of dogs (Hardham et al, 2005; Syed et al, 1980; Wunder et al, 1976; Hennet and Harvey, 1991, 1991a, 1991b; Allaker et al, 1997; Isogai et al, 1989; Svanbert et al, 1982) and cats (Mallonee et al, 1988). The inflammation and destruction that accompanies periodontal disease results from the direct action of bacteria and their by-products on periodontal tissues and the indirect activation of the host immune response (Genco, 1990). Thus, bacterial plaque is the most important substrate in the development of periodontal disease.

Box 47-3. Do Commercial Cat Foods Cause Tooth Resorption?

Although the etiology of tooth resorption in cats is unknown, examination of skulls that pre-date the 1960s revealed a lower prevalence of tooth resorption than current estimates, which suggests a relatively recent increase. Commercial foods have been implicated as a causative factor in the increased detection of tooth resorption in cats based on several physical and chemical properties of these foods.

Questions have been raised that relate to the common practice of applying an acidic coating to dry cat foods (i.e., feline digest) to enhance palatability. Human studies have demonstrated that consumption of a food or beverage with an acidic pH contributes to erosive lesions. Additionally, chronic vomiting/regurgitation have been associated with these lesions because vomitus is acidic. To address this issue, Zetner and Steurer investigated the tooth surface pH of cats with 1) tooth resorption, 2) chronic oral inflammatory disease and 3) cats with no oral lesions. These researchers also measured tooth surface pH after cats consumed either a commercial moist food or a commercial acid-coated dry food. Results from this study demonstrated that cats with tooth resorption had lower tooth-surface pH values than healthy cats, but that consumption of the dry food was not associated with the pathogenesis of odontoclastic resorptive lesions.

It has also been suggested that hard dry cat foods cause microfractures that predispose teeth to infection and initiate the inflammatory cascade leading to odontoclastic activation. However, it must also be noted that teeth that are not normally associated with mechanical forces related to consuming dry foods are also susceptible to tooth resorption.

Finally, recent work has implicated dietary vitamin D in the etiology of tooth resorption. Evidence in support of this theory includes the correlation between cats with tooth resorption and increased blood levels of 25-hydroxyvitamin D, and histologic comparisons of the effects of excessive intake of vitamin D to the effects of tooth resorption. Because cats cannot synthesize vitamin D, they must rely on their diet to supply the nutritional requirement.

Definitive studies that document a cause-and-effect relationship implicating a single etiologic factor have not yet been done, and care must be taken to maintain distinctions between casual and causal relationships when evaluating current information. In addition, it is possible that tooth resorption has a multifactorial etiology, highlighting the complexity of the problem and emphasizing the need for additional research.

MATERIA ALBA AND OTHER ORAL DEBRIS

Materia alba is a soft mixture of salivary proteins, bacteria, desquamated epithelial cells and leukocyte fragments. Materia alba and dental plaque are two distinct materials. Materia alba

does not have the organized bacterial structure or the adherence properties of dental plaque (Schwartz et al, 1971); it can generally be washed off with a forced water spray. The role of materia alba in the etiopathogenesis of plaque accumulation and periodontal disease remains unclear.

Other debris commonly observed in the oral cavity of dogs and to some extent in cats includes food, impacted hair and miscellaneous foreign materials acquired through chewing behaviors. Food debris retained in the mouth after eating can usually be removed by the action of the tongue and saliva.

Dogs and cats fed soft, sticky foods, particularly those breeds compromised by occlusal abnormalities, may retain more food debris. No reports directly correlate retention of food debris with increased plaque accumulation and periodontal disease in dogs and cats. Egelberg reported that neither the frequency of feeding nor bypassing the oral cavity by tube feeding affected the accumulation of plaque and the development of gingivitis in a group of six mixed-breed dogs with medium to large body size (1965). The effect of food retention in small and brachycephalic breeds is unknown. Retained or impacted debris may act as a nidus for plaque accumulation and exacerbate gingival inflammation. The role of food type and texture in oral health and disease is discussed below.

DENTAL CALCULUS

Dental calculus is mineralized plaque. Calculus is a hard substrate formed by the interactions of salivary and crevicular calcium and phosphate salts with existing plaque. Dental calculus is observed frequently in dogs and cats (Harvey, 1992; Harvey et al, 1994; Richardson, 1965; Coignoul and Cheville, 1984) but differs in its composition. Feline calculus is comprised mostly of carbonate-containing hydroxyapatite, whereas canine calculus is comprised mostly of calcium carbonate (calcite) (Clarke, 1999; Legeros and Shannon, 1979). Calculus accumulates supragingivally and subgingivally; calculus deposits thicken with time. Undisturbed calculus is always covered by vital dental plaque. Aged calculus may chip or break off with mastication; however, a film of plaque remains that is rapidly mineralized. Calculus provides a roughened surface to enhance plaque attachment and accumulation and chronically irritates gingival tissues (Lindhe, 1989a; Mandel, 1990; Schroeder, 1969). A study in dogs demonstrated that calculus control in the absence of plaque control is cosmetic only; thus, preventive or therapeutic protocols to control periodontal disease should always include anti-plaque measures (Warrick et al, 2003).

DENTAL STAIN

Acquired dental stain (extrinsic stain) is initially stained pellicle that becomes part of the mineralized, layered laminate of pellicle, plaque and calculus. Dental stain occurs frequently in dogs (Schemehorn et al, 1982). Various nutritional, chemical and bacterial factors affect the presence and intensity of stain. Although nonpathogenic, dental stain is of aesthetic concern to pet owners and may signal teeth abnormalities.

Enamel staining (intrinsic stain) occurs due to trauma or antibiotic administration during development or before tooth eruption. Erupted teeth may also be injured with resulting discoloration due to hemorrhage into the dentinal tubules.

Enamel staining varies in intensity and distribution of discoloration and is distinguished from acquired stain by its irreversible nature (Robinson et al, 1983).

Pathophysiologic Basis of Clinical Signs

PERIODONTAL DISEASE

In susceptible patients, plaque accumulation along the gingival margin induces inflammation in adjacent gingival tissues. Without plaque removal or control, gingivitis progresses in severity to include local changes that allow subsequent bacterial colonization of subgingival sites. Inflammatory mediators damage the integrity of the gingival margin and sulcular epithelium, allowing further infiltration of bacteria. The immune response of the host attempts to localize the invasion of periodontal tissues; the result may be further destruction of local tissues due to cytokines released from inflammatory cells (Grove, 1982; Genco, 1984, 1990; DeBowes, 2000; Harvey, 2005).

Periodontal disease is episodic with periods of active tissue destruction followed by periods of inactivity and healing (**Figure 47-3**). Additionally, not all teeth are affected at the same rate or to the same degree. Periodontal disease begins with gingivitis and progresses through increased destruction of the periodontal apparatus, resulting in tooth mobility and eventual tooth loss. Generally, a stage classification system is used, beginning with a healthy periodontium and ending with tooth exfoliation (**Table 47-2** and **Figure 47-4**) (Wiggs and Lobprise, 1997a).

Periodontal disease is often a silent process that progresses without detection. Even in severe cases, dogs and cats may not demonstrate obvious discomfort. One signal often noticed by pet owners is oral malodor (Hennet et al, 1995), but even then, pet owners may not link bad breath to periodontal disease. Oral disease is a primary cause of offensive breath odor, but other metabolic processes may be involved (Tonzetich, 1977, 1978; Preti et al, 1992; Chen et al, 1970). A positive correlation between periodontal disease and malodor has been found in beagles (Simone et al, 1997).

Other signs of periodontal disease include: 1) accumulation of dental substrates on tooth surfaces, 2) gingival redness, 3) swelling and bleeding of the gingival margin, 4) gingival recession, 5) periodontal pocket formation, 6) accumulation of purulent material in the gingival sulcus or periodontal pocket and 7) tissue destruction with loss of attachment, furcation exposure and tooth mobility (**Table 47-3**).

Systemic Complications of Periodontal Disease

Periodontal disease may predispose affected pets to systemic complications. In people, periodontal disease has been linked to arthritis, low birth weight and pre-term birth, cardiovascular disease, stress and anxiety, diabetes, obesity and stroke (Hamilton, 2005; Mandel, 2004; Newman, 1996; O'Reilly and Claffey, 2000; Rutkauskas, 2000; Gaffar and Volpe, 2004; Klages et al, 2005; Roman, 2003; Dorfer et al, 2004).

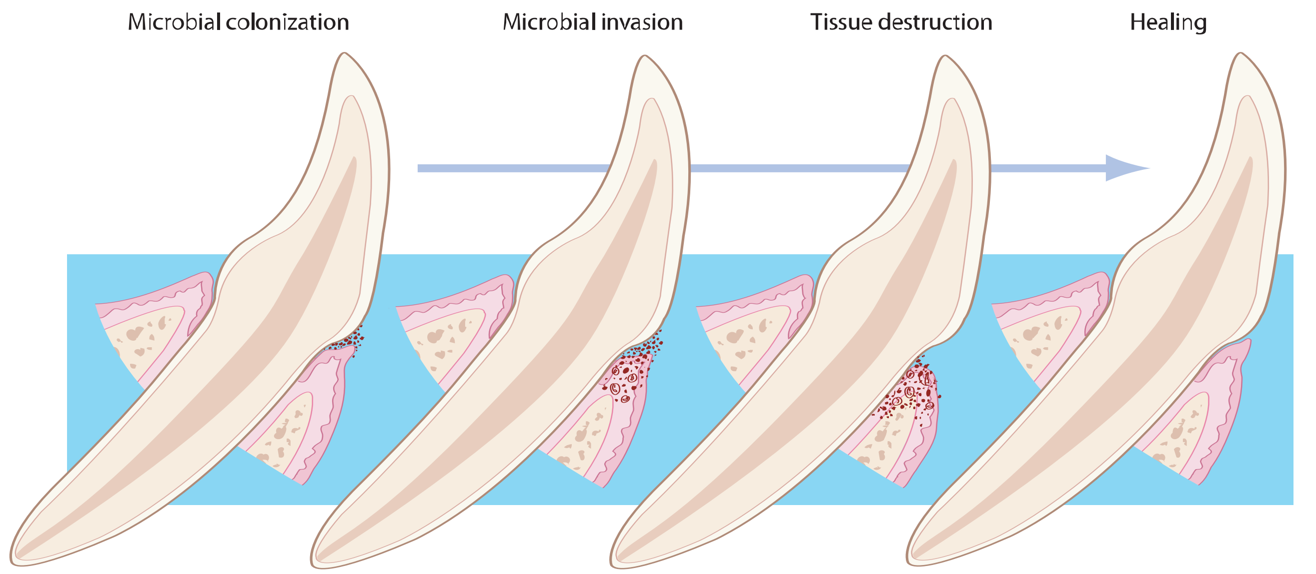

Figure 47-3. Host-bacterial interactions in the pathogenesis of periodontal disease. Periodontal disease is cyclic with bursts of tissue destruction followed by periods of healing and relative quiescence. Four stages in the pathogenesis of periodontal disease have been proposed: 1) Microbial colonization. Salivary pellicle is deposited on the enamel surface and is soon colonized by oral bacteria that multiply forming plaque. 2) Microbial invasion. Plaque bacteria and their by-products invade the gingival tissues and initiate a host inflammatory response. 3) Tissue destruction. Direct toxic effects of bacteria and their by-products and indirect host-mediated toxic responses lead to destruction of periodontal tissue. 4) Healing. Periods of disease remission are characterized by a reduction in the inflammatory response and gingival healing. (Adapted from Genco RJ, Goldman HM, Cohen WD, eds. Contemporary Periodontics. St Louis, MO: CV Mosby Co, 1990; 189.)

Although much of the evidence is based on documentation of correlations between oral and systemic health, and the effect of systemic diseases on the health of the oral cavity (particularly in the case of diabetes) (Mealey, 1998; Levin et al, 1996), data are emerging that suggest a more causal and two-way relationship that makes a case for periodontal therapy as an adjunctive treatment to classic disease therapies (D'Aiuto et al, 2004; Montebugnoli et al, 2005; Montebugnoli, 2004; Farooqi et al, 2004; Kiran et al, 2005; Mealey, 2000; Miller et al, 1992; Pucher and Stewart, 2004; Taylor et al, 2004; Rahman et al, 2005; Mercanoglu et al, 2004).

In dogs, numerous reports speculate on the association between chronic periodontal disease and conditions affecting the heart valves and pulmonary airways (Hamlin, 1990; Prueter and Sherding, 1985; Calvert and Dow, 1990; Bonagura, 1981). Furthermore, a positive correlation has been found between the severity of periodontal disease and histopathologic changes in the kidneys, myocardium and liver (DeBowes et al, 1996). Periodontal infections allow bacterial migration into lymphatic and blood vessels, resulting in bacteremia and are associated with increased levels of many of the systemic markers associated with the diseases described above, including C-reactive protein, proinflammatory cytokines, serum cholesterol, plasma fibrinogen, white blood cells and blood glucose (Harari et al, 1993, 1991; Slade et al, 2000; Ide et al, 2004; D'Aiuto et al, 2004, 2005; Joshipura et al, 2004; Lowe, 2004; Holzhausen et al, 2004). The host defenses of normal healthy pets can effectively clear transient bacteremia; however, blood-borne bacteria may colonize distant sites in patients impairing immune function and/or compromising organ function, including development of atherosclerotic lesions (Calvert and Green, 1986; Glurich et al, 2002).

Table 47-2. Stages of periodontal disease.*

Stage 0	**Clinically normal** No gingival inflammation or periodontitis clinically evident.
Stage 1	**Gingivitis only** No attachment loss. Height and architecture of the alveolar margin are normal.
Stage 2	**Early periodontitis** Less than 25% attachment loss or Stage 1 furcation involvement in multirooted teeth.
Stage 3	**Moderate periodontitis** 25 to 50% attachment loss or Stage 2 furcation involvement in multirooted teeth.
Stage 4	**Advanced periodontitis** Greater than 50% attachment loss or Stage 3 furcation involvement in multirooted teeth.

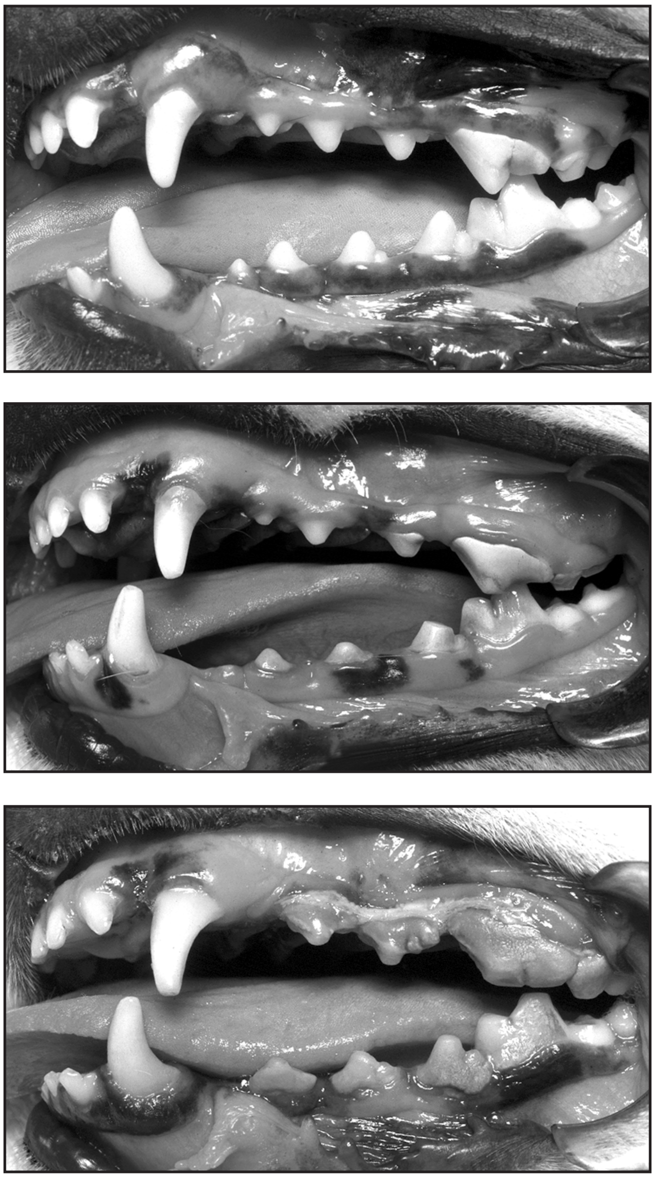

Figure 47-4. Photographic representations of mild, moderate and severe periodontal disease in dogs. (Top) Mild periodontal disease. Some accumulation of plaque and calculus is evident on tooth crowns. There is slight gingival recession around the maxillary canine tooth and the gingival margins are slightly rounded, particularly around the caudal premolar teeth. (Middle) Heavy plaque and calculus accumulation is evident on most teeth. Accumulations are abundant on the maxillary fourth premolar and first molar. A distinct margin of gingival inflammation is present around the maxillary fourth premolar. Inflammatory changes including swelling, reddening and recession are evident around most teeth. (Bottom) Gross plaque and calculus accumulation is present on premolar and molar teeth. Distinct marginal gingivitis with severe gingival recession and periodontal tissue loss is present. Impaction of hair and foreign material occurs commonly at sites of severe tissue destruction.

Key Nutritional Factors

The key nutritional factors for oral health should provide a sufficient level of plaque control to prevent periodontal disease and gingivitis. Proper food texture and composition can directly affect the oral environment through: 1) maintenance of tissue integrity, 2) alteration of bacterial plaque metabolism, 3) stimulation of salivary flow, 4) cleansing of tooth and oral surfaces by appropriate physical contact and/or 5) chelation of calculogenic constituents (**Box 47-4**). However, control of calculus is a secondary consideration because calculus control by itself has not been shown to decrease gingivitis and periodontal disease. Calculus along with stain and malodor are more of a cosmetic concern.

Assessing the relative efficacy of an oral health related key nutritional factor is complex. It is more practical to determine the overall benefit of these constituents in a finished product. However, it can be very confusing for veterinarians, and particularly for pet owners, to discern which products provide significant dental benefits and thus warrant use as oral hygiene agents. The Center for Veterinary Medicine of the Food and Drug Administration (CVM-FDA) monitors and regulates dental health claims in the United States. Cosmetic claims are not objectionable and structure-function claims are not stringently regulated; thus, the wide availability of products that make some type of plaque or calculus claim with little or no research to document their effectiveness. Phrases such as "cleans teeth, freshens breath" are commonplace on commercial food and treats packages. Because "crunchy" texture provides little dental benefit, the purported ability of these types of products to provide any significant level of oral hygiene is a misrepresentation to pet owners.

However, standardized scientific methods by which plaque (and calculus) accumulation are measured in dogs and cats for evaluating product efficacy have been established by the international veterinary dental community (Boyce, 1992; Logan and Boyce, 1994; SVOC, 1994; Harvey, 1995; Logan et al, 1995; Logan, 1996, 1996a; Hennet, 1999; Harvey, 2002; Hennet et al, 2006). **Box 47-5** discusses these methods and the VOHC Seal of Acceptance. The presence of a VOHC Seal of Acceptance for plaque or plaque and calculus and/or published evidence-based studies helps determine which products are effective.

Because foods that provide dental health benefits replace regular maintenance foods, several key nutritional factors are included because of their relationship to general health rather than specific benefits for periodontal disease. The key nutritional factors for dental foods for dogs and cats are summarized in **Table 47-4** and discussed in more detail below.

Food Texture

The physical consistency, or texture, of foods and treats has long been thought to affect the oral health of dogs and cats. Many of the recommendations made about the effect of food texture on oral health are unsubstantiated and several have turned out to be untrue when exposed to rigorous study, including "natural foods" (**Box 47-6**). However, food texture can be a very effective means of controlling dental plaque and ultimately periodontal disease.

Numerous studies have reported that dogs and cats fed soft foods have increased accumulation of plaque and calculus and a higher prevalence or severity of periodontal disease when com-

Table 47-3. Clinical signs associated with periodontal disease.

Anorexia	Red, swollen or bleeding gingivae
Behavioral changes	Substrate accumulation (plaque, calculus, stain)
Difficulty eating	Tooth mobility
Halitosis	Ulcerations on gingivae or oral mucosa
Head shaking	
Ptyalism	

Box 47-4. Hexametaphosphate and Tartar Control.

Calcium chelators such as hexametaphosphate (HMP) are sequestrants that bind salivary calcium, making it unavailable for incorporation into the plaque biofilm to form calculus. HMP is delivered as a coating on various treats, dental chews and foods. The purported benefits of these compounds are that they are released during chewing and remain for prolonged periods of time in the oral cavity. It has been demonstrated that the addition of HMP to the surface of baked biscuit treats, rawhide chews and dry foods results in reduced calculus accumulation. However, there is also evidence that shows no significant differences in plaque or calculus accumulation in dogs fed dry foods plus HMP-coated biscuits. Polyphosphates like HMP have no known direct effect on oral microflora populations or plaque accumulation. An effective plaque control regimen should always be the primary recommendation for prevention or post-therapeutic care of periodontal disease.

The Bibliography for **Box 47-4** can be found at www.markmorris.org.

pared with the same parameters in pets fed hard foods. These studies are difficult to compare because different methods were used to assess substrate accumulation and gingival health, and different populations of patients were studied.

Feeding recommendations for oral health commonly include feeding a dry pet food. Hard food purportedly increases mastication, which aids oral health by exercising the gums, increasing keratinization of the gingivae and reducing accumulation of plaque and calculus (O'Rourke, 1947). But many of the studies traditionally cited to substantiate claims that dry foods reduce accumulation of plaque and calculus are old reports that used small numbers of subjects, had varying evaluation methods and did not report data analysis (Burwasser and Hill, 1939; Egelberg, 1965a; Krasse and Brill, 1960; Studer and Stapley, 1973).

Consumption of soft foods may promote plaque accumulation. However, the general belief that dry foods provide significant oral cleansing should be regarded with skepticism. A moist food may perform similarly to a typical dry food in affecting plaque, stain and calculus accumulation (**Figure 47-5**) (Boyce and Logan, 1994). In a large epidemiologic survey, dogs consuming dry food alone did not consistently demonstrate improved periodontal health when compared with dogs eating moist foods (Harvey et al, 1996). Also, periodontal disease is the most common disease in dogs and cats (Lund et al, 1999); however, most dogs and cats eat dry foods.

Thus, typical commercial dry dog and cat foods contribute

Table 47-4. Key nutritional factors for foods for dogs and cats for prevention of periodontal disease and maintenance of overall health.*

Factors	Dogs	Cats
Food texture	VOHC Seal for plaque control	VOHC Seal for plaque control
Antioxidants		
Vitamin E (IU/kg)	≥400	≥500
Vitamin C (mg/kg)	≥100	100-200
Selenium (mg/kg)	0.5-1.3	0.5-1.3
Phosphorus (%)	0.4-0.8	0.5-0.8
Sodium (%)	0.2-0.4	0.2-0.5
Magnesium (%)	-	0.04-0.1
Average urinary pH	-	6.2-6.4

Key: VOHC = Veterinary Oral Health Council Seal of Acceptance for plaque control.
*All values are amounts in food on a dry matter basis unless otherwise stated.

Box 47-5. Veterinary Oral Health Council: A System for Recognizing Effective Veterinary Dental Products.

The Veterinary Oral Health Council (VOHC) was established in 1997 after 10 years of open meetings, which included representatives from the American Veterinary Dental College, Academy of Veterinary Dentistry, American Veterinary Dental Society, American Veterinary Medical Association, American Animal Hospital Association, United States Food and Drug Administration, private practice and industry. The purpose of the VOHC is to provide an independent, objective and credible means of recognizing veterinary dental products that effectively control accumulation of plaque and/or calculus (tartar). The VOHC system is similar to the American Dental Association (ADA) Seal of Acceptance system and is recognized worldwide.

The VOHC does not conduct efficacy testing; the council reviews results of tests performed in accordance with approved protocols set by the VOHC. The VOHC awards the Seal in two claim categories: 1) Helps control plaque and 2) Helps control tartar. It is important to recognize the difference between the two claims; plaque is the primary cause of periodontal disease and tartar control in the absence of plaque control is primarily cosmetic. If a product with the "helps control tartar" claim is recommended it is critical to recommend a proven plaque control method. In addition to noting the type of Seal awarded, it is important to be aware of the study design and application (feeding) recommendations associated with meeting the claim requirements. A product that is awarded the Seal based on a specific application (daily) may not perform similarly when applied less frequently.

The first canine and feline dental products to receive the VOHC Seal of Acceptance were Hill's Prescription Diet t/d Canine and t/d Feline, respectively. A complete list of products that have been awarded the VOHC Seal of Acceptance is available at vohc.org.

Box 47-6. Natural Food Sources and Periodontal Disease.

Early literature reported that the typical foods of wild canids and felids had a plaque-retardant effect and that wild canids and felids were not afflicted with the generalized form of periodontal disease seen in domesticated pets. Pet food commercialization is often implicated as a contributing factor to the increased prevalence and severity of periodontal disease in domestic dogs and cats (**Box 47-3**). The constituents of natural foods for wild canids and felids probably depend on geographic location, environmental season and individual hunting capabilities. However, historically a natural food refers to small rodents/mammals that would typically fall prey to wolves, coyotes, etc. Colyer specifically refers to "flesh that the animals must rend with their teeth." Wild canids in particular probably eat fruits and vegetables and an array of tissues including blood, intestines plus contents, muscle, cartilage, bone marrow and bones.

Despite these assertions, there are no published data that compare controlled populations of domestic dogs or cats consuming natural food sources with those consuming a commercial food. In addition, even if it were possible to make such comparisons, confounding variables might include dramatic changes in food form (moist, semi-moist, dry and evolving pet owner preferences) through development of commercial pet foods, specific nutrient variation and selective breeding, which has resulted in dramatic differences in body size and head types of dogs and cats.

Reports exist about the oral condition of small populations of dogs and cats consuming natural foods. One study involved 67 English foxhounds, one to nine years of age that were routinely fed raw carcasses consisting of the bony skeleton, muscle and associated tissues. Oral examinations revealed that all dogs had varying signs of periodontal disease as well as a high prevalence of tooth fractures. Another study examined 45 small feral cats from an Australian national park and reported conditions including calculus deposits, periodontal disease, fractured teeth, attrition and tooth resorption. Examination of gastrointestinal contents of these cats revealed the presence of natural food sources including small mammals, birds, lizards and insects. These findings cast skepticism on the long-held view that a natural food source prevents development of oral disease, particularly periodontal disease, in dogs and cats. **Box 47-8** describes the role of chew toys in periodontal health.

The Bibliography for **Box 47-6** can be found at www.markmorris.org.

little dental cleansing. As a tooth penetrates a kibble or treat the initial contact causes the food to shatter and crumble with contact only at the coronal tip of the tooth surface (**Figure 47-6**). To provide effective mechanical cleansing, a food should promote chewing and maximize contact with the tooth surface (**Figure 47-6**).

Foods with enhanced textural characteristics promote oral health. Several maintenance pet foods are available that provide clinically significant oral cleansing compared with regular commercial dry or moist foods and/or snacks. Numerous studies have demonstrated that foods possessing an appropriate combination of shape, size and mechanical structure provide significant plaque, calculus and stain control in dogs and cats (Logan, 1996, 1996a; Boyce, 1992; Jensen et al, 1995; Logan et al, 1995; Finney, 1996). A six-month study investigating the effects of food on plaque accumulation and gingival inflammation in 40 adult mongrel dogs reported that dogs fed the test food had 39% less plaque accumulation and 36% less gingival inflammation than dogs fed the control food (**Figure 47-7**). These studies used a clean-tooth model in which plaque, calculus and stain were evaluated at a specified time following a dental prophylaxis.

One study reported that feeding a food with appropriate physical characteristics to beagles with existing plaque, calculus and gingivitis resulted in a significant decrease in mean plaque and calculus indices after two weeks and in the gingival index after six weeks (**Figure 47-8**). Beagles eating the control food had a significant increase in plaque and calculus accumulation and no change in gingival inflammation over the 16-week test period (Finney et al, 1996).

Fiber-containing foods have long been viewed as "nature's toothbrush." Investigators have theorized that fibrous foods: 1) exercise the gums, 2) promote gingival keratinization and 3) clean the teeth. Fiber in foods, especially as it relates to texture, has been shown to affect plaque and calculus accumulation and gingival health in dogs and cats (Watson, 1994; Boyce and Logan, 1994; Logan, 1996). Certain types of fiber combined with specific manufacturing processes can affect a food's texture. Fiber characteristics that maximize tooth contact time (e.g., orientation within the kibble matrix), combined with a size and shape that promote chewing, are critical to obtaining a dental benefit. A typical dry food does not possess the mechanical characteristics for adequate dental cleansing. Simply enlarging the kibble or varying the shape of the product is likewise inadequate. In the absence of effective plaque control

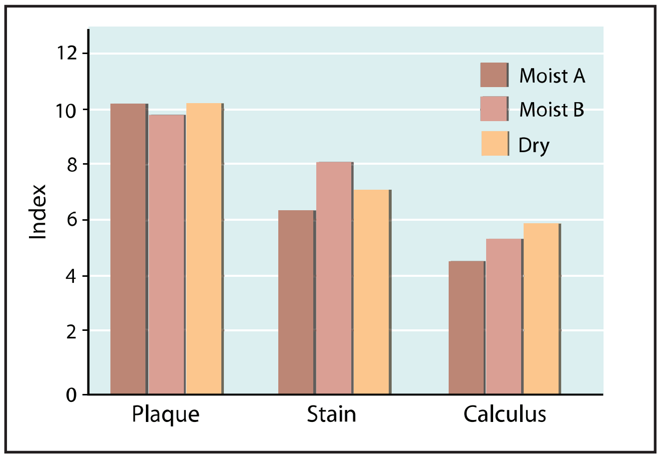

Figure 47-5. Comparison of plaque, stain and calculus accumulation in dogs fed a specialty brand moist food (Moist A), a grocery brand moist food (Moist B) and a grocery brand dry food. There is no significant difference in substrate accumulation among dogs fed the three foods. Moist foods do not always promote increased plaque and calculus formation in comparison to dry foods.

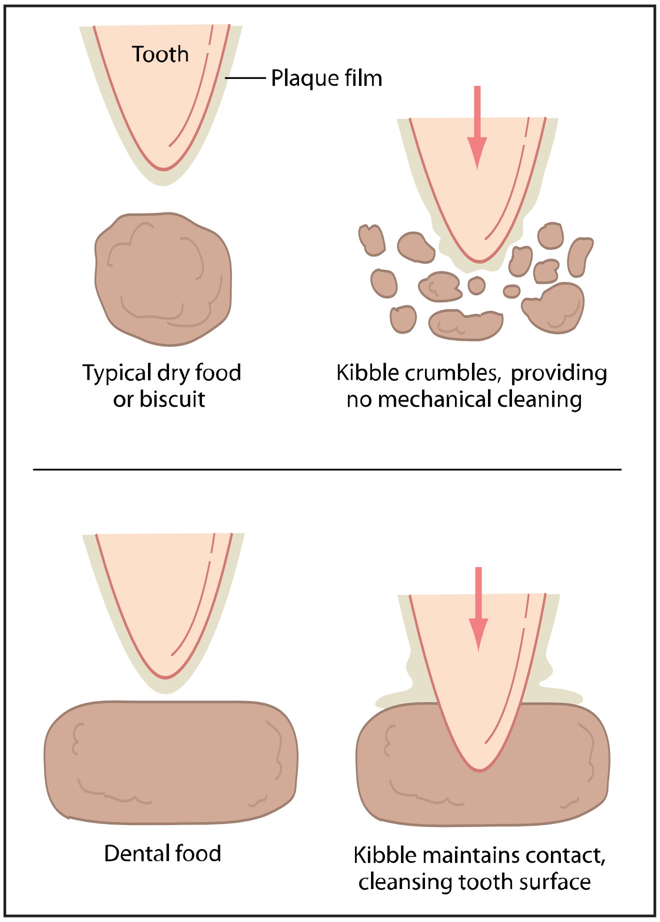

Figure 47-6. This illustration depicts the mechanical cleansing properties of commercial dog and cat foods. The top illustration demonstrates what occurs when a dog or cat chews a typical dry food. The kibble crumbles providing little to no mechanical cleansing. The bottom illustration demonstrates what happens when a dog or cat chews a dental food. The kibble stays together, maintaining contact with the tooth surface and providing mechanical cleansing.

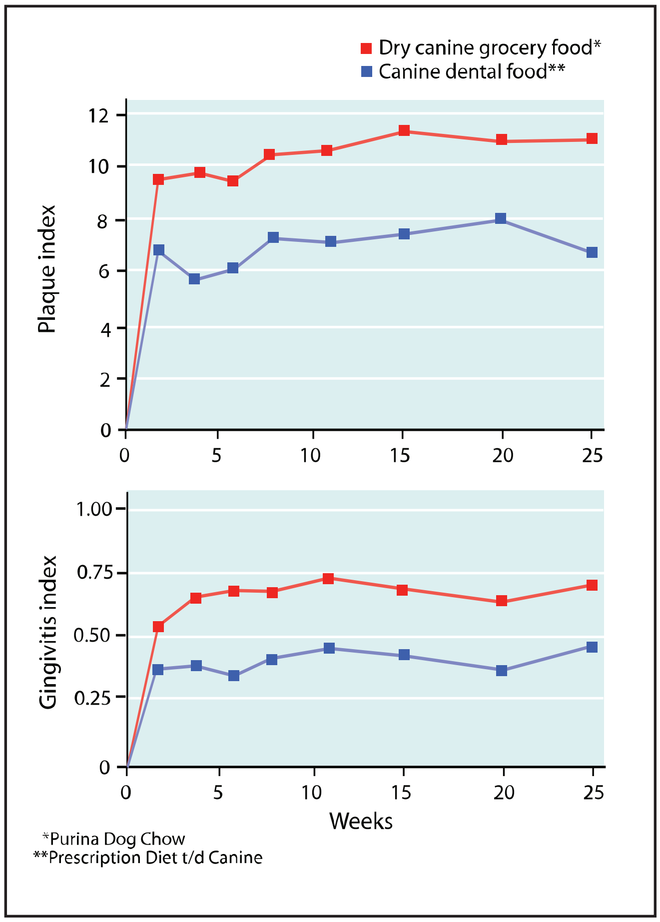

Figure 47-7. The effects of commercial dog foods on plaque accumulation and gingival health in dogs. These graphs compare plaque accumulation and gingival inflammation in dogs fed two different foods for six months. Each group of dogs began the study with a plaque index of zero and clinically healthy gingivae. At all time points, the dogs consuming the test food (Prescription Diet t/d Canine) had significantly lower scores for plaque accumulation and gingival inflammation than the dogs consuming the control food (Purina Dog Chow).

through other measures, or in cases demanding adjunctive plaque control, mechanical attenuation of plaque and calculus accumulation daily with a maintenance dental food is a reasonable alternative. Given the prevalence of periodontal disease in dogs and cats, effective homecare products that improve owner compliance can be a valuable addition to an oral health maintenance regimen.

One way to assess whether the texture of a specific dog or cat food is effective in preventing accumulation of dental plaque (or calculus) is whether or not the product's label carries the VOHC Seal of Acceptance, specifically stating that the product is effective in controlling plaque. Published Grade 1 or 2 evidence-based studies are also reliable indicators of product efficacy.

Antioxidants

Oxidative stress may be important in the etiology of periodontal disease. In one study, dogs with severe periodontitis had gingival crevicular fluid and serum with lower total antioxidant capacity than dogs with gingivitis or mild periodontitis (Pavlica et al, 2004). The body synthesizes many antioxidants but relies on food for others. Vitamins E and C and selenium are proposed as antioxidant key nutritional factors for foods for periodontal disease because: 1) they are biologically important, 2) they act synergistically (e.g., vitamin C and selenium-containing glutathione peroxidase regenerate vitamin E after it has reacted with a free radical) and 3) much is known about their safety.

VITAMIN E

Vitamin E (α-tocopherol) is the main lipid-soluble antioxidant in plasma, erythrocytes and tissues (NRC, 2006). It is one of the most effective antioxidants for protecting cell membrane constituent polyunsaturated fatty acids from oxidation. Vitamin E inhibits lipid oxidation by scavenging lipid peroxyl radicals faster than these radicals can react with adjacent fatty acids or membrane proteins (Gutteridge and Halliwell, 1994).

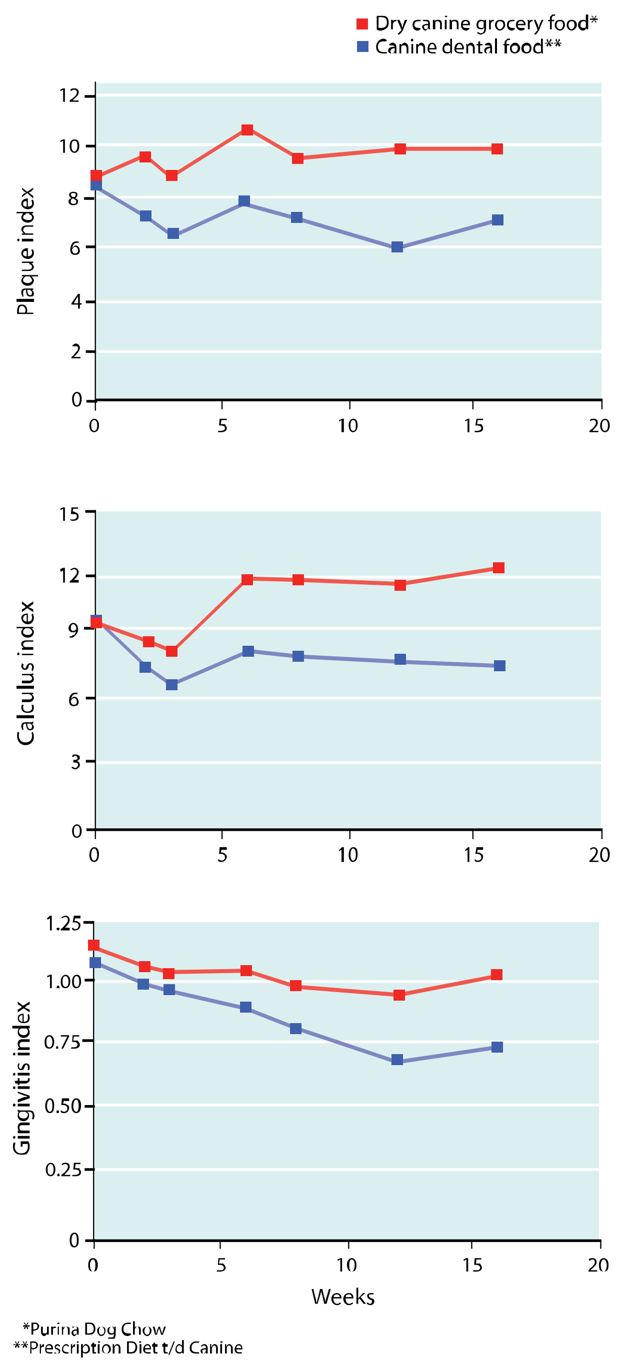

Figure 47-8. The effects of commercial dog foods on existing plaque, calculus and gingivitis in dogs. Each group of dogs entered the study with similar amounts of plaque, calculus and gingivitis. Dogs were fed either a control food (Purina Dog Chow) or a test food (Prescription Diet t/d Canine). Plaque, calculus and gingivitis were evaluated over a four-month period. Dogs eating the test food demonstrated a highly significant reduction in plaque, calculus and gingival inflammation whereas dogs eating the control food had a significant increase in plaque, a highly significant increase in calculus and no significant change in gingivitis.

Research indicates that a level of vitamin E higher than the requirement confers specific biologic benefits (Hayes et al, 1969; Hall et al, 2003; Meydani et al, 1998; Jewell et al, 2002). Based on antioxidant biomarker studies in dogs and cats, for improved antioxidant performance, foods for oral health should contain at least 400 IU/kg dry matter (DM) (dog foods) and at least 500 IU/kg DM (cat foods) (Jewell et al, 2000).

VITAMIN C

Vitamin C (ascorbic acid), is the most powerful reducing agent available to cells. Ascorbic acid: 1) regenerates oxidized vitamin E, glutathione and flavonoids, 2) quenches free radicals intra- and extracellularly, 3) protects against free radical-mediated protein inactivation associated with oxidative bursts of neutrophils, 4) keeps transition metals in reduced form and 5) may quench free radical intermediates of carcinogen metabolism.

Although dogs and cats can synthesize enough vitamin C to fulfill minimum requirements (Naismith, 1958), in vitro studies indicated that dogs and cats have from one-quarter to one-tenth the ability to synthesize vitamin C as other mammals (Chatterjee et al, 1975). Whether or not this translates to a reduced ability in vivo is unknown. For improved antioxidant performance, and in conjunction with recommended levels of vitamin E, foods for adult dogs and cats should contain at least 100 and 100 to 200 mg vitamin C/kg DM, respectively.

SELENIUM

Glutathione-peroxidase is a selenium-containing antioxidant enzyme that defends tissues against oxidative stress by catalyzing the reduction of H_2O_2 and organic hydroperoxides and by regenerating vitamin E. The minimum requirement for selenium in foods for dogs and cats is 0.13 mg/kg DM (Wedekind et al, 2003, 2003a). Animal studies and clinical intervention trials in people have shown selenium to be anticarcinogenic at levels much higher (five to 10 times) than the recommended allowances for people or the minimal requirements for dogs and cats (Combs, 2001; Neve, 2002). Therefore, for increased antioxidant benefits, the recommended range of selenium for dog and cat foods is 0.5 to 1.3 mg/kg DM.

Phosphorus, Sodium, Magnesium and Urinary pH

Phosphorus and sodium are considered key nutritional factors for apparently healthy adult dogs and cats for purposes of ameliorating or slowing the progression of subclinical kidney disease and/or hypertension. The recommended allowances for phosphorus and sodium in foods for adult dogs are 0.4 to 0.8% and 0.2 to 0.4% DM, respectively. For foods for adult cats, the recommended allowances for phosphorus and sodium are 0.5 to 0.8% and 0.2 to 0.5% DM, respectively. In addition, for adult cats, magnesium and urinary pH are also key nutritional factors, based on their role in feline lower urinary tract disease. The recommended allowance for magnesium in foods for adult cats is 0.04 to 0.1% DM. Foods for adult cats should produce a urinary pH in the range of 6.2 to 6.4. For more information see Chapters 13 and 20.

Other Nutritional Factors

Calcium

Foods deficient in calcium and excessive in phosphorus may lead to secondary nutritional hyperparathyroidism and significant loss of alveolar bone (Bawden et al, 1995; Becks and Weber, 1931). Experiments in dogs have demonstrated resorption of alveolar bone following consumption of a food with a low ratio of calcium to phosphorus (Henrikson, 1968). Krook and colleagues proposed that periodontal disease results from a nutritional deficiency of calcium, an excess of phosphorus or both (1972, 1972a). Svanberg and colleagues reported that nutritional secondary hyperparathyroidism occurred in a group of beagles fed a food deficient in calcium. The food did not have any effect on the initiation or rate of progression of periodontal disease when compared with findings in a control group fed a nutritionally adequate food (1973). It is unlikely that dietary deficiencies in calcium and phosphorus are primary causes of periodontal disease; however, they may contribute to the progression of the disease process and exacerbate bone loss. Calcium deficiency occurs rarely in dogs and cats that consume commercial pet foods that contain calcium levels that meet Association of American Feed Control Officials' (AAFCO) allowances (2007). Improperly formulated homemade foods are more likely to be deficient in calcium.

Vitamin Deficiencies

Adequate vitamin content can be a problem in improperly formulated homemade foods. Vitamins that have been studied in relation to periodontal disease include A, B, C, D and E. Vitamin A deficiencies have been reported to cause marginal gingivitis, gingival hypoplasia and resorption of alveolar bone (King, 1940; Reifen, 2002). Deficiencies of B-complex vitamins (including folic acid, niacin, pantothenic acid and riboflavin) have been associated with gingival inflammation, epithelial necrosis and resorption of alveolar bone (Becks et al, 1943). Vitamin C, besides functioning as an antioxidant (discussed above), also plays a key role in collagen synthesis. Ascorbic acid deficiencies reportedly affect periodontal tissues adversely in people, including gingival inflammation (Ismail, 1983; Leggott et al, 1986). Vitamin D helps regulate serum calcium concentrations. Vitamin D deficiencies affect calcium homeostasis and reportedly affect the gingivae, periodontal ligament and alveolar bone (Becks and Weber, 1931). Deficiencies of these vitamins are highly unlikely to occur in dogs and cats fed commercial foods that contain levels that meet AAFCO allowances.

Vitamin E is an antioxidant and in one study, dogs with more severe periodontitis also had lower total antioxidant capacity of their gingival crevicular fluid and serum than dogs with gingivitis or mild periodontitis (Pavlica et al, 2004).

FEEDING PLAN

How to Feed Dogs and Cats for Optimal Oral Health

If properly fed as puppies and kittens (**Box 47-7**), most dogs and cats enter adulthood with healthy mouths. In most cases, periodontal disease can be prevented with appropriate plaque control. The level of plaque control necessary to maintain oral health must be assessed for each individual patient. Frequent plaque removal (daily, if possible) is widely recommended. Brushing, when done correctly and conscientiously, is a very effective method for achieving the level of plaque control necessary to control gingivitis.

After oral disease is present, it should be treated with appropriate professional therapy. However, aftercare, or continued dental hygiene provided by the pet owner, will determine the overall success of professional therapy. A regimen of soft food may be recommended after invasive or advanced procedures during the initial healing phase. Chemical plaque control should be provided in these instances until mechanical plaque control can be resumed. However, many pets can resume their normal food regimen immediately after receiving professional care, provided the client has been instructed in appropriate plaque control procedures (**Box 47-1**).

If the pet owner is able to provide effective plaque control through toothbrushing, then an oral benefit from foods and/or treats may be of less concern (Lindhe and Rylander, 1975; Tromp et al, 1986, 1986a). Realistically, however, compliance with toothbrushing is a problem for many pet owners. In addition, certain patients may require aggressive plaque control combined with frequent professional care to maintain optimal oral health. Thus, in many cases, a food/treat approach to plaque control is necessary. The feeding plan includes assessing and selecting the best food and feeding methods for the individual patient.

Assess and Select the Food

After the oral and general health status of the patient has been assessed and the key nutritional factors and their target levels have been determined, the adequacy of the food can be assessed. The steps to assessing foods include: 1) assuring the nutritional adequacy of the food by a credible regulatory agency such as AAFCO and 2) comparing the food's key nutritional factors with the recommended levels. Because dental foods are used in place of regular maintenance foods, the key nutritional

Box 47-7. Feeding Puppies and Kittens for Optimal Dentition.

Puppies and kittens are born edentulous. However, the nutrition they receive from the bitch or queen can affect oral development. The bitch or queen should receive an appropriate growth/lactation food during lactation to ensure adequate milk production and to meet ongoing needs. Deciduous teeth begin to erupt at about three weeks of age. Most puppies and kittens can be given access to soft food at this age. Full deciduous dentition should be present in puppies by 12 weeks of age and in kittens by six weeks of age. The permanent tooth bud will already be formed, so it is essential to dental health that puppies and kittens receive appropriate nutrition during the early weeks of development. This is also the ideal time to train a pet to accept oral hygiene.

Vomiting and diarrhea have a myriad of causes and feeding plans vary according to the underlying condition. The feeding plans for acute gastroenteritis are most appropriate when a specific cause of acute vomiting or diarrhea is unknown. When a specific cause of chronic small bowel diarrhea is not identified, then feeding plans as outlined for exocrine pancreatic insufficiency are most appropriate. Finally, when a specific cause of chronic large bowel diarrhea is not identified, then feeding plans for colitis are most appropriate.

Each patient should be seen as an individual variant of the norm; therefore, multiple dietary manipulations should be considered, as needed, for each patient (**Box 48-2**). Because of the

Box 48-1. Herbal Remedies for Gastrointestinal Disorders.

Herbal remedies have become a major factor in human health care. Various botanicals have become household words, and sales of herbal remedies are increasing dramatically. As herbs move out of health food stores and into mainstream supermarkets, drug stores and even pet stores, use of these products in pets will also increase.

A wide variety of herbal or botanical products are advocated for patients with gastrointestinal (GI) disorders, including individuals with diarrhea, vomiting, constipation, stomatitis, colitis and flatus. There are also long lists of herbs and botanicals that are described as "gastrointestinal agents." Although today's herbal remedies exhibit varying degrees of therapeutic value, most have not been investigated thoroughly for safety and efficacy. It is beyond the scope of this textbook to list all the herbal and botanical remedies that may have use in pets. Interested readers are referred to books listed in the Bibliography for further information about human herbal remedies that might be used in pets with GI disorders.

The Bibliography for **Box 48-1** can be found at www.markmorris.org.

Box 48-2. Performing Dietary Trials in Patients with Gastrointestinal Disease.

Nutritional therapies are extremely useful for treating gastrointestinal (GI) disease in dogs and cats. Several commercial and homemade foods are available to practitioners and pet owners for this purpose. Unfortunately, there is no historical or clinical finding that will predict the success of a specific food type. Therefore, selection of the most appropriate food for an individual patient is often based on results of a dietary trial.

Dietary trials are easily performed in most clinical and home settings. Oral food consumption is preferred for managing GI diseases, except in those rare situations in which the patient is intolerant of enteral feeding.

After the veterinarian identifies those foods to be included in the trial, selection of the initial test food is often based on clinical experience and the patient's nutritional history. In general, foods that have been used unsuccessfully in the past to manage the patient should be avoided. Typically, highly digestible GI or elimination foods are good first choices for patients with gastric or small intestinal disorders. Fiber-enhanced foods are often the initial selection when large bowel signs predominate.

No other foods, supplements, table foods or treats should be offered during the dietary trial. Dietary trials are most useful if continued for at least seven to 10 days. In certain settings (e.g., adverse reactions to food), trials lasting two to four weeks (12 weeks in cases with dermatologic signs) may be necessary to determine efficacy (Chapter 31). Successful dietary trials are marked by partial or complete resolution of clinical signs.

The Bibliography for **Box 48-2** can be found at www.markmorris.org.

Box 48-3. Food Types Useful in the Management of Gastrointestinal and Exocrine Pancreatic Diseases.

GASTROINTESTINAL FOODS

Several commercial veterinary therapeutic foods have been specially formulated for managing gastrointestinal (GI) disease in dogs and cats. Typically, these products are highly digestible and have consistent ingredient and nutrient profiles.

The term highly digestible is not defined in a regulatory sense. However, highly digestible has generally been reserved for products with protein digestibility ≥87% and fat and carbohydrate digestibilities ≥90%. The average digestibility coefficients for popular commercial foods are 78 to 81%, 77 to 85% and 69 to 79% for crude protein, crude fat and carbohydrate, respectively. Commercial veterinary therapeutic foods formulated for GI disease usually contain highly refined meat and carbohydrate sources to increase digestibility.

Carbohydrates make up the largest nonwater fraction of foods formulated for managing GI diseases. Carbohydrate digestibility of pet foods is influenced by source and processing. Dogs digest most properly cooked starches very well, including starch components in corn, rice, barley and wheat. Other starches, including potato and tapioca, are less digestible, particularly when inadequately cooked. Although cats also efficiently digest carbohydrates, some clinicians feel that cats with small bowel disorders are less tolerant of dietary carbohydrate than dogs with similar causes of malassimilation.

There is a link between particle size and carbohydrate digestibility of moist foods. As a result, carbohydrate ingredients (e.g., rice, corn, etc.) should be chopped or ground before they are incorporated into moist foods. This relationship apparently is not an issue for extruded dry products. There is almost complete ileal carbohydrate digestibility in dogs consuming extruded grains (dry products).

The requirements for many macro- and microminerals in the face of GI disease are not well understood. However, sodium, potassium and B-vitamin losses are expected with vomiting and diarrhea. Therefore, foods formulated for managing GI diseases should contain sodium, potassium and B vitamins in excess of maintenance allowances. Patients with fat malabsorption are at risk for developing fat-soluble vitamin deficiencies. Highly digestible foods formulated for feeding steatorrheic patients should, therefore, be fortified with fat-soluble vitamins.

It is unusual for GI foods to contain crude fiber levels greater than 5% dry matter (DM) because fiber reduces dry matter digestibility and decreases pancreatic enzymatic activity in vitro. More recently, manufacturers of some highly digestible commercial veterinary therapeutic foods have added small amounts (<5% DM) of soluble or mixed fibers because short-chain fatty acids produced by intestinal microbial fermentation of fiber may positively affect the large intestinal mucosa.

Veterinarians recommend GI foods most often for managing acute gastroenteritis or malassimilation associated with small bowel disease or exocrine pancreatic insufficiency. The utility of highly digestible foods has been demonstrated through anecdotal reports and by the use of such foods in clinical trials involving animals with spontaneous and experimental exocrine pancreatic insufficiency. Some gastroenterologists also recommend these foods for patients with certain colonic disorders to reduce exposure of the colonic mucosa to ingesta. This therapeutic strategy has been suggested for management of inflammatory colitides and constipation.

FIBER-ENHANCED FOODS

Commercial veterinary therapeutic foods contain varying levels and sources of fiber. Based on the combined knowledge obtained from research in people, ongoing research in dogs and cats and clinical experience, fiber is beneficial in managing many large and some small bowel diseases.

Soluble fibers (e.g., pectins and gums) increase the viscosity of intestinal contents, which delay gastric emptying and slow small bowel transit time. Viscosity markedly affects the extent of intraluminal mixing of digesta and digestive enzymes, which can shift sites of absorption and subsequently the rate of nutrients entering the bloodstream. Bacteria in the colon ferment soluble fiber to short-chain fatty acids, including acetic, propionic and butyric acids. Colonocytes apparently use butyrate, whereas propionic and acetic acids are absorbed. Short-chain fatty acids are nutritive to the colonic mucosa and foster normal colonic flora while discouraging pathogenic flora. These properties result in an acidic colonic pH and increased colonic bacterial numbers, colonic mucosal mass and fecal dry matter and water content. Soluble fiber may bind and decrease macronutrient absorption and decrease protein digestibility. Certain fiber types, especially gels and gums, may be of benefit in GI disease because they bind toxins and irritating bile acids. This binding effect prevents these substances from further damaging the intestinal mucosal surface.

Insoluble fiber is primarily composed of cellulose and structural polysaccharides that are relatively resistant to digestion and that ferment slowly, increase intestinal residue and normalize intestinal transit time. These fibers have little or no effect on gastric emptying, mineral absorption or colonic microflora unless fed in high concentrations (>20% DM). One of the most profound effects of fiber on the GI tract is the normalization of gut motility, particularly in the stomach, proximal small bowel and colon. This effect appears to be greatest for insoluble fibers such as cellulose. In general, increasing the insoluble fiber content of the food resolves or modulates most cases of colitis. There are several plausible mechanisms by which insoluble fiber controls large bowel diarrhea. Undigested residues absorb water and increase bacterial mass, which increases fecal bulk. Fecal bulk provides physical intraluminal stimulation to reestablish neuromuscular-endocrine coordinations and normalize intestinal transit times. Fecal bulk increases intestinal residue, which absorbs toxins and offending agents. For more basic information about fiber see Chapter 5.

RESTRICTED- AND MODERATE-FAT FOODS

In general, dietary fat is more digestible than digestible carbohydrate and protein and provides 2.25 times more calories by weight. Average fat digestibility in commercial dog food is approximately 90%. Average fat digestibility of commercial cat foods ranges from 74

Box 48-3 continued

to 91%. Patients with GI or pancreatic disease may not tolerate high-fat foods (>25% DM), which may contribute to diarrhea and steatorrhea. Foods containing moderate amounts of fat (12 to 15% DM for dogs and 15 to 22% DM for cats) are generally tolerated and have sufficient caloric density for most patients. Commercial veterinary therapeutic foods containing less than 10% DM fat need to be fed in larger volumes to meet the patient's caloric requirement. Some patients may not tolerate this volume of food.

Restricted-fat foods are often recommended for patients with gastroenteritis in which the complex process of fat digestion and absorption may be disrupted. Unabsorbed fat in the bowel lumen may cause secretory diarrhea. Dietary fat should be reduced when fat maldigestion or malabsorption is present due to exocrine pancreatic insufficiency or reduced bowel surface area. The latter occurs in short bowel syndrome and other conditions in which inflammation, infectious agents, neoplasia or surgery markedly reduces the intestinal villus surface area. For example, intestinal malabsorption of fat is seriously impaired in primary and secondary lymphangiectasia. Fat restriction is also useful in small intestinal bacterial overgrowth in which many of the side effects of the condition can be ameliorated by removing the inciting cause of the secretory diarrhea.

ELIMINATION FOODS

Elimination foods are most often recommended for patients with GI signs due to suspected food intolerance or food hypersensitivity. Protein sources and amounts are of key importance for elimination foods. Chapter 31 discusses adverse food reactions and elimination foods in more detail.

GLUTEN- AND GLIADIN-FREE FOODS

Several potential antigens are found in flour when cereal grains are processed. One polypeptide, gliadin, is found in wheat, barley, rye, buckwheat and oat flours. Gliadin is responsible for gluten-sensitive enteropathies in people and dogs. Homologous gliadin polypeptides are not present in whole grains and flours produced from rice and corn.

In people, gluten-induced enteropathy or celiac disease is an important malabsorptive disorder. An analogous condition, termed wheat-sensitive enteropathy, has been identified in Irish setter dogs and is suspected to affect dogs of other breeds. Affected animals develop small bowel diarrhea due to malabsorption secondary to villous atrophy. Gluten- and gliadin-free foods are most commonly recommended for managing dogs suspected of having wheat-sensitive enteropathy. In most cases, withdrawal of the offending gliadin antigen from the diet results in resolution of the villous atrophy and clinical signs.

MONOMERIC FOODS

Monomeric foods are water-soluble, liquid foods containing nutrients in their simplest absorbable form. Amino acids are most commonly provided by a mixture of di- and tripeptides and/or individual amino acids. Fats are present as triglycerides or as fatty acids. Carbohydrates are generally present as mono- or disaccharides. Minerals and vitamins are present to meet requirements. These foods minimize GI and pancreatic secretions and allow nutrient usage with minimal requirements for digestion. In addition, relative to complete proteins, the small size of amino acids, dipeptides and tripeptides in monomeric products ensures delivery of a truly "hypoallergenic" food. Monomeric foods should be considered for patients with severe malabsorption or short bowel syndrome and in initial refeeding of patients with acute pancreatitis. In addition, these foods may provide "bowel rest" for patients with severe inflammatory bowel disease. Monomeric foods are often unpalatable and are not well accepted by cats. Thus, these foods are usually administered for several days via indwelling feeding tubes. Chapter 25 lists monomeric foods.

diverse nature of GI and exocrine pancreatic disorders, a number of food types may be appropriate (**Box 48-3**). Nutrient profiles should be considered as *starting points* on a continuum of possible nutrient concentrations that can be adjusted for each patient as necessary. All too often, relative terms such as "low" vs. "high" are used without stating the point of reference. The reference point should be the current food that the owner feeds. Changes include increases or decreases, usually in 5 to 10% increments, of nutrient concentrations relative to the previous food.

Oral Diseases

Deborah J. Davenport
Rebecca L. Remillard
Ellen I. Logan

"If you have no Honey in your Pot, have some in your mouth."
Benjamin Franklin, Poor Richard's Almanac

CLINICAL IMPORTANCE

The oral cavity is susceptible to a number of acquired and congenital disorders. In comparison to the high incidence of dental disease, however, these conditions are relatively uncommon. Chapter 47 discusses periodontal disease in detail. Among the more common conditions affecting the oral cavity are inflammatory lesions and physical abnormalities such as neoplasia, trauma and congenital malformations (e.g., cleft palate).

Acquired inflammatory lesions of the oral cavity and tongue are relatively uncommon in dogs and cats but appear to be increasing in frequency (Lyon, 2005). These conditions include eosinophilic granuloma complex, gingivostomatitis, labial granuloma immune-mediated diseases (e.g., pemphigus) and mucositis due to radiation therapy of the head and neck (Ulbricht, 2008; Quimby, 2007). Infectious oral disorders (e.g., candidiasis or fusospirochetal infections) are rare and usually occur in immunocompromised animals. Oral ulcerations may be seen in cats in association with herpesvirus and calicivirus infections. Oral neoplasia is relatively common in dogs and cats (Theilen and Madewell, 1987; Smith, 2005). Malignant melanoma, squamous cell carcinoma and fibrosarcoma are the most commonly reported oral malignancies. Trauma to the oral cavity may arise from fights among animals, falls (high-rise syndrome), motor vehicle accidents, chemical and electrical burns and penetrating foreign bodies.

Oral congenital anomalies such as cleft palate are uncommon but may have nutritional causes (e.g., copper deficiency in pregnant queens) or profound consequences due to malnutrition and secondary aspiration pneumonia in growing animals.

PATIENT ASSESSMENT

History and Physical Examination

Dogs and cats with oral disease have variable clinical signs depending on the type and location of the lesions. Patients may exhibit dysphagia or pain associated with eating. Owners may report excessive salivation, oral hemorrhage, halitosis and reluctance to eat resulting in loss of body weight and condition. In some cases, careful questioning of the owner will reveal ingestion of foreign bodies or caustic materials or a history of trauma. Puppies and kittens with congenital anomalies such as cleft palate may be presented to veterinarians for ineffectual suckling, poor weight gain and coughing or gagging following attempts at nursing.

Sedation may be required to facilitate examination of the oropharynx and tongue. Various conditions may present with specific signs. Congenital defects may be noted in the soft or hard palate. Epulides originate from periodontal stroma and are most commonly located in the gingiva near the incisor teeth and appear as pedunculated or smooth, non-ulcerated masses. Odontogenic tumors (e.g., ameloblastoma and odontoma) are

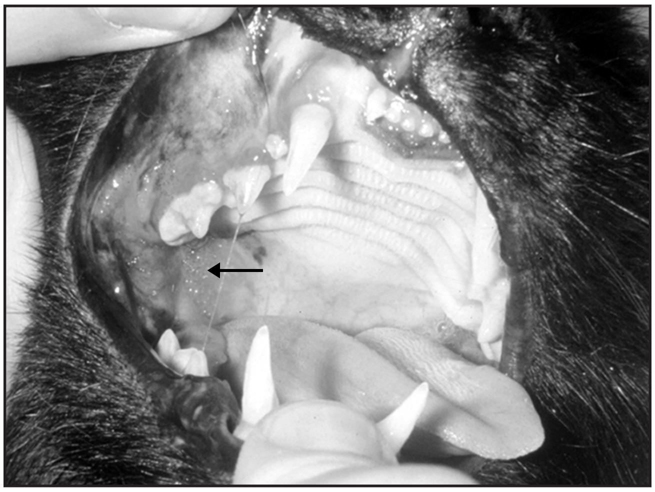

Figure 49-1. Severe lymphoplasmacytic gingivitis and stomatitis in a cat. Note the raised, cobblestone-like lesions (arrow) at the right glossopalatine arch. (Courtesy Dr. Michael Leib, Virginia-Maryland Regional College of Veterinary Medicine, Blacksburg, VA.)

Box 49-1. Feeding Patients Undergoing Radiation Therapy.

Dogs and cats undergoing radiation therapy for oral and nasal tumors often develop mucositis within the third week of a four- to five-week therapeutic protocol. This oral mucosal inflammation is painful; therefore, most animals will stop eating during this time but will drink voluntarily. A change in food form from moist or dry to a liquid is necessary for most animals to continue consuming at least their daily resting energy requirement. Most patients will consume variable quantities of a palatable chilled liquid veterinary therapeutic food during this time even if they won't consume a mixture of their regular food and water. Mixing the liquid with the patient's regular food one week before the expected onset of mucositis allows acclimation to the liquid food. Patients usually voluntarily consume their regular food as the mucositis resolves.

Some patients stop eating and drinking voluntarily when they develop mucositis and may require intravenous administration of fluids and nutrients. Discontinuing radiation therapy for a few days is also beneficial. Nasogastric or orogastric feeding tubes are not appropriate, whereas pharyngeal or esophageal feeding tubes may be useful if placed in advance and if they are not in the field to be irradiated (Chapter 25). Most patients recover quickly from mucositis (i.e., within three to four days) and consume food and water again, eliminating the need for a gastrostomy tube. Radiation treatments can usually then be continued uneventfully.

The Bibliography for **Box 49-1** can be found at www.markmorris.org.

typically expansile, slow-growing odontogenic masses that often form in the incisor region. Malignant tumors (e.g., squamous cell carcinoma, malignant melanoma and fibrosarcoma) grow rapidly and are characterized by early invasion of the gingiva and bone. Pets with suspected oral or tonsillar tumors should be carefully evaluated for peripheral lymphadenopathy.

Gingivostomatitis is characterized by raised, erythremic cobblestone-like lesions at the glossopalatine arches (**Figure 49-1**), whereas feline eosinophilic granuloma complex manifests as ulcers, plaques and granulomas on the maxillary lips, tongue and palate. In dogs, inflammatory lesions are most often present on the tongue or palatine and labial mucosa.

Head trauma in pets often results in mandibular symphyseal fractures, maxillary fractures, displaced teeth and separation of the hard palate. These injuries may result in reluctance or inability to eat.

Chemical, electrical and thermal burns are characterized by ulceration and necrosis of affected tissues. Animals with oral burns may suffer life-threatening consequences such as pulmonary edema or cardiogenic shock.

Laboratory and Other Clinical Information

Laboratory values are often unremarkable in patients with oral disease and generally reflect underlying conditions when present. Leukocytosis and a polyclonal hyperglobulinemia are frequent findings in cats with lymphoplasmacytic stomatitis. Radiography is often of value in cases with suspected trauma to assess the extent of bony injury. Radiography is invaluable for tumor staging in patients with oral neoplasia. Generally, both skull and thoracic films are evaluated. In addition, thoracic films allow assessment of aspiration pneumonia in young animals with cleft palate. Diagnosis of lesions within the oral cavity often requires biopsy and histopathologic examination.

Risk Factors

Age and breed are risk factors for several oral disorders. Young patients are more likely to present with congenital and traumatic lesions, whereas older dogs and cats are more likely to suffer from oral neoplasia and inflammatory disorders. Patients undergoing radiation therapy of the head and neck for cancer are susceptible to radiation-induced mucositis (**Box 49-1**). In addition, certain breeds are predisposed to various oral disorders (**Table 49-1**).

Etiopathogenesis

Pets with oral disease often exhibit dysphagia or reluctance to eat resulting in malnutrition. Often this nutritional state is compounded by inflammatory, traumatic or neoplastic processes. The etiology of oral inflammatory lesions such as gingivostomatitis and faucitis, and eosinophilic granuloma complex is unknown. Gingivostomatitis in cats has been theorized to be an aberrant immunologic response to antigenic stimuli. Various bacterial, viral, periodontal, dietary and immune factors have been implicated (Quimby, 2008). There is a strong association between this disorder and infection with feline immunodeficiency virus (FIV) or calicivirus (DeBowes, 1997). Approximately 50% of cats with FIV infection and 60% of cats with calicivirus infection have chronic oral disease (DeBowes, 1997). These findings do not prove causality, however. The response of some cats with the disorder to radical extraction of teeth and the isolation of antibodies to plaque

bacteria (*Actinobacillus* and *Bacteroides* spp.) from affected cats also suggest the potential of "plaque intolerance" (DeBowes, 1997).

Key Nutritional Factors

The key nutritional factors for foods for oral diseases are discussed below and summarized in **Table 49-2**.

Water

Dehydration is a frequent problem in dogs and cats with oral disorders that interfere with consumption of water. Whenever possible, fluid balance should be maintained via oral consumption of fluids. However, parenteral fluid administration is often needed for dehydrated patients and those unable or unwilling to drink adequate amounts of water.

Energy Density

A food with a relatively high energy density concentration is helpful in meeting the patient's caloric requirement in a small volume of food. Foods with energy densities in excess of 4.5 kcal/g (18.8 kJ/g) dry matter (DM) for dogs and 5 kcal/g (20.9 kJ/g) DM for cats are recommended.

Food Form

The veterinarian or owner should experiment with foods of differing consistency. Often liquid foods or slurries made from moist pet food and water are more readily accepted. A dilute consistency is often associated with less discomfort and is less likely to accumulate in oral lesions or adhere to surgical sites within the oral cavity.

FEEDING PLAN

The goals of dietary management for patients with oral disease are to provide adequate nutrition while minimizing discomfort to the pet and enhancing resolution of the oral lesions.

Assess and Select the Food

The key nutritional factors recommended for foods for patients with oral diseases should be compared with the levels in the foods under consideration for feeding. Underweight patients may need a nutrient profile similar to that found in a growth or recovery-type formula to regain normal body condition. In addition, the food should be suitable for any other conditions present that are amenable to dietary management.

Patients with extensive oral injuries or inflammation of the oral cavity may benefit from foods designed for assisted feeding or recovery (Chapter 25). Patients with oral neoplasia may benefit from foods specifically formulated for patients with cancer (Chapter 30).

Assess and Determine the Feeding Method

Because the feeding method is often altered in patients with oral disease, a thorough assessment should include verification of the feeding method currently being used. Items to consider include feeding frequency, amount fed, how the food is offered, access to other food sources including table food and who feeds the animal. All of this information should have been gathered when the history of the animal was obtained.

Dogs and cats with oral disease should initially be fed several small meals daily if they are able and willing to consume food voluntarily. After each meal, the oral cavity should be flushed with water to remove particulate matter adhered to the oral mucous membranes. In many cases, tube-feeding methods are preferred until oral discomfort is reduced, oral lesions are healed and voluntary food consumption resumes (Chapter 25).

Table 49-1. Breed-associated oral disorders.

Disorders	Breeds
Cleft palate	Brachycephalic dogs and cats
Epulides	Boxer
Gingivitis/stomatitis	Maltese dog Siberian husky
Lymphoplasmacytic stomatitis	Abyssinian cat Burmese cat Himalayan cat Maltese cat Persian cat Siamese cat
Neoplasia	Cocker spaniel German shepherd dog German shorthaired pointer Golden retriever Weimaraner

Table 49-2. Key nutritional factors for foods for patients with oral diseases.

Factors	Dietary recommendations
Water	Maintain fluid balance with oral, and if necessary, parenteral fluids
Energy	For dogs: >4.5 kcal/g (>18.8 kJ/g) dry matter For cats: >5 kcal/g (>20.9 kJ/g) dry matter
Food form	Liquid foods and slurries made from moist food are often more readily accepted

REASSESSMENT

Body condition scores and hydration status should be evaluated to determine adequacy of food and water consumption. Assisted feeding should be instituted if oral feeding is inadequate to maintain body weight and condition (Chapter 25).

Pharyngeal and Esophageal Disorders

Deborah J. Davenport

Michael S. Leib

Rebecca L. Remillard

"The Chinese do not draw any distinction between food and medicine."
Lin Yutang

CLINICAL IMPORTANCE

Compared with vomiting and diarrhea, swallowing disorders are relatively uncommon in dogs and cats. However, these conditions are often profoundly debilitating due to undernutrition (i.e., lack of adequate food intake) and recurrent pulmonary infections resulting from aspiration. Pharyngeal and esophageal disorders most commonly encountered include: 1) motility disorders (e.g., cricopharyngeal achalasia, megaesophagus), 2) inflammatory disorders (e.g., esophagitis, gastroesophageal reflux) and 3) obstructive lesions (e.g., vascular ring anomalies, strictures and foreign bodies).

PATIENT ASSESSMENT

History and Physical Examination

Congenital pharyngeal and esophageal disorders are typically diagnosed in young animals soon after weaning. In some young dogs, clinical and subclinical esophageal dysmotility may improve with age, whereas the disorder progresses in other patients (Bexfield et al, 2006). Rarely, dogs with congenital malformations of the aortic arches, also known as vascular ring anomalies, may present with late-onset regurgitation as adults (Fingeroth and Fossum, 1987; Muldoon et al, 1997).

Acquired pharyngeal and esophageal disease can affect dogs and cats of any age. Owners of pets presenting for suspected pharyngeal and esophageal disorders should be asked about feeding dental chew treats (Leib and Sartor, 2008), bones or bone and raw food diets, which can result in esophageal foreign bodies. The history of a recent anesthetic procedure may suggest reflux esophagitis (Wilson et al, 2005). Owners of cats presenting with signs of esophageal disease should be asked about recent oral antibiotic administration (Westfall et al, 2001; Beatty et al, 2006; German et al, 2005).

Owners of dogs with dysphagia due to pharyngeal disease typically report coughing or gagging as the dog chews and swallows its food. In dogs and cats, the hallmark of an esophageal disorder is regurgitation (**Box 50-1**). Additional clinical signs include ptyalism, frequent swallowing, gurgling esophageal noises, halitosis and apparent pain on swallowing. Affected cats may vocalize in conjunction with gagging or regurgitation. The frequency of regurgitation is variable. Owners may report immediate postprandial regurgitation of undigested food, water or saliva or describe signs manifested several hours after feeding. Affected dogs and cats often have a voracious appetite despite regurgitation unless they have secondary aspiration pneumonia. Dyspnea, coughing, weakness and fever may be referable to severe respiratory compromise associated with aspiration pneumonia.

Esophageal disorders may be associated with neuromuscular diseases and endocrinopathies. Owners may describe their pets as being weak or uncoordinated. The evidence for association of megaesophagus and hypothyroidism is tenuous and uncommon.

Poor body condition is often evident (body condition score [BCS] 1/5 or 2/5). Body condition should be monitored close-

Box 50-1. Regurgitation vs. Vomiting.

Differentiating regurgitation from vomiting is important in distinguishing esophageal from gastric disease. Characteristics of vomiting include expulsion of digested and bile-stained food and retching with involuntary abdominal contractions. Gastric contents are often highly acidic, which may be reflected in the pH of the vomitus. However, vomiting often involves reflux of bicarbonate-rich fluid into the stomach from the duodenum, which buffers gastric acid. The vomited material may then have a neutral or near-neutral pH.

Regurgitation involves less forceful casting up of tubular, bile-free, undigested food. Mucoid secretions mixed with the undigested food will usually have a pH of 6.5 to 7.0. Copious salivation may also be a confusing sign; it may be a primary sign of esophageal diseases (e.g., foreign body) or it may be part of the nausea that often accompanies vomiting.

The Bibliography for **Box 50-1** can be found at www.markmorris.org.

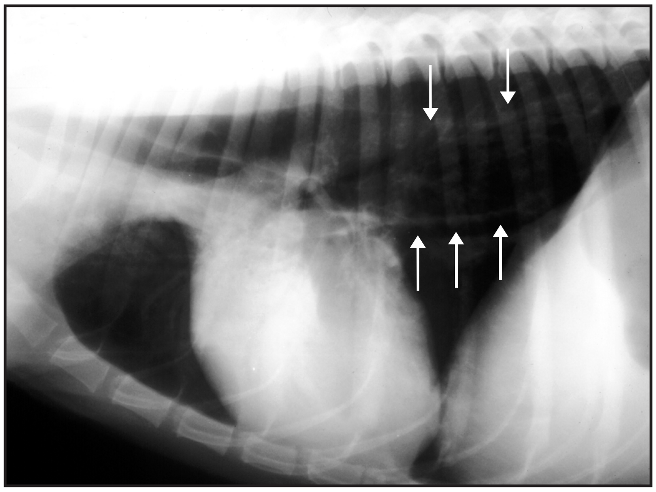

Figure 50-1. Lateral thoracic radiograph demonstrating esophageal dilatation in a dog with acquired megaesophagus. The arrows depict the dorsal and ventral margins of the dilated esophagus. (Courtesy Dr. Joanne Burns, Veterinary Imaging Services, Topeka, KS.)

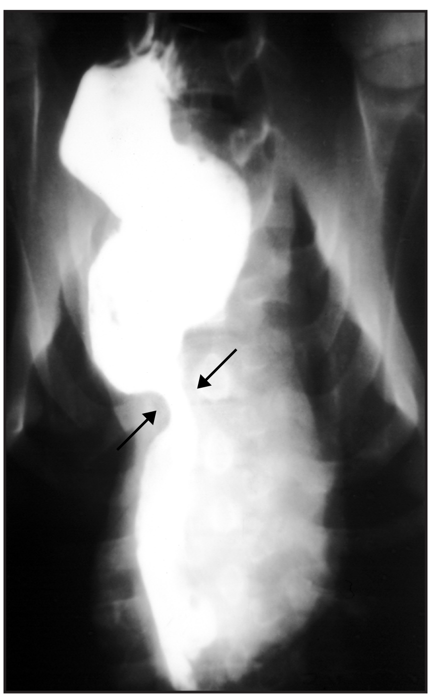

Figure 50-2. Ventrodorsal thoracic radiograph with a positive-contrast esophagram demonstrating an esophageal stricture due to a persistent right aortic arch in a puppy. Note the narrowed esophageal lumen at the base of the heart (arrows) and dilatation of the esophagus on either side of the obstruction.

ly during reassessment and the BCS should be recorded. Young patients with congenital megaesophagus, vascular ring anomalies or cricopharyngeal dysphagia are often stunted compared to littermates.

Auscultatory findings often indicate secondary aspiration pneumonia and may include crackles and prominent bronchovesicular sounds. Dogs with aspiration pneumonia may be febrile and have a mucopurulent nasal discharge.

A complete neurologic examination should be performed on adult dogs with swallowing disorders because acquired megaesophagus is often associated with neuromuscular disorders. Signs of lower motor neuron disease may provide evidence of a generalized polymyopathy, polyneuropathy or neuromuscular junctionopathy (e.g., myasthenia gravis).

Laboratory and Other Clinical Information

A complete blood count may provide evidence of aspiration pneumonia and some sense of the severity of infection. In chronically affected patients, serum protein and albumin concentrations may provide an indication of nutritional status. Additionally, other serum biochemical abnormalities may provide evidence for an underlying disorder (e.g., hypoadrenocorticism, hypothyroidism).

Radiography is a vital diagnostic aid for evaluating dogs and cats with suspected swallowing and esophageal disorders. Survey films may provide definitive information in cases of megaesophagus and esophageal foreign bodies (**Figure 50-1**). Radiographic findings in dogs and cats with megaesophagus include a dilated, air-filled esophagus. In the case of vascular ring anomalies, characteristic esophageal dilatation proximal to the heart base can be identified. Thoracic radiography also allows the clinician to assess the patient for aspiration pneumonia. Additionally, thoracic films may reveal a cranial thoracic mass. Thymoma and thymic lymphosarcoma have been associated with secondary acquired megaesophagus and generalized inflammatory myopathies.

An esophagram offers additional diagnostic information, especially in cases of obstructive lesions, esophagitis and esophageal hypomotility without megaesophagus (**Figure 50-2**). When coupled with video fluoroscopy, an esophagram allows sensitive evaluation of the swallow reflex and esophageal motility (Bexfield et al, 2006) (**Figure 50-3**).

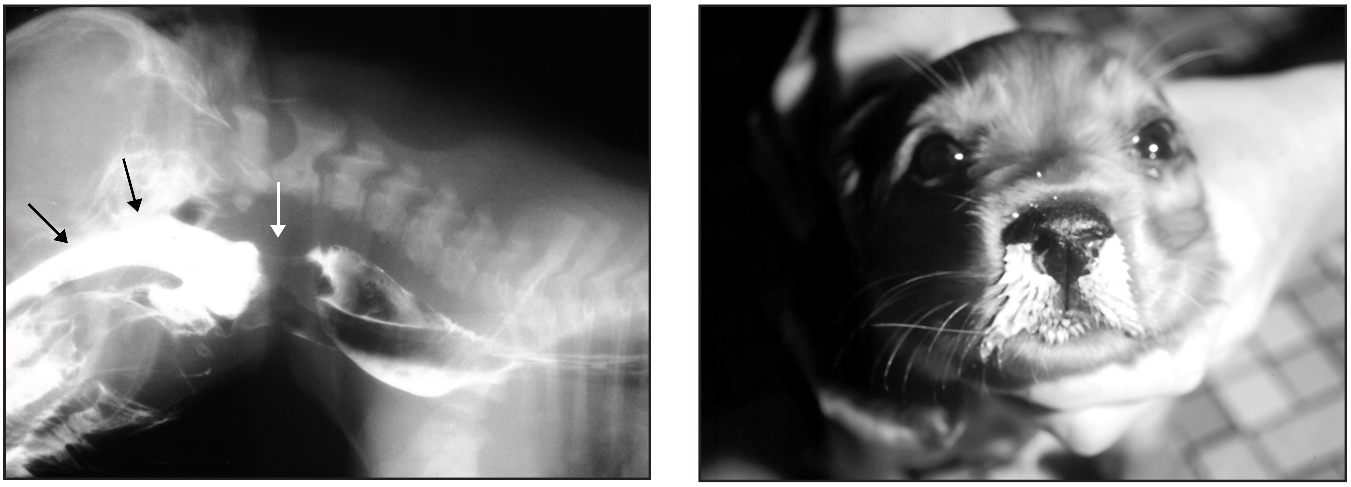

Figure 50-3. Cricopharyngeal achalasia in a cocker spaniel puppy presented for dysphagia. A barium swallow (Left) demonstrated that the cricopharyngeal region (white arrow) did not relax normally during swallowing, which resulted in reflux of barium into the nasopharynx (black arrows). Only a small amount of barium entered the esophagus. The puppy had a difficult time swallowing liquids as shown by regurgitation of milk back through the nose (Right). (Courtesy Dr. Philip Roudebush, Topeka, KS.)

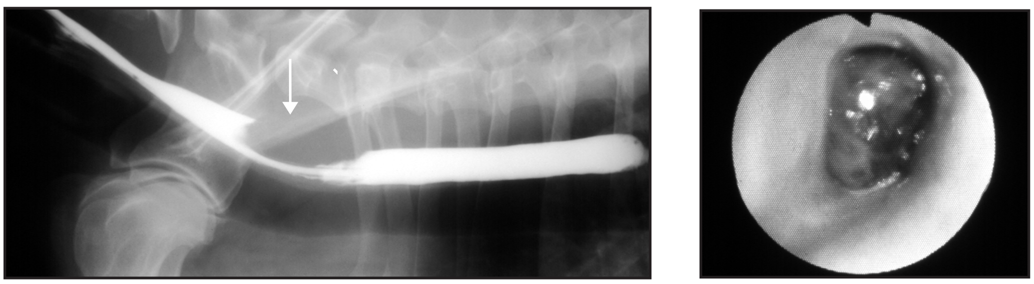

Figure 50-4. Positive-contrast esophagram (Left) from a 12-year-old mixed-breed dog presented for worsening regurgitation. A filling defect is noted in the dorsal wall of the esophagus (arrow). Endoscopy demonstrated a mass lesion (Right) that was confirmed by examination of biopsy specimens as a squamous cell carcinoma. This lesion developed at the site of an acquired esophageal stricture secondary to an episode of postsurgical gastroesophageal reflux. (Courtesy Dr. Michael Leib, Virginia-Maryland Regional College of Veterinary Medicine, Blacksburg, VA.)

Esophagoscopy is a valuable tool for evaluating dogs and cats with suspected obstructive, neoplastic or inflammatory lesions of the esophagus and pharynx (**Figure 50-4**). This tool allows visualization of the entire area and collection of tissue specimens for microbiologic and histopathologic examination, if indicated. Additionally, in cases of esophageal foreign bodies or strictures, the flexible endoscope can provide definitive treatment of the lesion. Foreign bodies can be retrieved or pushed into the stomach using a variety of forceps, whereas esophageal strictures are best managed with endoscopic bougienage, balloon dilatation or both procedures (Weyrauch and Willard, 1998; Leib et al, 2001).

Acquired megaesophagus can occur secondary to several neuromuscular disorders such as myasthenia gravis, dysautonomia, hypothyroidism, hypoadrenocorticism, systemic lupus erythematosus and other causes of generalized myopathy or neuropathy (Dewey et al, 1995; Shelton, 1996, 1996a; Gaynor et al, 1997; Bartges and Nielson, 1992; Harkin et al, 2002).[a] Consult internal medicine and gastroenterology textbooks for a more complete discussion of the diagnosis of these disorders.

Risk Factors

Swallowing disorders have been thought to occur rarely in cats. However, several recent reports have described esophagitis and esophageal strictures in cats after administration of oral antibiotics (tetracycline, doxycycline and clindamycin) (Leib et al, 2001; Beatty et al, 2006; German et al, 2005). Cats may also develop esophageal disease as a result of anesthesia-associated gastroesophageal reflux (Pearson et al, 1978; Leib et al, 2001), gastroesophageal reflux disease (Han et al, 2003) and foreign bodies (Augusto et al, 2005).

In dogs, risk factors for swallowing disorders are primarily breed and age related. Several breeds appear to be predisposed to the development of congenital disorders such as cricopharyngeal dysphagia, congenital megaesophagus and vascular ring anomalies (**Table 50-1**).

No gender predisposition for idiopathic acquired swallowing disorders is apparent. The condition, however, occurs more often in large-breed dogs (Leib and Hall, 1984). One report indicated that Great Dane, golden retriever, German shepherd and Irish setter dogs are at risk for the disease (Gaynor et al,

Table 50-1. Breed-associated disorders of the pharynx and esophagus.

1997). Middle-aged to older dogs are more likely to develop myasthenia gravis and other neuromuscular disorders resulting in esophageal disease. Nearly 90% of dogs with focal or generalized myasthenia gravis develop megaesophagus (Shelton et al, 1990). In addition, those breeds predisposed to endocrinopathies (e.g., hypothyroidism and hypoadrenocorticism) are at risk for development of megaesophagus as a rare manifestation of their disease. Dogs with laryngeal paralysis are also at risk for development of megaesophagus (Gaynor et al, 1997). In certain areas (e.g., northeastern United States), exposure to lead has been linked to cases of secondary acquired megaesophagus. In the Midwest, dysautonomia may be associated with acquired megaesophagus (Harkin et al, 2002).

Etiopathogenesis

Pharyngeal and esophageal disorders can generally be attributed to one of three basic pathophysiologic mechanisms: aberrant motility, obstructive lesions or inflammatory degenerative conditions that cause esophagitis/gastroesophageal reflux (**Table 50-2**) (Twedt, 1995).

Aberrant Motility

Cricopharyngeal dysphagia is characterized by asynchrony of the swallowing reflex (Papazoglou et al, 2006). In this condition, the cricopharyngeal muscle fails to relax in coordination with pharyngeal muscle contractions, thus preventing passage of a food bolus from the oropharynx to the esophagus.

Historically, dogs with megaesophagus were presumed to have esophageal achalasia. In this condition, the lower esophageal sphincter fails to relax as esophageal peristaltic activity delivers food to the gastroesophageal junction (GEJ). However, lower esophageal sphincter pressure is normal and activity is synchronous with esophageal motility in dogs with congenital and acquired megaesophagus. The work of several investigators suggests that the efferent pathway in many dogs with megaesophagus is functional, whereas the afferent pathway is dysfunctional (Tan and Diamant, 1987; Holland et al, 1993, 1994). Using intraluminal balloon distention, investigators demonstrated that dogs with idiopathic megaesophagus have a defect in their afferent neural pathway (Washabau, 1992). Other investigators have suggested a defect in esophageal compliance (Holland et al, 1993). These findings have clinical implications because they suggest that foods containing more bulk or prepared in larger boluses may have the capacity to stimulate esophageal motility in mildly affected animals (**Box 50-2**).

Obstructive Lesions

Persistent right aortic arch is the most common vascular ring anomaly recognized in dogs and cats (Muldoon et al, 1997). This anomaly results in constriction of the esophagus at the level of the heart base by the right fourth aortic arch and the ligamentum arteriosum. Esophageal dilatation develops proximal to the vascular ring, leading to regurgitation. Esophageal motility defects may persist if the obstructive lesion is not surgically corrected before irreversible damage to esophageal function occurs.

Esophageal obstruction due to stricture formation may occur as a consequence of recurrent or severe esophageal injury. Strictures occur most commonly due to esophageal foreign bodies or as sequelae to gastroesophageal reflux during general anesthesia. Rarely, infectious (e.g., pythiosis), parasitic (e.g., *Spirocerca lupi*) or neoplastic conditions can result in obstructive esophageal lesions (Mylonakis et al, 2008).

Box 50-2. Swallowing Reflex.

In animals with simple stomachs, deglutition is a sequential, complex, coordinated action that transports food and liquid from the oral cavity to the stomach. It has been divided into three phases: oropharyngeal, esophageal and gastroesophageal.

The oropharyngeal phase begins with the formation of a bolus in the mouth and ends as the bolus passes through the cricopharyngeal area. Pharyngeal contraction is coordinated with relaxation of the upper esophageal sphincter. Following passage of the bolus, the upper esophageal sphincter contracts to close the upper esophagus and to initiate the esophageal phase of swallowing.

The esophageal phase of deglutition begins with the arrival of the bolus in the cranial esophagus. This phase encompasses passage of the bolus from the cranial esophagus to the gastroesophageal junction (GEJ). Four sequences of events that might occur during the esophageal phase have been described.

1. A swallow is followed immediately by an esophageal peristaltic wave, which progresses uninterrupted to the GEJ (primary peristalsis).
2. Liquid and some solid boluses remain in the proximal esophagus until a second or third swallow occurs, then a peristaltic wave carries the combined boluses to the GEJ (primary peristalsis). Other solids immediately move down the esophagus.
3. A bolus temporarily pauses in the proximal esophagus, then a stimulated peristaltic wave carries it to the GEJ (secondary peristalsis).
4. Several boluses accumulate in the proximal esophagus, then a stimulated peristaltic wave carries them to the GEJ (secondary peristalsis).

Direct stimulation of the esophageal wall by a bolus initiates a second peristaltic wave. This is also the pathway for perpetuation of the primary wave; sensory stimulation from the bolus continues as it moves down the esophagus. Progression of primary or secondary peristaltic contractions depends on the presence, size and location of the bolus in the esophagus. In the absence of a bolus, peristalsis in the esophagus does not follow the act of swallowing. In the thoracic esophagus, contractions are facilitated by, but do not depend on a bolus. Thus, two mechanisms are involved in the regulation of esophageal contraction: 1) a central regulatory mechanism (swallowing center) in the brainstem and 2) afferent nerve impulses that originate in the esophagus in the presence of a bolus.

The lower esophageal sphincter (LES) is not a true anatomic sphincter, but rather a physiologic high-pressure zone. This zone is found in the most distal portion of the esophagus and separates the esophagus from the stomach. The LES is the functional term used for this region, but many authors use the anatomic term GEJ. During peristalsis, the LES relaxes and allows the bolus to pass into the stomach (gastroesophageal phase). A prevalent misunderstanding is that LES relaxation and opening are synonymous. Relaxation and opening of the LES are related but distinct events. LES opening is a passive mechanical event affected by the force of an oncoming bolus, whereas LES relaxation occurs as an active reflex process mediated neurologically. The average canine LES begins to relax several seconds before the esophageal pressure wave peaks in the distal esophagus. Even if the LES opens and closes normally, synchronization of LES with the esophageal wave is still required for normal passage of a bolus. It closes after passage of the bolus to prevent gastroesophageal reflux.

The GEJ is the only area of the gastrointestinal tract in which luminal structures having opposite cavitary pressures are in continuity. Mechanical factors and intrinsic LES tone serve as the major control mechanisms to prevent reflux of gastric contents. Whatever external force or positive pressure is applied to the stomach is also exerted on the terminal abdominal esophagus; therefore, no pressure gradient occurs between the stomach and thoracic esophagus. Other mechanical factors that prevent gastroesophageal reflux include: 1) interdigitating gastric rugal folds, 2) focal thickening of the distal esophageal muscle coat (in the dog there is an inner section of smooth muscle), 3) oblique implantation of the distal esophagus into the stomach and 4) the flap-like cardiac incisura, which is pushed against the GEJ by the enlarging gastric fundus. Gastrin and other gastrointestinal hormones at pharmacologic doses appear to increase LES tone. Whether these hormones function to increase LES tone when released physiologically during normal food ingestion is still speculative.

The Bibliography for **Box 50-2** can be found at www.markmorris.org.

Inflammation/Degeneration

Esophagitis arises most often as a consequence of gastroesophageal reflux or foreign body ingestion (Sellon and Willard, 2003). The GEJ serves as a barrier preventing reflux of gastric contents including pepsin and hydrochloric acid into the lumen of the esophagus. Postprandially, GEJ pressure increases in response to neural and hormonal stimuli. Certain gastrointestinal (GI) hormones, including gastrin, pancreatic polypeptide, motilin and substance P increase GEJ pressure, whereas others (i.e., secretin, cholecystokinin) reduce GEJ pressure. Dietary influences on the GEJ pressure are presumably mediated via GI hormone release. High-protein meals increase GEJ pressure through gastrin release, whereas high-fat foods reduce GEJ pressure via cholecystokinin release.

The most common cause of esophagitis in dogs and cats appears to be anesthesia-associated reflux of gastric contents into the esophagus (Sellon and Willard, 2003). Certain sedatives, including acepromazine, xylazine and diazepam reduce GEJ pressure and may predispose an animal to reflux esophagitis following anesthetic episodes (Strombeck and Harrold, 1985; Hall et al, 1987). Recently, anesthetic-associated gastroesophageal reflux has been demonstrated to occur equally in dogs maintained under anesthesia for orthopedic procedures with isoflurane, halothane or sevoflurane (Wilson et al, 2006). Fifty-one of 90 dogs studied developed acid reflux within 30 to 90 minutes following induction and 13 of 90 patients regurgitated.

Foreign body ingestion is most commonly reported in young patients. However, certain feeding practices can result in esophageal foreign bodies in adult patients. Feeding vegetable-based dental chews and treats, bones and rawhide

Table 50-3. Key nutritional factors for foods for patients with swallowing disorders due to obstructive lesions or aberrant motility.*

Factors	Recommended levels

*Nutrients expressed on a dry matter basis; food form is also a key nutritional factor but varies with individual patients (see text).

Table 50-4. Key nutritional factors for foods for dogs and cats with esophagitis/gastroesophageal reflux.*

Factors	Recommended levels
Energy density	≥4 kcal/g (≥16.7 kJ/g)
Fat	≤15% for dog foods
	≤20% for cat foods
Protein	≥25% for dog foods
	≥35% for cat foods

*Nutrients expressed on a dry matter basis; food form is also a key nutritional factor, but varies with the disease and individual patients (see text).

chews have resulted in esophageal foreign bodies (Rousseau et al, 2007; Leib and Sartor, 2008). In a recent retrospective review, 46 of 60 esophageal foreign bodies removed from dogs were bones (Rousseau et al, 2007). Occasionally, consumption of irritative substances such as strong acids or alkalis may cause serious esophagitis. Drug-induced esophageal disease is common in people (Sellon and Willard, 2003) and has been reported to occur in cats receiving antibiotic tablets or capsules via a "dry swallow." In cats, esophageal transit times are prolonged following the administration of dry capsules as compared to capsules followed by a water bolus (Westfall et al, 2001). Administration of oral antibiotics to cats should be accompanied by wet food and/or a water bolus (Westfall et al, 2001; Beatty et al, 2006).

Iatrogenic esophagitis may occur as a sequela to nasoesophageal intubation when the feeding tube crosses the GEJ, resulting in incompetence of the sphincter (Lantz et al, 1983). Hiatal hernias are rarely reported in dogs and cats, but can interfere with the function of the GEJ.

Key Nutritional Factors

Key nutritional factors for patients with swallowing disorders are summarized in **Tables 50-3** and **50-4** and discussed in detail below. Patients with swallowing disorders are often debilitated and growth of very young patients is often stunted. In addition to the key nutritional factors discussed here, other nutritional factors may be important depending on the lifestage and body condition of the patient.

Energy and Fat

In patients with motility and obstructive disorders, a relatively high energy density is helpful in meeting the patient's caloric requirement in a small volume of food relative to lower fat foods. Foods with at least 25% dry matter (DM) fat and energy densities of at least 4.5 kcal/g (18.8 kJ/g) DM are recommended. However, a lower fat content (≤15% DM for dogs and ≤20% DM for cats) is a better option for cases of esophagitis due to gastric reflux. High dietary fat delays gastric emptying and reduces lower esophageal sphincter pressure, which promotes reflux of food and gastric secretions into the esophagus (Washabau and Hall, 1997). However, these patients also need relatively energy dense foods (at least 4 kcal/g DM [16.7 kJ/g]). An energy dense, moderate fat food is recommended for patients with esophagitis/gastroesophageal reflux. Foods with these characteristics tend to be highly digestible.

Protein

Protein is required in amounts adequate for tissue repair and to support growth in young patients. Additionally, dietary protein may play an important role in reducing episodes of gastroesophageal reflux because protein stimulates an increase in gastroesophageal sphincter pressure. This effect is linked to dietary protein's stimulatory effect on gastrin and gastric acid secretion (Guilford, 1996). By increasing the lower esophageal sphincter pressure, episodes of gastroesophageal reflux are decreased, thus limiting the potential for further esophageal injury or aspiration pneumonia. For these reasons, dietary protein content should be at least 25% DM for foods for adult dogs and at least 35% DM for foods for adult cats.

Food Form

Foods of differing consistency should be used to determine the best texture for individual patients. A liquid or gruel consistency is usually best for patients with cricopharyngeal dysphagia, esophageal obstructive lesions and/or esophagitis and may be effective in patients with megaesophagus. Esophageal performance may improve in patients with megaesophagus when the swallowing reflex is maximally stimulated by the texture of dry foods or when moist foods are formed into large boluses. Dry food or boluses of moist food may act as a stimulus (secondary peristalsis) to any remaining normal esophageal tissue. Gruels or liquids may not stimulate secondary peristalsis, thereby increasing the risk of aspiration pneumonia.

FEEDING PLAN

The goals of dietary management for patients with megaesophagus are to minimize regurgitation, avoid secondary aspiration pneumonia and to provide adequate nutrition to regain or maintain proper body weight and condition.

Assess and Select the Food

The appropriate key nutritional factor profile and the form of the food recommended for use in patients with pharyngeal/esophageal disorders depend on whether the problem is due to obstructive lesions/aberrant motility or underlying inflammatory conditions.

Table 50-5. Key nutritional factor content of selected commercial veterinary therapeutic foods for dogs with esophagitis/gastroesophageal reflux compared to recommended levels.*

**Energy density values are listed on an as fed basis and are useful for determining the amount to feed; cup = 8-oz. measuring cup. To convert to kJ, multiply kcal by 4.184.

Obstructive Lesions and Aberrant Motility

Feeding a high-calorie, high-fat balanced growth or recuperative food (a working/sporting food for dogs) is appropriate for most patients with megaesophagus, cricopharyngeal achalasia or obstructive lesions. The food consistency that best promotes flow through the esophagus to the stomach is determined in each case by trial and error.

Gruels often work well, which necessitates using foods with high water content (>80%). Moist foods are typically made with ingredients that blenderize easily with water. For example, meat ingredients containing connective tissue and bone do not blenderize as easily as skeletal muscle and organ protein sources. Therefore, using nutrient-dense products made from highly digestible ingredients is more likely to meet the nutrient requirements of the patient in the smallest volume possible. Recommending larger cans of calorically dense cat food can help reduce the volume and cost of feeding a large dog.

However, esophageal performance may improve in megaesophagus patients when the swallowing reflex is maximally stimulated by the texture of dry foods or moist foods formed into large boluses. These food forms may act as a stimulus (secondary peristalsis) to any remaining normal esophageal tissue whereas, gruels or liquids may not stimulate secondary peristalsis, thereby increasing the risk of aspiration pneumonia.

Comparing the key nutritional factor content of a food being considered with the recommendations in **Table 50-3** will facilitate the selection process. Tables 17-4, 18-12, 24-3, 25-8 and 25-9 are also useful.

Inflammatory Conditions

Foods with lower levels of dietary fat are recommended for managing patients with esophagitis and gastroesophageal reflux. Higher dietary fat levels may precipitate gastroesophageal reflux by delaying gastric emptying and reducing lower esophageal sphincter pressure. Increased dietary protein enhances lower esophageal sphincter tone. **Tables 50-5** and **50-6** compare the key nutritional factor content of selected veterinary therapeutic foods to the recommended levels for canine and feline patients, respectively, with esophagitis and gastroesophageal reflux. As mentioned above, moist foods are usually more readily liquefied.

Assess and Determine the Feeding Method

Patients with swallowing disorders often require specialized feeding methods because the current feeding protocol of one to three meals per day fed in a bowl on the floor is rarely appropriate. In addition to a change to the appropriate food (including form), the key tools of nutritional management in these cases are a change in the feeding method.

Small-volume, frequent meals are recommended when feeding patients with swallowing disorders. Gruel-type foods are often necessary because the liquid form is more amenable to gravity fill of the stomach. Feeding a high-calorie food to a patient in an upright position and maintaining this position for 20 to 30 minutes after feeding provides ample time for gravitational flow of the food through the esophagus to the stomach. Upright feeding can be accomplished by several methods. The most common technique is to elevate the food bowl so that the dog or cat has to sit down or stand on its hind legs to eat. Pets can be trained to eat on stairs or from a counter or stool. Alternatively, small dogs and cats can be cradled in an upright position in the owner's arms while eating (**Figure 50-5**). Large dogs can be trained to sit after eating or lie in sternal recumbency on an inclined board for the required period of time. Several companies manufacture devices to facilitate upright feeding (**Figure 50-6**).

In some patients, upright feeding is inadequate to control regurgitation or is impractical because of the pet's temperament or

Figure 50-6. Feeding device that can be used to maintain an upright feeding position for patients with megaesophagus.

the owner's schedule. In those cases, placement of a gastrostomy or enterostomy tube is recommended to bypass the esophagus entirely. Nasoesophageal, nasogastric and esophagostomy tubes are not appropriate in this situation because they deliver food into the esophagus where it can be regurgitated. Patients with ongoing signs of malnutrition at presentation should receive a large-bore gastrostomy feeding tube, if possible, and immediate alimentation via the tube until adequate oral intake can be achieved. Gastrostomy tubes have been used successfully for long periods to maintain the nutritional status of dogs with megaesophagus. A permanent button-type gastrostomy tube should be considered in cases in which owners are willing to feed their pet long-term via gastrostomy tube. Even with the use of gastrostomy tubes, regurgitation of saliva and food refluxed from the stomach may still occur, which can result in aspiration pneumonia. Some clinicians prefer feeding via enterostomy tube because of the potential for gastroesophageal reflux and recurrent aspiration. Owners should be made aware that regurgitation might not completely cease even if all food and water is administered through the gastrostomy tube. Many patients will continue to regurgitate fluid, which is most likely salivary secretions. However, the likelihood of aspiration pneumonia is reduced greatly.

Pharyngeal and esophageal tissues heal slowly and are susceptible to secondary bacterial infections. Therefore, surgeons have traditionally recommended withholding oral feedings of regular pet foods for three to four days for patients with inflammation, trauma or surgery to these tissues. Patients with no history or evidence of malnutrition may be safely held off food (but not water) for two to three days if necessary, but should receive nutrition by the fourth day. Percutaneous endoscopic gastrostomy tube placement may be useful in patients after dilatation of esophageal strictures or in pets with severe esophagitis secondary to foreign body removal. The tubes can be placed at the time of an endoscopic esophageal examination. Dietary goals in

these patients are to provide adequate nutrition to the patient using foods that minimize irritation and trauma to sensitive pharyngeal and esophageal tissues.

CONCURRENT THERAPY

The feeding plan is often used in conjunction with other therapeutic modalities including surgery (e.g., cricopharyngeal myotomy, esophageal stricture, vascular ring anomaly, esophageal foreign bodies), bougienage (e.g., esophageal stricture), endoscopy (e.g., foreign body removal) and drugs (e.g., antibiotics, prokinetic agents, corticosteroids, antacids, H_2-receptor blockers, mucosal protective agents).

REASSESSMENT

Nutritional reassessment of patients with swallowing disorders includes: 1) monitoring changes in body weight and condition, 2) evaluating owner compliance regarding feeding the proper amount of food to the patient, 3) determining the extent of ongoing dysphagia or regurgitation and 4) monitoring resolution of other concurrent disease processes (e.g., pneumonia, myopathies, endocrinopathies). Daily food dosage should be adjusted as indicated by changes in the patient's body weight and condition.

CASE 50-1

Regurgitation in a Collie

Deborah J. Davenport, DVM, MS, Dipl. ACVIM (Internal Medicine)
Hill's Science and Technology Center
Topeka, Kansas, USA

Patient Assessment

A six-year-old, neutered female collie dog was examined for regurgitation and coughing of two weeks' duration. The owners had first noticed what they described as vomiting two weeks earlier. Further questioning confirmed that the problem was probably regurgitation because the process involved casting up undigested food in a tubular form with little or no force, rather than forceful expulsion of digested food with retching and involuntary abdominal contractions. Soft coughing and a mucoid nasal discharge began about a week after the onset of regurgitation. The dog was also somewhat lethargic.

Physical examination revealed a quiet, thin (body condition score [BCS] 2/5), mildly febrile (39.1°C [102.5°F]), 23-kg dog with an increased respiratory rate (45 breaths/min.). Slight mucopurulent discharge was noted in both external nares. Low-pitched, coarse crackles were heard over the entire lung field, but were loudest in the ventral half of the thorax. The coat appeared dry and lusterless. When this finding was mentioned to the owners, they confirmed that a change in coat quality had occurred more than a year ago.

Initial diagnostic evaluation included a complete blood count (neutrophilic leukocytosis), serum biochemistry profile (normal), urinalysis (normal), fecal flotation (whipworm ova) and thoracic radiography (changes consistent with megaesophagus and mild bronchopneumonia).

Further testing was done to rule out secondary or acquired causes of megaesophagus. A thorough neurologic examination failed to reveal neurologic deficits. Tests for myasthenia gravis (i.e., acetylcholine receptor antibody test) and lead toxicosis were negative. A positive-contrast esophagram revealed no evidence of strictures, granulomas, foreign bodies, neoplasia or extraesophageal compression. Results of a thyroid-screening panel included decreased serum concentrations of total thyroxine (T_4) and free T_4, and increased serum concentrations of thyrotropin (TSH).

The tentative diagnoses were hypothyroidism, megaesophagus and aspiration pneumonia.

Assess the Food and Feeding Method

The dog was normally fed a dry specialty brand food twice daily mixed with a small amount of various moist grocery brand foods. A homemade mixture of chicken and rice had also been offered during the past week in an effort to control the regurgitation.

Questions
1. What are the key nutritional factors to consider for this patient?
2. Outline an appropriate feeding plan (foods and feeding method) for this dog.

Answers and Discussion
1. Key nutritional factors for patients with megaesophagus and other motility or obstructive-type swallowing disorders include energy, fat, protein and food form. These patients are often debilitated because of inadequate food intake and secondary aspiration pneumonia. A relatively high-fat (≥25% dry matter [DM] fat) energy-dense (≥4.5 kcal/g [18.8 kJ/g] DM) food helps meet the patient's caloric requirement in small volumes. Protein is required in amounts adequate to support tissue repair and help reduce episodes of gastroesophageal reflux. Dietary protein should generally be at least 25% DM. The food form may influence esophageal motility and subsequent clinical signs. Esophageal performance in patients with congenital or acquired esophageal dilatation may improve when the swallowing reflex is maximally stimulated by the texture of coarse, dry foods. Dry food boluses may stimulate any remaining normal esophageal tissue; therefore, dry foods are the form of choice because gruels may increase the risk of aspiration pneumonia.
2. The goals of dietary management for patients with megaesophagus are to minimize regurgitation, avoid secondary aspiration pneumonia and provide adequate nutrition to regain or maintain proper body weight and condition. In this case, the feeding plan was used in conjunction with thyroid hormone replacement and treatment of the aspiration pneumonia. (See Progress Notes below.) The acquired esophageal motility defect may or may not be reversible. A high-fat, high-calorie recuperative, working/sporting dog or growth-type food is appropriate for this patient. The food should be given in small-volume, frequent meals and offered so the dog eats in an upright position. The food consistency and feeding method that best promote flow through the esophagus to the stomach in individual patients are often determined by trial and error.

Progress Notes
Thyroid hormone replacement therapy was started using 0.6 mg per day of oral synthetic levothyroxine sodium[a] (L-thyroxine). The pneumonia was treated with one injection of enrofloxacin (Baytril[b]) followed by oral enrofloxacin tablets (68 mg, b.i.d.) for three weeks. The whipworm infection was treated with a broad-spectrum anthelmintic (Drontal Plus[b]). The food was changed to a commercial dry veterinary therapeutic food designed for stress and recovery. This food has increased fat levels (25% DM) and energy density (4.8 kcal/g [20.1 kJ] DM) and increased protein levels (38.1% DM) to support recovery and weight gain. Daily energy requirement was estimated to be 1,400 kcal (5.86 MJ) for an ideal body weight of 27 kg. The food was given in small, frequent meals and offered from a bowl placed on the edge of a table.

The coughing and nasal discharge gradually improved so the antibiotic was discontinued. Regurgitation continued but gradually lessened in frequency. Radiographs six weeks later revealed no evidence of aspiration pneumonia, but the megaesophagus was still evident. Body weight (26.5 kg) and body condition (BCS 3/5) had improved. The food was changed to the commercial dry specialty brand food originally fed to the dog but it was offered from an elevated position. This feeding plan successfully reduced the regurgitation to a few episodes per week.

Chapter 51

Introduction to Gastric Diseases

Deborah J. Davenport
Rebecca L. Remillard

"Content the stomach and the stomach will content you."
Thomas Walker (1784-1836)

CLINICAL IMPORTANCE

Vomiting is the hallmark of gastric disorders in dogs and cats (Box 52-1). Vomiting may be acute or chronic with a long list of possible etiologies (Twedt, 2005; Simpson, 2005). Vomiting requires a forceful coordinated musculoskeletal effort to eject food from the stomach to the mouth.

Table 51-1 lists breed-associated gastric disorders. Certain gastric diseases (gastritis, gastroduodenal diseases and gastric motility/emptying diseases) may also require management with pharmacologic agents (**Table 51-2**).

Dietary goals are to meet the nutritional requirements of the patient with foods that minimize gastric irritation, promote gastric emptying and normalize gastric motility. In most vomiting cases of less than 48 hours' duration, withholding water for 24 hours and food for 24 to 48 hours generally controls the episode. The patient's regular food should then be gradually reintroduced in small frequent meals over two to three days. Episodes of acute vomiting that occur for longer than three days and cases of chronic vomiting (i.e., persisting longer than 21 days) with signs of malnutrition require more intensive nutritional and medical management.

Chapters 52 through 54 include feeding plans for patients with gastric disorders. Tables in those chapters list the key nutritional factors for such patients as well as tables that include the levels of key nutritional factors of commercial veterinary therapeutic foods marketed for patients with gastric disorders. For comparative purposes, these tables also include the recommended levels of key nutritional factors for patients with gastric disorders.

Chapter 52

Gastritis and Gastroduodenal Ulceration

Deborah J. Davenport

Rebecca L. Remillard

Christine Jenkins

"If your stomach disputes you, lie down and pacify it with cool thoughts."
Satchel Paige

CLINICAL IMPORTANCE

Gastritis is one of the most common causes of vomiting in dogs and cats (Van der Gaag, 1988). Acute gastroenteritis is covered in Chapter 56. The prevalence of gastritis in the pet population is unknown, but is thought to be high because many different insults can result in gastric mucosal inflammation (**Table 52-1**). In one survey, 9% of research beagles had histologic evidence of gastritis in the absence of clinical signs (Hottendorf and Hirth, 1974). Gastritis has been diagnosed in 35% of dogs presented for chronic vomiting and has been identified in 26 to 48% of asymptomatic dogs. The prevalence in cats is unknown (Simpson, 2006). The National Companion Animal Study was developed in the early 1990s to determine the most common disorders affecting dogs and cats examined at private veterinary practices in the United States. In 1995, 31,484 dogs and 15,226 cats were examined at 52 private veterinary clinics in 31 states. In this study, the prevalence of vomiting was 2.1% for dogs and 2.2% for cats (Lund et al, 1999). Acute gastritis often accompanies acute enteritis and is called acute gastroenteritis.

Previously, the prevalence of gastroduodenal ulcers in dogs and cats was thought to be low compared with the prevalence reported in people. In many cases, the historical infrequent diagnosis of gastroduodenal ulceration was possibly due to the absence of obvious clinical signs. For example, in experimental studies involving dogs, extensive gastroduodenal ulceration was present, whereas only mild clinical signs were evident (Dow et al, 1990). However, gastroduodenal ulceration is now diagnosed more frequently in veterinary patients. While advances in diagnostics (endoscopy) have provided improved capability to identify gastroduodenal ulcers, the apparent increase in prevalence has been associated with the use of nonsteroidal antiinflammatory drugs (NSAIDs) for pain management and treatment of inflammatory conditions. The actual incidence of gastroduodenal ulceration related to NSAID use in dogs is unknown (Hinton et al, 2002; Lascelles et al, 2005; Dowers et al, 2006).

PATIENT ASSESSMENT

History and Physical Examination

Although some patients are asymptomatic, vomiting is the most common presenting complaint for patients with acute or chronic gastritis. Typically, owners report intermittent vomiting of food or bile-stained fluid. Fresh or digested blood appearing as "coffee grounds" may be present in the vomitus. Associated signs may include diarrhea, abdominal pain and melena. Anorexia is the presenting sign in many patients with gastritis. The clinician should obtain details regarding frequency, duration and progression of the vomiting episodes. In addition, the vomitus should be characterized (e.g., color, contents). It is important to differentiate vomiting from regurgitation (Simpson, 2005; Willard, 2005). Some owners may report that their dog

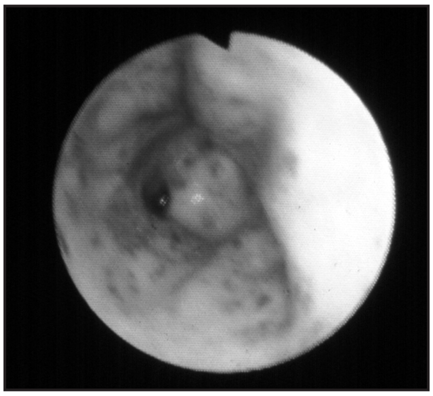

Figure 52-1. Endoscopic appearance of antral gastritis in a dog with chronic vomiting. Note the multiple hemorrhagic erosive lesions of the gastric mucosa. (Courtesy Dr. Michael Leib, Virginia-Maryland Regional College of Veterinary Medicine, Blacksburg, VA.)

assumes a "praying posture," which is considered a manifestation of upper abdominal pain.

Patient history often is adequate to provide a presumptive diagnosis of gastritis. Owners should be questioned closely about potential for toxin exposure (e.g., lead, arsenic) and foreign body ingestion (e.g., bones, coins, garbage) by the patient. A history of NSAID administration provides a presumptive diagnosis of drug-induced gastroduodenal erosions or ulcerations. The veterinarian should question the owner specifically about the use of over-the-counter agents (e.g., aspirin, ibuprofen) in addition to prescription NSAIDs.

Physical examination is often unremarkable in dogs and cats with gastritis or gastroduodenal ulcerations. Reduced skin turgor and tacky mucous membranes indicate dehydration. Abdominal pain may be recognized, particularly in those patients that develop peritonitis as a consequence of a perforated ulcer. In chronic cases, weight loss and poor body condition may be noted. Pallor and weakness may be present in patients with significant gastrointestinal (GI) blood loss. Other findings may reflect the underlying cause of gastritis (e.g., cutaneous masses or hepatosplenomegaly associated with mastocytosis).

Laboratory and Other Clinical Information

Routine hematology, serum biochemistry profiles and urinalyses help rule out metabolic causes of gastritis. These tests readily identify renal disease, hepatopathies and hypoadrenocorticism. The hematocrit and hemogram are useful in assessing severity and chronicity of gastric disease. Inflammatory leukograms may be identified in animals with neoplasia, perforated GI ulcers, inflammatory bowel disease (IBD) and pythiosis. Eosinophilia may indicate parasitism or eosinophilic gastritis. In cats, extreme eosinophilia is suggestive of hypereosinophilic syndrome or systemic mastocytosis. Identification of circulating mast cells is generally diagnostic for mast cell tumors, which are associated with GI ulcer disease due to hyperhistaminemia.

Fecal examinations for parasites and occult blood are important screening tests. Parasites are an unlikely cause of gastritis, but should be considered. Gastric parasites, such *Ollulanus tricuspis* or *Physaloptera* spp., are identified more readily in vomitus or gastric juice or on endoscopic visualization. The accuracy of fecal occult blood testing has been confirmed in dogs consuming dry foods (Dow et al, 1990; Gilson et al, 1990). Moist meat-based foods often yield false-positive results. Both the modified guaiac and orthotoluidine tests are sensitive and specific for detecting occult blood in feces (Gilson et al, 1990).

Imaging modalities (e.g., survey and contrast radiography and ultrasonography) are noninvasive diagnostic techniques for evaluating pets with gastritis or GI ulceration. Abdominal radiographs frequently are normal in patients with gastritis (Simpson, 2005). Survey radiography may be useful in the diagnosis of radiopaque foreign bodies. Abnormalities in renal size or shape may suggest renal insufficiency as the cause of gastritis. Hepatosplenomegaly in cats suggests systemic mastocytosis or alimentary lymphosarcoma. Free air in the abdomen is diagnostic for viscus rupture associated with a perforated GI ulcer and indicates the need for immediate exploratory surgery.

Contrast radiographic examinations may be useful. Iodinated contrast agents[a] should be used if GI perforation is suspected. Otherwise, barium sulfate is the contrast agent of choice for GI studies because of its superior ability to coat the GI mucosa. More complete descriptions of radiographic findings in gastric disease are available (Moon and Myer, 1986).

Endoscopic examination is the most sensitive test for detection of gastritis and gastroduodenal ulcerative disease. Gastric fluid can be collected for parasitic and microbiologic examination. Endoscopic evaluation allows for the identification of mucosal and submucosal hemorrhages, erosions and ulcers, tumors and foreign bodies (**Figure 52-1**). Gastric and duodenal biopsy specimens for histopathologic examination and brush cytology samples can be collected endoscopically (Jergens et al, 2000). *Helicobacter* spp. can be identified in impression smears prepared from such samples (Simpson, 2005). Gastric biopsy specimens can be evaluated for *Helicobacter* spp. using the rapid urease test[b] (Leib and Duncan, 2005).

Risk Factors

Dogs with liver or kidney disease, hypoadrenocorticism, spinal cord disease, shock, stress, neoplasia, mastocytosis and systemic disease are at increased risk for gastroduodenal ulceration (Lascelles et al, 2005; Simpson, 2005; Henderson and Webster, 2006).

Older pets are more likely to be suffering from metabolic or neoplastic causes of gastritis. Dogs of any age receiving NSAIDs, corticosteroids, or both, for management of osteoarthritis are at risk for gastritis and gastroduodenal ulceration.

Younger dogs and cats and unsupervised pets are more likely to suffer from gastritis secondary to foreign bodies or dietary indiscretion. Several breed-associated causes of gastritis have been recognized (Table 51-1). Dachshunds, miniature schnauzers, toy poodles and other small- and toy-breed dogs are most commonly affected with hemorrhagic gastroenteritis (Guilford and Strombeck, 1996). Several breeds are at risk for chronic

gastritis including the basenji, Norwegian lundenhund and Drentse patrijshond (Slappendel et al, 1997; Hart, 2004; Simpson, 2005, 2006; Berghoff et al, 2007). Racing sled dogs in competition are at increased risk for gastroduodenal erosions and ulceration although dogs in training are not (Davis et al, 2006). Nearly 50% of dogs completing the Iditarod race were found to have gastric lesions (Davis et al, 2003, 2003a).

Etiopathogenesis

Acute Gastritis and Gastroduodenal Ulceration

Acute gastritis is characterized by sudden-onset vomiting, resulting from gastric mucosal insult or inflammation. Hematemesis usually indicates that gastroduodenal erosions or ulcerations are present (Willard, 2005). Gastroduodenal ulceration occurs following disruption of the gastric mucosal barrier. The gastric mucosal barrier is a group of physical and chemical defense mechanisms designed to protect the gastric mucosa from insults leading to erosions or ulcers. Disruption of the gastric mucosal barrier may involve direct injury, decreased mucosal blood flow, alterations in protective prostaglandins (prostaglandin E_2 [PGE_2]) or hypersecretion of gastric acid (e.g., gastrinoma) (Simpson, 2005; Henderson and Webster, 2006).

Several metabolic disorders are associated with acute gastritis and gastroduodenal ulceration (**Table 52-1**). Uremia may result in diffuse GI tract hemorrhage. GI erosions and ulcers are thought to result from effects of uremic toxins on the gut mucosa. Additionally, increased circulating concentrations of gastrin have been identified in patients with uremia. The kidneys normally excrete up to 40% of circulating gastrin. Clearance of gastrin is decreased with chronic kidney disease. The resulting hypergastrinemia leads to increased acid production. Studies suggest that hypersecretion of gastrin may contribute to gastric ulceration in chronic kidney disease (Thornhill, 1983; Peters et al, 2005; Polzin et al, 2005; Henderson and Webster, 2006).

GI signs and histopathologic changes are seen in dogs with chronic kidney disease. A retrospective study was done to determine the prevalence of gastric histopathology in necropsy samples from 28 dogs with chronic kidney disease and to characterize the histopathologic changes. All dogs presented with GI signs, including anorexia and vomiting. Twenty-two (79%) of the 28 dogs had gastric pathology. The most common pathology included edema, vasculopathy, glandular atrophy and mineralization. No evidence of ulceration was seen histopathologically and only one dog had ulceration noted on gross necropsy. Dogs with higher serum biochemistry scores (i.e., blood urea nitrogen, creatinine and calcium-phosphorus product) were more likely to have gastric pathology. The authors concluded that gastric ulceration may be uncommon in dogs with chronic kidney disease (Peters et al, 2005).

Liver disease is a common cause of GI ulcerations, which may be manifested as hematemesis. Liver disease was one of the two most common risk factors (the other being treatment with NSAIDs) in a retrospective study of 43 dogs with gastroduodenal ulceration (Henderson and Webster, 2006). The pathogenesis of mucosal ulceration associated with hepatopathies is multifactorial and associated coagulopathies may worsen clinical manifestations. Potential mechanisms include altered gastric blood flow due to portal hypertension, delayed epithelial turnover, gastric hyperacidity and hypergastrinemia. Experimental evidence suggests that hypergastrinemia is a less important mechanism than previously suspected (Booth, 1990; Henderson and Webster, 2006).

A variety of adverse drug reactions have been reported following the use of NSAIDs in dogs. These include GI bleeding, ulceration or both and hepatotoxicity and nephrotoxicity (Sennello and Leib, 2006). The adverse GI effects occur because some NSAIDs have a topical irritant effect on the gastric mucosa and can inhibit protective prostaglandins (McCarthy, 1999; Enberg et al, 2006). Experimentally induced and spontaneous gastritis and gastroduodenal ulcerations have been reported to occur in dogs in conjunction with the use of NSAIDs, including aspirin, indomethacin, naproxen, ibuprofen, phenylbutazone, flunixin meglumine, piroxicam, sulindac and meclofenamic acid (Dow et al, 1990; Lipowitz et al, 1986; Wallace et al, 1990; Davenport, 1992). The ulcerogenicity of NSAIDs is attributed to inhibition of the enzyme cyclooxygenase (COX) in the prostaglandin synthesis pathway, resulting in the loss of the gastric protective effects of prostacyclin and prostaglandin E (Davenport, 1992).

Table 52-2. Key nutritional factors for dogs and cats with gastritis and/or gastroduodenal ulceration.*

Factors	Recommended levels
Potassium	0.8 to 1.1%
Chloride	0.5 to 1.3%
Sodium	0.3 to 0.5%
Protein	***Highly digestible food approach:*** ≤30% for dogs and ≤40% for cats ***Elimination food approach:*** Limit dietary protein to one or two sources Use protein sources that the patient has not been exposed to previously or feed a protein hydrolysate (Chapter 31) 16 to 26% for dogs 30 to 40% for cats
Fat	<15% for dogs <25% for cats
Fiber	≤5% crude fiber; avoid foods with gel-forming fiber sources such as pectins and gums (e.g., gum arabic, guar gum, carrageenan, psyllium gum, xanthan gum, carob gum, gum ghatti and gum tragacanth)
Food form and temperature	Moist foods are best; warm foods to between 70 to 100°F (21 to 38°C)

*Nutrients expressed on a dry matter basis.

Isoforms of COX have been identified. COX-1 is a constitutive form that is found in many tissues (e.g., gastric mucosa), where it is involved in the production of protective prostaglandins. COX-2 is primarily an inducible enzyme that is involved in the production of inflammatory mediators, including proinflammatory prostaglandins. Newer NSAIDs have been developed to minimize the effects on COX-1 and thereby, to decrease the adverse effects on gastric mucosa. The newer NSAIDs are selective inhibitors of COX-2 and generally are considered to be "gastric sparing." However, despite the selective inhibition of COX-2, these newer NSAIDs still carry risk of GI ulceration and perforation. Newer veterinary-approved selective COX inhibitors include flunixin meloxicam, carprofen, etodolac, ketoprofen, tepoxalin, previcox and deracoxib (McCarthy, 1999; Enberg et al, 2006; Dowers et al, 2006; Sennello and Leib, 2006). The use of NSAIDs in patients with underlying renal or hepatic insufficiency may increase the risk of GI ulcerative disease. Concurrent NSAID and corticosteroid use should also be avoided due to the risk of gastric injury.

GI ulcers are recognized complications of critical illnesses (e.g., hypotension, coagulopathy, sepsis) in people. They are thought to develop as a response to the stress of the critical illness and are termed "stress ulcers" (Henderson and Webster, 2006). Stress ulcerations are poorly defined entities in veterinary patients. However, gastroduodenal ulcerations have been noted in companion animals in conjunction with severe burns, heat stroke, multiple trauma, head injuries and spinal cord disorders. In addition, hypovolemic shock and sepsis may be complicated by development of GI ulcers. Experimentally, endotoxin in septic dogs decreases gastric blood flow resulting in mucosal ischemia. Histamine release stimulated by catecholamines worsened the mucosal damage (Henderson and Webster, 2006).

Gastrin-producing pancreatic tumors, histamine-producing tumors (e.g., mast cell tumors, basophilic leukemia) and a polypeptide-producing pancreatic tumor have been associated with gastric or duodenal ulceration in dogs and cats. Persistent gastric hyperacidity stimulated by gastrin, histamine or pancreatic polypeptide was thought to induce ulcers in these patients.

Helicobacter pylori has a recognized association with gastritis, gastroduodenal ulcers and gastric neoplasia in people. The role of *Helicobacter* spp. in GI disease in dogs is unclear although the prevalence is high. These spiral bacteria have been found in 67 to 100% of clinically healthy dogs and 74 to 90% of vomiting dogs. Gastric inflammation has been present in some, but not all, infected dogs. No significant relation has been demonstrated between *Helicobacter* spp. infection and clinical signs or GI ulceration in dogs. *Helicobacter* spp. have been identified in 40 to 100% of healthy and sick cats (Simpson, 2005; Henderson and Webster, 2006; Happonen et al, 2001; Rohrer et al, 1999; Simpson et al, 1999; Peters et al, 2005; Lecoindre et al, 2000).

Chronic Gastritis

Chronic gastritis generally is defined as intermittent vomiting that occurs for more than one to two weeks' duration (Hart, 2004) (**Box 52-1**). Vomiting of food or bile is the primary clinical manifestation of chronic gastritis. Other signs include decreased appetite, weight loss, hematemesis or melena (Simpson, 2005, 2006). Chronic gastritis is diagnosed based on histopathologic examination of gastric biopsy specimens. The histopathology (e.g., cellular infiltrate, architectural abnormalities and severity) and etiology, if identified, determine the type of chronic gastritis affecting the patient (Simpson, 2006).

The etiopathogenesis of chronic gastritis in dogs and cats is not fully understood. In some cases, an underlying etiology, such as parasitism or a metabolic disorder (e.g., uremia, liver disease), can be identified. In most cases, however, an immune-mediated response is hypothesized to be responsible for inflammatory infiltrates within the gastric mucosa (Simpson, 2005, 2006). Experimentally, chronic gastritis can be produced in dogs via mucosal irritants, systemic administration of gastric juices or prenatal thymectomy (Smith et al, 1958; Hennes et al, 1962; Krohn and Finlayson, 1973; Fukuma et al, 1988). Each of these treatments disturbs oral tolerance to antigens.

Chronic idiopathic gastritis is probably a subset of the IBD syndrome or may arise as an adverse reaction to food antigens. Chronic idiopathic gastritis may be localized or can occur with more diffuse IBD of the small or large bowel. Chapters 31 and 57 discuss adverse food reactions and IBD, respectively. Once present, inflammation interferes with gastric motility and reservoir function leading to vomiting. Nutrients including proteins are lost through the inflamed mucosal surface.

Key Nutritional Factors

Key nutritional factors for patients with gastritis and gastroduodenal ulceration are listed in **Table 52-2** and discussed in detail below.

Box 52-1. Hairballs.

Hairballs occur commonly in cats because of their normal grooming behavior and sharp barbs on the tongue that enhance hair ingestion. Cats with longer, thicker coats and those with fastidious grooming behavior usually have more problems with hairballs. Swallowed hair initially accumulates as loose aggregates or more compacted, soft aggregates mixed with mucus. Hairballs are regurgitated periodically from the oropharynx or esophagus or vomited from the stomach, or they pass into the intestinal tract, where they are voided in the feces. Owners observe periodic gagging, retching and regurgitation or vomiting of hair and mucus (usually not containing food or bile). Hairballs are often tubular.

Trichobezoars are harder concretions within the stomach or intestines formed of hair, mucus and other material. Trichobezoars probably begin as simple aggregates of hair, but progress to larger and harder concretions. They are less common in cats than typical hairballs, but are more likely to cause severe clinical signs. Trichobezoars are a common cause of anorexia in pet rabbits (Chapter 70). Large trichobezoars may obstruct pyloric outflow or the intestines and must be removed by surgery or endoscopy.

How cats eliminate aggregates of hair is probably similar to how they eliminate the pelts of small mammals that are ingested as part of a natural diet. Cats that hunt frequently may be seen vomiting the pelts of voles, mice, small rabbits and other mammals. This may be a protective mechanism for eliminating less digestible portions of prey.

Although hairballs do not usually cause significant clinical disease, their associated clinical signs are considered to be a nuisance by many cat owners. Hairballs generally can be controlled. Various laxatives, lubricants, treats and foods are available for routine management of these problems. Several commercial foods are available to help reduce the frequency with which cats vomit hairballs. Most of these foods have increased amounts of dietary fiber. Insoluble fiber, specifically cellulose, increases fecal hair content as compared to other fibers when incorporated in complete foods. Kibble size is another important feature of foods designed to reduce vomiting associated with hairballs. Radiographic gastrointestinal transit studies indicate that a larger kibble size is associated with an increased tendency for hairballs to exit the stomach and be eliminated in the feces, thereby reducing the frequency of vomiting. There is little or no evidence to support the use of lubricants (e.g., petroleum jelly) or papain for the treatment of hairballs in cats. If used, laxatives and lubricants should be given intermittently because large daily doses may interfere with normal digestion and nutrient absorption.

Frequent regurgitation or vomiting of hairballs (i.e., every day) with or without diarrhea, weight loss, anorexia or abdominal pain usually indicates an underlying problem (e.g., gastric motility defect or lymphoplasmacytic enteritis). Cats with severe or frequent clinical signs should be evaluated more extensively with diagnostics including hematology, serum biochemistry profiles, radiography and upper gastrointestinal endoscopy.

The Bibliography for **Box 52-1** can be found at www.markmorris.org.

Water

Water is the most important nutrient for patients with acute vomiting because of the potential for life-threatening dehydration due to excessive fluid loss and inability of the patient to replace those losses. Patients with persistent nausea and vomiting should be supported with subcutaneous or intravenous rather than oral fluids. Moderate to severe dehydration should also be corrected with appropriate parenteral fluid therapy.

Electrolytes

Gastric and intestinal secretions differ from extracellular fluids in electrolyte composition, so their loss can result in systemic electrolyte abnormalities. Dogs and cats with vomiting and diarrhea may have low, normal or high serum potassium, chloride and sodium concentrations. The derangement that predominates in a particular animal depends on several factors, such as the severity of the disease, nutritional status of the patient and site of the disease process. Serum electrolyte concentrations are helpful in tailoring appropriate fluid therapy and nutritional management of these patients. Mild hypokalemia, hypochloremia and either hypernatremia or hyponatremia are the electrolyte abnormalities most commonly associated with acute vomiting (and diarrhea).

Total body depletion of potassium is a predictable consequence of severe or chronic GI disease because the potassium concentration of gastric and intestinal secretions is high. Hypokalemia in association with GI disease will be particularly profound if losses are not matched by sufficient intake of potassium.

Electrolyte disorders should be corrected initially with appropriate parenteral fluid and electrolyte therapy. Foods for patients with acute gastroenteritis should contain levels of potassium, chloride and sodium above the minimum allowances for normal dogs and cats. Recommended levels of these nutrients are 0.8 to 1.1% potassium (dry matter [DM]), 0.5 to 1.3% DM chloride and 0.3 to 0.5% DM sodium.

Protein

Foods for patients with acute gastritis and/or gastroduodenal ulcers should probably not provide excess protein (no more than 30% for dogs and 40% for cats). Products of protein digestion (peptides, amino acids and amines) increase gastrin and gastric acid secretion (Feldman and Grossman, 1980; Delvalle and Yamada, 1990).

Some authors recommend "hypoallergenic" or elimination foods for patients with chronic idiopathic gastritis because dietary antigens are suspected to play a role in the etiopathogenesis (Guilford, 1997). In some cases, elimination foods may be used successfully without pharmacologic intervention because mild to moderate chronic gastritis may respond to dietary management alone. Ideal elimination foods should: 1) avoid protein excess (16 to 26% for dogs; 30 to 40% for cats), 2) have

high protein digestibility (≥87%) and 3) contain a limited number of novel protein sources to which the patient has never been exposed. Alternatively a food containing a protein hydrolysate may be fed (Chapter 31).

Fat
Solids and liquids higher in fat are emptied more slowly from the stomach than similar foods with less fat. Fat in the duodenum stimulates the release of cholecystokinin, which delays gastric emptying. Foods with less than 15% DM fat for dogs and less than 25% DM fat for cats are appropriate for dietary management of gastritis and gastroduodenal ulcers.

Fiber
Many grocery brand moist foods contain gelling agents such as gums or hydrocolloids to enhance the aesthetic characteristics of the food. Foods containing gel-forming soluble fibers should be avoided in patients with gastric emptying and motility disorders because they increase the viscosity of ingesta and slow gastric emptying. Such fibers include pectins and gums (e.g., gum arabic, guar gum, carrageenan, psyllium gum, xanthan gum, carob gum, gum ghatti and gum tragacanth). However, increased levels (>8% DM crude fiber) of insoluble fiber (powdered cellulose) in dry foods fed to cats had no effect on gastric emptying (Armbrust et al, 2003). Other reports show that the ratio of slowly to rapidly fermentable fibers is important. Because of the variability of fiber types on gastric emptying, in general, the crude fiber content of foods for patients with gastritis and gastroduodenal ulcers should probably not exceed more than 5% DM.

Food Form and Temperature
Moist foods are best because they reduce gastric retention time. For the same reason, clients should warm foods to between room and body temperature (70 to 100°F [21 to 38°C]).

Other Nutritional Factors
Vitamins and Trace Minerals
Iron, copper and B vitamins may benefit patients with gastroduodenal ulceration and GI blood loss. Hematinics should be used in patients with nonregenerative, microcytic/hypochromic anemias attributable to iron deficiency. Hematinics probably are unnecessary in most animals that receive blood transfusions.

Acid Load
Alkalemia should be expected if vomiting patients lose hydrogen and chloride ions in excess of sodium and bicarbonate. Hypochloremia perpetuates the alkalosis by increasing renal bicarbonate reabsorption. Mild alkalemia is common, but profound alkalemia is more likely to occur with pyloric or upper duodenal obstruction rather than with acute gastritis.

Acidemia may occur in vomiting patients if the vomited gastric fluid is relatively low in hydrogen and chloride ion content (e.g., during fasting) or if concurrent loss of intestinal sodium and bicarbonate occurs. Severe acid-base disorders are best corrected with parenteral fluid and electrolyte therapy. Foods for

patients with acute vomiting and diarrhea should avoid excess dietary acid load. Foods that normally produce alkaline urine are less likely to be associated with acidosis.

FEEDING PLAN

The first objective in managing vomiting patients should be to correct dehydration and electrolyte and acid-base imbalances, if present. The dietary goals are to provide a food that meets the patient's nutrient requirements, allows normalization of gastric motility and function and controls vomiting. In most cases of acute vomiting, initial fasting for 24 to 48 hours, with parenteral fluid administration, reduces or resolves vomiting by simply removing the effects of undigested food and the offending agents from the stomach and duodenum. Chronic vomiting cases generally require a more detailed diagnostic and therapeutic (i.e., combined medical and nutritional) approach.

Assess and Select the Food

Bland foods often are recommended for veterinary patients with gastritis. This recommendation probably originated from physicians' orders for people recovering from GI upsets to eat bland foods. The term "bland" is poorly defined, but it is most often applied to easily digested/absorbed and nonirritating, non-spicy foods. Most pet foods fall within this category. The use of topical digests on dry foods may be construed as potentially irritating because many digests contain high concentrations of reactive amines (Guilford et al, 1994). The term "bland" is not a useful recommendation to pet owners; instead specific ingredients or nutrients to avoid should be clearly stated.

Tables 52-3 and **52-4** include the key nutritional factor content of selected commercial veterinary therapeutic foods marketed for GI diseases and compare them to the recommended levels for vomiting patients (dogs and cats, respectively). Food selection should be based on a product closely matching the key nutritional factor target levels.

Liquids are emptied from the stomach more quickly than solids due to lower digesta osmolality. Water is emptied most quickly, whereas liquids containing nutrients are emptied more slowly. High-osmolality fluids are emptied more slowly than dilute fluids. Solids are the slowest to be emptied from the stomach. Dry foods empty more slowly than moist foods in cats (Goggin et al, 1998). Thus, foods for patients with gastritis and gastroduodenal ulcers should have a liquid or semi-liquid consistency. Cold meals slow gastric emptying so food should be between room and body temperature (70 to 100°F [21 to 38°C]). Refrigerated or frozen foods should be warmed before being fed.

Assess and Determine the Feeding Method

Two feeding methods have been described for patients with acute gastric disorders. The more classic feeding method for patients with acute gastritis begins by discontinuing oral intake of food and water (i.e., nothing per os [NPO]) for 24 to 48 hours. After this period, patients should be offered small amounts of water or ice cubes every few hours. If water is well tolerated, small amounts of food can be offered several times (i.e., six to eight times) a day. In cats and probably dogs, larger meals are emptied more slowly than smaller meals (Goggin et al, 1998); thus, smaller meals promote gastric emptying. If the patient eats food without vomiting, the amount fed can be increased gradually over three to four days until the patient is receiving its estimated daily energy requirement in two to three meals per day. Food should be withdrawn and offered again after a few hours if the patient begins to vomit during this period.

In some cases, persistent vomiting may complicate refeeding. If so, metoclopramide or other antiemetic agents are rec-

ommended after GI obstruction has been ruled out (Table 51-2). Rarely, some patients may require parenteral feeding (Chapter 26).

The second approach, known as "feeding through vomiting," has been a successful alternative to NPO therapy in some vomiting patients. Pregnant women suffering hyperemesis reported feeling less nausea and preferred the placement of a nasogastric tube with slow frequent self feeding of small liquid meals to eating small regular meals or NPO therapy (MacBurney, 1993). This feeding method has also been used successfully in dogs with parvoviral enteritis (Mohr et al, 2003). A possible explanation for persistent vomiting is that the normal motility pattern throughout the length of the bowel cannot be reestablished without strong intraluminal stimulation. In fact, vomiting and mucosal atrophy probably perpetuate bowel dysfunction. Feeding restarts normal patterns of motility beginning in the esophagus and food may reestablish motility patterns as it passes down the bowel. The physical presence of food and nutrients serves as mechanical and chemical stimuli to normalize bowel motility and function.

Simply refeeding dogs (orally) and cats (via nasoesophageal tube) has stopped protracted vomiting (i.e., lasting more than seven days) successfully without using antiemetic drugs.[c] Feedings are continued although the patient may vomit. Most cases of protracted vomiting cease within 24 hours of administering liquid food. These patients then are offered small frequent meals of a highly digestible, moderate-fat food 24 hours after the last episode of vomiting (**Tables 52-3** and **52-4**).

CONCURRENT MEDICAL THERAPY

Nutritional management often is used in conjunction with other therapeutic modalities including parenteral fluids, antacids, histamine (H_2)-receptor antagonists, cytoprotective drugs, PGE_2 analogs, antibiotics and anthelmintics (Table 51-2).

REASSESSMENT

Nutritional reassessment of patients with gastritis or gastroduodenal ulcers includes monitoring changes in body weight and condition and determining the extent of vomiting. Daily food dosage should be adjusted as indicated by changes in body weight and condition.

If vomiting persists in the face of appropriate medical and nutritional therapy, further diagnostics are warranted. Additionally, different foods should be tried (**Tables 52-3** and **52-4**). If anemia was identified as a problem in pets with GI ulcers, reassessment of the hemogram is recommended to ensure adequate repletion of iron and copper. In addition, frequent monitoring of fecal occult blood loss is recommended.

Chapter 53

Gastric Dilatation and Gastric Dilatation-Volvulus in Dogs

Deborah J. Davenport
Rebecca L. Remillard
Christine Jenkins

"Size counts. That's all."
Gina Gershon

CLINICAL IMPORTANCE

Gastric dilatation (GD) is distention of the stomach with a mixture of air, food and fluid. GD often occurs intermittently, usually in young dogs, particularly as a result of overeating or some other dietary indiscretion. Gastric dilatation-volvulus (GDV) is characterized by rotation of the stomach on its mesenteric axis, entrapping gastric contents and compromising vascular supply to the stomach, spleen and pancreas. Acute GDV is a medicosurgical emergency with high morbidity and mortality (Monnet, 2003; Buber et al, 2007). Rarely, chronic, intermittent GDV may occur associated with a partial (i.e., <90 degree) rotation of the stomach.

GDV most commonly affects large-breed, deep-chested dogs and has been estimated to affect 40,000 to 60,000 dogs annually (Lantz et al, 1992). Based on necropsy findings, GDV accounted for 3.4% of deaths of military dogs (Jennings, 1992) and has been reported to occur at a monthly rate of 2.5 cases/1,000 military dogs (Herbold et al, 2002). A review of data from the Veterinary Medical Database, Purdue University, West Lafayette, IN, suggests a 1,500% increase in the frequency of GDV from 1964 to 1974 within cases presented to veterinary teaching hospitals (Glickman, 1996).

PATIENT ASSESSMENT

History and Physical Examination

Clinical signs of GD include nausea, belching and vomiting. Conversely, there may be no effort to vomit, but instead lethargy, reluctance to move and grunting sounds with respiratory effort. The onset of GDV is usually acute and often occurs at night or in the early morning. Owners often report some precipitating stressful event. Boarding, hospitalization, travel and participation in shows have been associated with GDV. Affected dogs exhibit restlessness, progressive abdominal distention with tympany, abdominal pain, hypersalivation and repeated, nonproductive attempts to vomit. Occasionally, owners will find affected dogs dead or in shock.

Chronic GDV is a rare manifestation of the syndrome. Dogs present with intermittent, progressive signs including vomiting, borborygmus, inappetence and weight loss. Periods of illness are interspersed with periods of normalcy. If untreated, these dogs often progress to acute GDV.

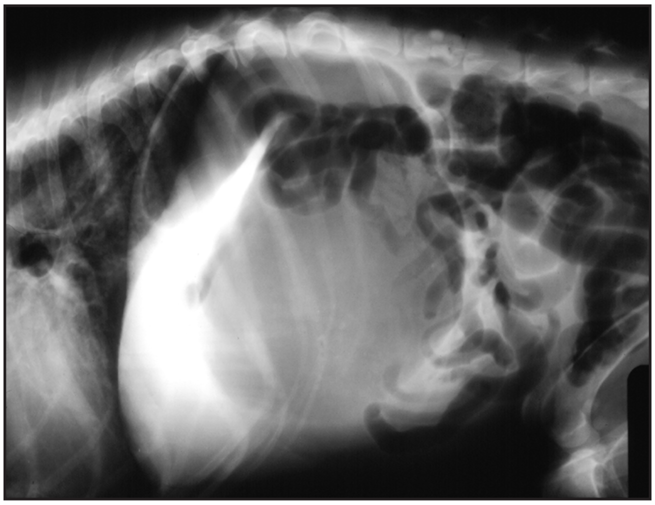

Figure 53-1. Lateral abdominal radiograph from a nine-year-old neutered male Doberman pinscher with a 180-degree gastric dilatation-volvulus. (Courtesy Dr. Joanne Burns, Veterinary Imaging Services, Topeka, KS.)

The most prominent sign of GD and GDV is abdominal distention. In some dogs, concurrent splenomegaly may be identified by abdominal palpation. Clinical manifestations of cardiovascular shock include tachycardia, delayed capillary refill time, pallor and weak pulses.

Laboratory and Other Clinical Information

Laboratory assessment of patients with GD or GDV should include a complete blood count, serum biochemistry profile, urinalysis and blood gas analysis. The complete blood count often reflects stress and can provide early evidence of disseminated intravascular coagulopathy if thrombocytopenia is present. If faced with thrombocytopenia, a complete coagulation panel is recommended before surgery.

Hypokalemia is common in patients with GDV and should be managed with intravenous potassium supplementation because hypokalemia can potentiate cardiac dysrhythmias. Metabolic acidosis, metabolic alkalosis, respiratory acidosis and mixed acid-base disorders have been reported to occur in dogs with GDV (Muir, 1987). Routine use of alkalinizing fluids and sodium bicarbonate, therefore, is not recommended.

Radiography is critical to the diagnosis of GD and GDV. Dorsoventral and right lateral views should be evaluated to distinguish simple GD from GDV (**Figure 53-1**). In most cases, gastric rotation is clockwise (i.e., with the dog in a dorsoventral position, viewed from above) and ranges from 90 to 360 degrees. Other significant findings may include splenomegaly and free abdominal air, which indicates gastric rupture.

Electrocardiographic recordings should be monitored in patients with GDV pre- and postoperatively because cardiac dysrhythmias occur in approximately half of patients (Muir, 1982; Brockman et al, 1995; Buber et al, 2007). The distended, malpositioned stomach compresses the caudal vena cava and portal vein resulting in cardiovascular compromise. Reduction in venous return and cardiac output leads to myocardial ischemia and cardiovascular shock. Cardiac dysrhythmias, gastric necrosis and multiple organ ischemia are potential consequences if gastric decompression is not performed expeditiously. Generally, dysrhythmias are ventricular in origin and can be life-threatening.

Risk Factors

Considerable effort has been expended over the last 30 years in attempts to identify the cause or causes of GD and GDV. Despite these efforts, no definitive cause for the syndrome has been identified. However, a number of predisposing and precipitating risk factors have been demonstrated through epidemiologic studies (**Table 53-1**).

GD and GDV occur most frequently in large-breed, deep-chested dogs, but may occur rarely in smaller dogs and in cats. A number of breeds including Great Danes, Irish setters, Gordon setters, Weimaraners, Saint Bernards, Doberman pinschers and basset hounds appear to be at risk. Other large breeds, notably the retriever breeds, have much smaller odds ratios. Attempts to assess the GDV risk in individual breeds demonstrated a lifetime incidence of 25% in Irish setters and a risk of 10% in Great Danes by the age of 2.6 years (Glickman, 1996). In a prospective cohort study, the likelihood of large- (bloodhounds, Akitas, Weimaraners, Irish setters, standard poodles, collies and rottweilers) or giant-breed dogs (Great Danes, Irish wolfhounds, Saint Bernards and Newfoundland dogs) developing GDV during their lifetime ranged from 21 to 24%, with the highest incidence occurring in Great Danes (Glickman et al, 2000).

Within breeds, certain anatomic and conformational factors increase the risk of GDV (Glickman et al, 1994). Increased adult body size compared with breed standards and specific types of thoracic conformation as determined radiographically appear to be related to the incidence of GDV. A chest depth-width ratio greater than 1.5 is associated with increased risk for developing GDV in certain breeds (Glickman et al, 1996; Schaible et al, 1997; Schellenberg et al, 1998). Dogs with GDV were found to have elongated hepatogastric ligaments as compared with control dogs of similar breeds (Hall et al, 1995). A longer hepatogastric ligament may allow increased gastric mobility or stretch as a consequence of GDV (Monnet, 2003).

GD or GDV appears not to have an age predisposition, but both occur more commonly in middle-aged dogs. The syndrome is also more common in male dogs (Glickman et al, 1997). Having a first-degree relative (sibling, sire, dam, offspring) with GDV also increases the risk by 63% (Glickman et al, 2000). This finding has led to the recommendation for prophylactic incisional, laparoscopic-assisted or endoscopically-assisted gastropexy for such dogs (Watson and Tobias, 2006; Ward et al, 2003; Rawlings et al, 2002; Dujowich and Beimer, 2008). These procedures can be performed in young female dogs (six to eight months) at the time of ovariohysterectomy. Percutaneous endoscopic gastrostomy is not recommended for prophylactic gastropexy because it is does not create consistently strong pexy sites and is associated with higher morbidity than

incisional or laparoscopic techniques (Waschak et al, 1997).

Other dog-related risk factors include a nervous or fearful temperament and being underweight. The incidence of GDV in dogs characterized by their owners as fearful was increased 257% compared to those considered non-fearful. Conversely, the owner-perceived personality trait of "happiness" appears to reduce the incidence of GDV by 78% (Glickman et al, 1997, 2000). Physiologic differences between happy and fearful dogs might influence gastrointestinal motility. These findings suggest that behavioral modification should be considered as part of a GDV preventive program in aggressive, nervous dogs.

A retrospective study identified intestinal lesions consistent with inflammatory bowel disease in approximately 25% of dogs with GDV (Braun et al, 1996). Splenectomy for treatment of hemangiosarcoma and splenic torsion has also been recognized as a risk factor for GDV in dogs (Monnet, 2003; Marconato, 2006; Millis et al, 1995; Neath et al, 1997). For that reason, large- and giant-breed dogs undergoing splenectomy should be recommended for a prophylactic gastropexy (Monnet, 2003).

Several dietary risk factors have been identified in one or more epidemiologic studies (Raghavan et al, 2006, 2004; Glickman et al, 2000, 2000a, 1994, 1997; Elwood, 1998; Theyse et al, 1998). Feeding from an elevated bowl, feeding a large volume of food per meal, feeding only one meal a day, feeding only one type of food, rapid eating, episodes of overeating, consumption of large volumes of water, postprandial exercise and a food particle diameter less than 5 mm have been implicated. Factors that appeared to decrease the risk of GDV in one case-control study were the inclusion of moist food or table foods as part of the diet (Glickman et al, 1997). In another study, consuming foods with a particle size greater than 30 mm was protective (Theyse et al, 1998).

In the past, consumption of dry dog food, unmoistened dry food, nutritional supplements and cereal- or soy-based foods were incriminated as dietary risk factors for GDV. More recent epidemiologic studies have not found these factors to increase the risk of GDV (Raghavan et al, 2004, 2006). In a European study of GDV cases, 40% of patients consumed dry food, 26% ate moist food and 25% received fresh meat diets, reflecting no increased risk associated with food form (Nagel and Neumann, 1992).

Attempts to reproduce GDV by dietary manipulation have been unsuccessful. In one study, researchers found no difference in gastric motility or emptying in large-breed dogs fed either a moist, meat-based food free of soybean meal or a dry, extruded, cereal-based food containing soybean meal with and without moistening (Burrows et al, 1985). A similar study evaluating Irish setters fed either a commercial dry food or a meat and bone mixture again showed no difference in gastric emptying or gastric acid secretion between diet types (Van Kruiningen et al, 1987). Investigators concluded that most large dogs are fed dry cereal-based food for reasons of cost and convenience, and that these foods may have been wrongly incriminated as a predisposing factor in GDV (Burrows et al, 1985; Raghavan et al, 2004).

In a nested case-control study of a group of dogs consuming dry foods as more than 95% of their diet, investigators found an association between dietary fat and GDV (Raghavan et al, 2006). If a vegetable oil or animal fat source was included as one of the first four label ingredients, dogs were at 2.4-fold increased risk of GDV. In such foods, the percent of metabolizable energy of the food derived from fat was higher than that in control foods. This unexpected finding contradicts the authors' earlier work in the same population of dogs, which demonstrated that patients with and without GDV consumed similar fat intakes (Raghavan et al, 2004). At this time, it is unclear which set of results from this population are most significant, suggesting the need for further investigation (Kass, 2006).

Table 53-1. Risk factors for canine gastric dilatation-volvulus.*

Consuming a food with vegetable oil or animal fat listed as one of the first four ingredients
Eating a large volume of food per meal
Eating from an elevated food bowl
Eating only one meal per day
Excluding moist food, table food and treats from the diet
Exclusive feeding of one food type
Exercising more than two hours per day
Fearful, nervous or aggressive temperament
Feeding food with a mean particle size <5 mm
Having an affected first-degree relative
Increased adult weight, based on breed standards
Increased chest or abdominal depth:width ratio
Increasing age
Large- or giant-breed status
Great Danes, Weimaraners, Saint Bernards, Gordon setters, Irish setters, standard poodles, basset hounds, Doberman pinschers, Old English sheepdogs, German shorthaired pointers
Lean body condition (body condition score ≤2/5)
Male gender
Purebred status
Rapid eating
Stressful events (boarding in kennel or travel)

Journal of the American Animal Hospital Association 2006; 42: 28-36.

Etiopathogenesis

A single cause of GDV will probably not be found. GDV is more likely a condition that arises because of the interaction of two or more risk factors. The gastric distention manifested in GDV is associated with an as yet uncharacterized functional or mechanical gastric outflow obstruction. This obstruction results in loss of the normal means for removing air from the stomach (i.e., eructation, vomiting and gastroduodenal flow). In some dogs, gastric volvulus apparently develops as a consequence of gastric distention, but, in others, gastric volvulus may precede the dilatation. Because gastropexy prevents recurrence of GDV, some authors have postulated that volvulus is the initial event.

Table 53-2. Key nutritional factor for dry foods for dogs for the prevention of gastric dilatation and volvulus.

Factor	Recommendation
Kibble size	Large particle size: >30 mm was protective against GDV in giant-breed dogs (Great Danes). Somewhat smaller kibble dimensions may be effective in medium- and large-breed dogs as long as the size of the kibble is sufficiently large to prevent rapid eating.

Table 53-3. Kibble size comparison of selected large-kibble dry commercial foods to consider for feeding medium-, large- and giant-breed dogs to reduce the risk of gastric dilatation and volvulus.*

Factor	Kibble cross sectional dimension(s)**
Recommendation	**>30 mm for giant-breed dogs** Somewhat smaller kibbles (<30 mm) may be effective in medium- and large-breed dogs as long as the kibble is sufficiently large to prevent rapid eating
Hill's Prescription Diet t/d Canine	28.3 x 26.4 mm
Medi-Cal Dental Formula	23.3 x 20.3 mm
Purina Veterinary Diets DH Dental Health	21.9 x 21.2 mm
Royal Canin Giant Adult 28	29.72 x 28.88 mm

*For additional key nutritional factors of importance for canine maintenance, see appropriate lifestage recommendations (Chapters 13 through 17).
**Kibble size represents the mean of measurements (diameter or width X thickness) made on three randomly selected kibbles from one bag of each product listed.

GD episodes may persist after gastropexy (Monnet, 2003).

Gas in the stomach of dogs with GDV is primarily atmospheric air, which differs greatly in composition from the gas produced by bacterial fermentation (Caywood et al, 1977). For that reason, aerophagia is believed to be the primary source of gastric gas in dogs with GDV. In some cases, carbon dioxide concentrations in the trapped stomach gas approached 10% (Caywood et al, 1977). The most likely source for this gas is the interaction between gastric acid and bicarbonate secretions. Normally, swallowed air is eructated and does not accumulate in excessive quantities. It has been hypothesized that dogs with GDV have defective eructation mechanisms. In one study, esophageal motility abnormalities were observed in 60% of dogs with GDV (Van Sluijs and Wolvekamp, 1993). It is possible that such abnormalities are linked to defective eructation complicated by the anatomic relationship of the stomach and esophagus in deep-chested, large-breed dogs, which also may interfere with effective eructation of air (Guilford, 1996). Aerophagia increases with rapid food consumption, excitement, stress and exercise; thus, controlling these factors is recommended in high-risk dogs.

Hypergastrinemia is present in dogs with acute GDV and persists after treatment and recovery, suggesting that dogs with GDV have a pre-existing hypergastrinemia (Leib et al, 1984). Gastrin increases gastroesophageal junction pressure and some investigators have postulated that hypergastrinemia may be a factor in the pathogenesis of GDV (Leib et al, 1984). However, further investigations revealed no relationship between the degree of gastric distention and the magnitude of plasma gastrin increase (Leib et al, 1985). Others suggest that hypergastrinemia in dogs with GDV is a result of the syndrome rather than a cause (Hall et al, 1989).

Key Nutritional Factor

The only key nutritional factor that may be of concern for dogs with an increased risk for GDV is food particle size. Fat content may play a role as described in the Risk Factor section above and the Other Nutritional Factor section below. The key nutritional factors for postoperative patients are similar to those for patients with acute gastritis (Chapter 52).

Kibble Size

Commercial dry extruded dog food particles having a diameter of less than 5 mm have been implicated as a risk factor for GDV. Also, in a study involving Great Danes, consuming foods with a particle size greater than 30 mm was protective (Theyse et al, 1998). The study included dry foods, moist chunky foods and homemade foods. The working assumption is that larger particles require more extensive and prolonged mastication, and in most dogs, probably prevents rapid eating of food. Somewhat smaller food particles might have a similar beneficial effect in medium- and large-breed dogs at risk for GDV, as long as the food particles are large enough to sufficiently slow eating. Thus, a practical consideration for medium-, large- and giant-breed dogs at risk for GDV would be to offer large kibble foods to slow eating (**Table 53-2**).

Other Nutritional Factor

Fat

Dietary fat can delay gastric emptying. One study found an association between dietary fat and GDV (Raghavan et al, 2006). If a vegetable oil or animal fat source was included as one of the first four label ingredients, dogs were at 2.4-fold increased risk of GDV. Unfortunately, percent dry matter content of fat was not recorded in the report. Ingredient order doesn't always reflect dietary fat content. Splitting ingredients on the first part of the product label can result in high fat ingredients being moved further down the label (Chapter 9). Thus, a food could be relatively high in dietary fat content but have a fat source ingredient at fifth or sixth place on the ingredient label. Until more information regarding dietary fat content and its relationship to GDV is available, this information cannot be reliably used. However, the data do suggest that lower fat is better.

FEEDING PLAN

Without early diagnosis and appropriate treatment, GDV is usually fatal. Initial management includes cardiovascular stabi-

Box 53-1. Recommendations from the 1990 Morris Animal Foundation Panel on Bloat in Dogs.

The following measures may reduce the incidence and recurrence of acute gastric dilatation-volvulus ("bloat"). These measures are especially important when managing purebred dog kennels and individual pet animals of the most susceptible breeds.

1. Large dogs should be fed two or three times daily, rather than once a day, and at times when the owner can observe post-feeding behavior.
2. Owners of susceptible breeds should be aware of prodromal signs (i.e., actions from the dog that signal abdominal discomfort). These signs include evidence of abdominal fullness after meals, whining, pacing, getting up and lying down, stretching, looking at the abdomen, anxiety and unproductive attempts to vomit. A veterinarian should examine animals with these signs as soon as possible.
3. Owners of susceptible breeds should establish a good working relationship with their local veterinarian and should discuss emergency measures in the event of bloat, including administration of antacids (e.g., Mylanta[a] and Di-Gel[b]), passing a stomach tube or piercing the abdomen with a hypodermic needle to relieve bloat.
4. Water should be available to dogs at all times, but should be limited immediately after feeding if overconsumption is a problem.
5. Vigorous exercise, excitement and stress should be avoided one hour before and two hours after meals. Walking, however, is permissible because it may help stimulate normal gastrointestinal function.
6. Food changes should be made gradually over three to five days.
7. Susceptible dogs should be fed individually and, if possible, in a quiet location.
8. Special attention should be paid to the above measures after animals return home from veterinary hospitals and boarding facilities.
9. Dogs that have survived bloat are at increased risk for future episodes; therefore, prophylaxis in the form of preventive surgery or medical management should be discussed with the veterinarian.

lization (i.e., treatment of shock and cardiac dysrhythmias), gastric decompression (i.e., orogastric intubation, gastric trocharization), surgery (i.e., gastric repositioning and permanent gastropexy) and appropriate postsurgical care (Monnet, 2003). If a permanent gastropexy is not performed after gastric repositioning, the recurrence rate of GDV approaches 80% (Wingfield et al, 1975) and median survival times fall from 547 to 188 days (Glickman et al, 1998). The feeding plan is implemented as part of a preventive strategy or after rapid, aggressive emergency management.

Assess and Select the Food

Foods that have relatively large kibble size and that are appropriate for the patient's current lifestage and activity level should be provided. Selected foods that have large kibble size are listed in **Table 53-3** along with their typical kibble dimensions. Other feeding practices can be used to slow eating. (See Assess and Determine a Feeding Method below.) Because foods are fed for adult maintenance, foods should be chosen that are appropriate for the dog's lifestage and activity level (Chapters 13 through 17). In the postoperative period, foods should be used that provide levels of the key nutritional factors outlined for acute gastritis (Chapter 52).

Assess and Determine the Feeding Method

Because feeding methods are often altered in postoperative patients and patients at risk for GD and GDV, a thorough assessment should include verification of the feeding method currently being used. Items to consider include feeding frequency, amount fed, how the food is offered, access to other food (e.g., access to other pets' food, table food, treats, etc.), relationship of feeding to exercise and who feeds the dog. All of this information should have been gathered when the history of the animal was obtained. If the animal has a normal body condition score (2.5/5 to 3.5/5), the amount of food it was fed previously (energy basis) was probably appropriate.

It appears prudent to recommend feeding a dog at risk for GDV two to three times per day in an environment that decreases competitive eating. At risk dogs should not be fed from an elevated platform or feeder. If the dog typically eats too fast, placing large balls or rocks in the food bowl or feeding the dog from a muffin tin may slow consumption of food and decrease aerophagia. A specially made food bowl[a] that has three large vertical cylinders protruding from the bottom to slow food consumption is available for dogs at risk for GDV. Feeding a mixture of moist and dry food appears to reduce the risk of GDV (Glickman et al, 1997). Alternatively, feeding foods with kibble sizes greater than 30 mm is also thought to reduce the risk of GDV (Theyse et al, 1998). To deliver foods with particle sizes this large, a mix of chunked moist food and dry food, a canine dental food,[b] formed complete meals[c] or a food formulated for giant breeds[d] may be used. However, none of these commercial products have been demonstrated to prevent or reduce the risk of GDV. Although no definitive link between exercise and GDV has been found, limiting exercise within three to four hours of eating (i.e., corresponds to normal gastric emptying time) is prudent. The Morris Animal Foundation Canine Bloat Panel recommends avoiding vigorous exercise at least one hour before and two hours after feeding (1990) (**Box 53-1**).

REASSESSMENT

Postoperative patients should be monitored closely for cardiac dysrhythmias, coagulopathies, surgical dehiscence, electrolyte and acid-base abnormalities and infections. Treatment with H_2-receptor blockers and sucralfate is indicated for most dogs with gastric mucosal damage. In most cases, food can be reintroduced within 24 to 36 hours postoperatively. Postoperative patients are best fed small meals frequently. Judicious use of antiemetics and/or metoclopramide in conjunction with continuous feeding may allow adequate caloric intake by patients with persistent vomiting. If tube gastrostomy was chosen as the method of permanent gastropexy, this indwelling catheter should be used for feeding (Chapter 25).

After the patient is discharged, the owner should monitor its appetite, activity level and attitude. Rechecks should include body weight and body condition assessment. Food dosages should be adjusted to maintain the dog at ideal body condition. The ultimate marker of success in GDV patients is the prevention of recurrent disease. Rarely, GD will develop in dogs that have had a gastropexy. Any episode of dilatation and precipitating factors should be reported and evaluated.

Persistent vomiting in a postoperative patient may indicate an outflow obstruction arising from an improperly positioned gastropexy site. If the angle between the pyloric antrum and duodenum is too acute, a functional obstruction may occur (Watson and Tobias, 2006).

CASE 53-1

Acute Vomiting in an Irish Setter

Michael S. Leib, DVM, MS, Dipl. ACVIM (Internal Medicine)
Virginia-Maryland Regional College of Veterinary Medicine
Blacksburg, Virginia, USA

Patient Assessment

A seven-year-old neutered female Irish setter was examined for vomiting and retching of two hours' duration. The dog vomited approximately 20 times during the hour before presentation, producing small amounts of phlegm each time. Earlier in the morning the dog had escaped from the yard and wandered freely. The owner reported no previous gastrointestinal (GI) problems.

Physical examination revealed a 28-kg dog with normal body condition (body condition score [BCS] 3/5) and a firm, distended abdomen. Vital signs (mucous membrane color, pulse rate and strength, capillary refill time, respiratory rate) were normal. Abdominal radiographs revealed a dilated stomach that was full of ingesta but appeared to be in its normal position. The ingesta contained a large amount of calcified material.

A tentative diagnosis of gastric dilatation (GD) was made and emergency treatment instituted. An orogastric tube was easily passed into the stomach but only a small amount of gas, fluid and nonspecific debris was recovered. Total decompression was not achieved even after warm water lavage. Intravenous fluids and a sedative were administered; gastric lavage with suction was continued. Large pieces of a plastic bag were removed and the lavaged gastric contents contained a large amount of shellfish debris. Sufficient decompression was still not obtained; therefore, an exploratory celiotomy was performed.

During surgery, the stomach was found to be in a normal position and a gastrotomy was performed. A large volume of shrimp and crab legs was removed and the stomach was lavaged with saline solution. The stomach was sutured closed and attached to the abdominal wall using a modified gastropexy technique. The abdomen was closed routinely and recovery from anesthesia was uneventful.

Assess the Food and Feeding Method

The dog was normally fed a combination of a commercial dry grocery brand dog food mixed with various commercial moist grocery brand dog foods and table foods. This food combination was offered in the early evening when the owner returned home from work. Water was available free choice.

Questions

1. What are risk factors for GD and gastric dilatation-volvulus (GDV) in dogs?
2. Outline a feeding plan (foods and feeding method) for this patient.

Answers and Discussion

1. Several risk factors for development of GD and GDV have been identified. These risk factors include large breed (i.e., Great Danes, Weimaraners, Saint Bernards, Gordon setters, Irish setters, standard poodles, Newfoundlands, basset hounds, Doberman pinschers), purebred dogs, older age (mean six to seven years old), heavier body weight (greater than 23 kg), rapid eating, feeding less moist dog food, feeding once daily rather than multiple times, feeding less table foods, feeding fewer snacks, gulping water, feeding small kibbles (<5 mm diameter; feeding large kibbles [>30 mm] is protective), excessive belching or flatulence, esophageal motility disorders, previous GI disease (e.g., inflammatory bowel disease) and personality (fearful or aggressive vs. happy and easy going). Other risk factors for GDV identified in Irish setter dogs included feeding a single food form, recent car journey (i.e., within preceding 24 hours), recent time in a boarding kennel (within preceding 24 hours), a history of aerophagia and thin body condition (BCS 1/5 or 2/5).
2. Dietary indiscretion obviously played an important role in development of GD in this dog and should be avoided. However, strategies to avoid other dietary risk factors for GD and GDV should also be considered, including offering a highly digestible food in multiple small meals. Meals should be avoided in association with exercise or traveling in a motor vehicle. Multiple small meals may also help eliminate rapid eating and significant aerophagia. Excessive or recurrent belching, flatus, vomiting, regurgitation and diarrhea may indicate underlying GI disease and warrant further diagnostic evaluation before implementing a feeding plan.

Progress Notes

The dog was offered a small amount of water and a moist highly digestible commercial veterinary therapeutic food (Prescription Diet i/d Canine[a]) the day following surgery. The amounts of water and food were gradually increased over the next couple of days. The dog was released to the owner's care with instructions to continue the therapeutic food in an amount to meet the daily energy requirement at home (1.6 x resting energy requirement = 1,450 kcal [6.07 MJ]). The food was to be offered in three separate meals (one can each meal) during the day (morning, immediately after work, late evening before bed). The owner was warned about the increased risk of GDV in Irish setter dogs, the potential for a fatal outcome, associated clinical signs and the need for emergency treatment if the problem recurred. Restricted exercise and avoiding rides in a motor vehicle in close association with meals were suggested. The owner was advised to make all attempts to avoid dietary indiscretion. Three months following surgery, the owner reported the dog was normal and doing well.

Chapter 54

Gastric Motility and Emptying Disorders

Deborah J. Davenport

Rebecca L. Remillard

Christine Jenkins

"Dyspepsia is the remorse of a guilty stomach."
A. Kerr

CLINICAL IMPORTANCE

Normally, the stomach should be emptied following an average meal in six to eight hours for dogs and four to six hours for cats (Twedt, 2005). The rate of gastric emptying is influenced by formulation and nutrient content of the food, size of the meal and body size (Nelson et al, 2001).

Gastric motility disorders arise from conditions that directly or indirectly disrupt three of the basic functions of the stomach: 1) storage of ingesta, 2) mixing and dispersion of food particles and 3) timely expulsion of gastric contents into the duodenum. Various processes can affect gastric emptying; however, some may not lead to clinical signs (Twedt, 2005). Delayed gastric emptying may be involved in the etiopathogenesis of gastric dilatation-volvulus (Wyse et al, 2001, 2003; Twedt, 2005; Burger et al, 2006).

Species differences in gastric emptying have been identified (Wyse et al, 2003). In addition, differences may be seen between breeds of dogs. A recent study of the long-term measurement of gastric motility using passive telemetry found significant differences in the postprandial motility patterns between the Labrador retriever test group and the beagle test group. Further studies in breed-related gastric motility are needed (Burger et al, 2006).

Table 54-1 outlines a number of primary and secondary causes of gastroparesis reported to occur in dogs and cats. The importance of these disorders in the general pet population is unknown, but primary gastric motility disorders are probably rare.

PATIENT ASSESSMENT

History and Physical Examination

Delayed gastric emptying due to any cause results in vomiting. Owners may report vomiting of undigested or partially digested food more than 12 hours after the pet eats. The onset of clinical signs may be gradual in acquired cases of chronic hypertrophic pyloric gastropathy or acute in the case of foreign body ingestion. Clinical signs may have been present since weaning in dogs and cats with congenital pyloric stenosis.

Weight loss and poor body condition are often present in chronic cases. Other manifestations may include intermittent gastric bloating, nausea, partial or complete inappetence and

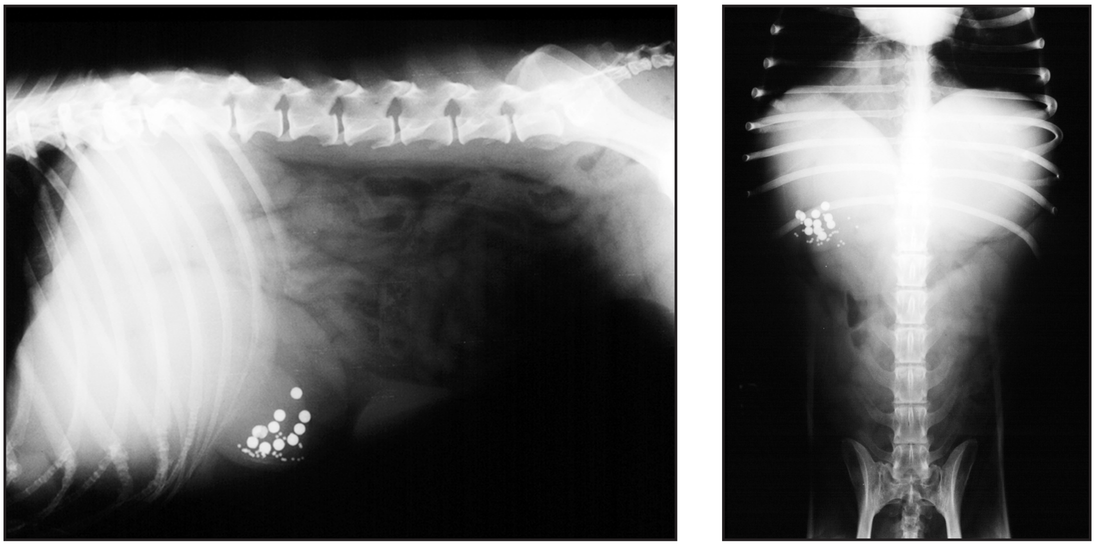

Figure 54-1. Lateral and ventrodorsal abdominal radiographs from an 11-year-old neutered female fox terrier with projectile vomiting demonstrating use of barium-impregnated polyethylene spheres (BIPS). A gastric emptying disorder was confirmed because the spheres were detected in the pyloric antrum 16 hours postadministration. (Courtesy Dr. Grant Guilford, Massey University, New Zealand.)

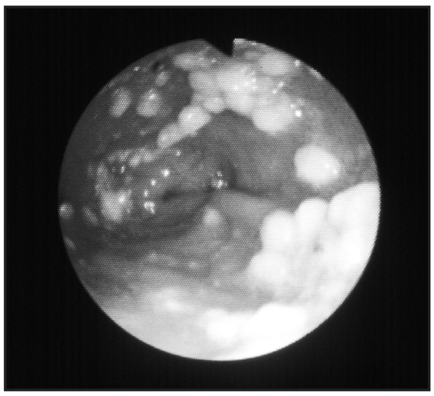

Figure 54-2. Endoscopic view of retained food in the stomach of a 12-year-old neutered female Scottish terrier presented for chronic intermittent vomiting. Food was found in the stomach 20 hours after consumption of a meal, which confirms delayed gastric emptying.

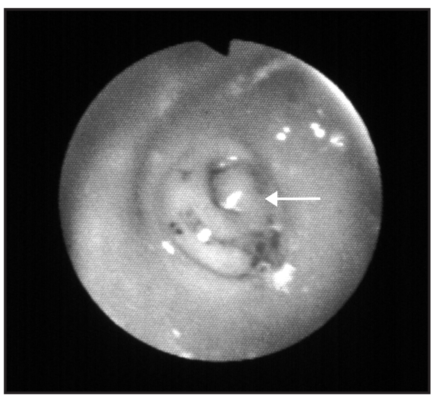

Figure 54-3. Gastroscopic photograph demonstrating hyperplastic mucosal folds (arrow) typical of chronic hypertrophic gastropathy in a 13-year-old neutered male Shih Tzu. (Courtesy Dr. Mike Matz, Southwest Veterinary Specialty Center, Tucson, AZ.)

belching. Occasionally, patients will present with unrelenting or projectile vomiting; complete gastric outflow obstruction should be suspected in such cases.

Physical examination findings are often unremarkable beyond evidence of weight loss. Body condition should be assessed and used as a reassessment tool. Gastric distention and tympany may be evident in some cases. Patients with unrelenting vomiting may present with dehydration, depression and malaise. In rare cases, severe electrolyte abnormalities resulting from persistent vomiting may manifest as weakness.

Laboratory and Other Clinical Information

Hematologic and serologic findings in patients with gastroparesis or gastric obstruction are nonspecific and may be more reflective of the underlying disorder. Chronic, persistent vomiting may precipitate dehydration and electrolyte (hypokalemia, hypochloremia) and acid-base abnormalities. Prerenal azotemia is common. Hypochloremic metabolic alkalosis with paradoxical aciduria may be present in dogs and cats with complete pyloric outflow obstruction.

Survey abdominal radiographs are often helpful for evaluating dogs and cats with gastric motility disorders. Typical findings include a stomach distended by fluid, air or food. The presence of food in the stomach 12 to 18 hours after the last meal is evidence of an emptying disorder. Occasionally, gastric wall thickening may be recognized on survey radiographs. Rarely, extraluminal masses causing pyloric obstruction may be identified.

Gastrointestinal (GI) contrast studies confirm delayed gastric emptying. If liquid contrast media (i.e., barium sulfate) remains in the stomach for more than four hours in dogs or 30 minutes in cats, gastroparesis or mechanical obstruction should be suspected (Moon and Myer, 1986). Liquid contrast media, however, is not representative of a typical meal. For that reason, feeding barium mixed with food or administering radiopaque particles (e.g., barium-impregnated polyethylene spheres, BIPS)[a] mixed with food[b] more completely assesses gastric function (**Figure 54-1**). Studies have demonstrated that radiopaque markers exit the stomach at a rate proportional to the disappearance of food (dry matter [DM]) in dogs (Sparkes et al, 1997; Wyse et al, 2001, 2003; Nelson et al, 2001; Twedt, 2005; Simpson, 2005). GI contrast studies also may identify thickened gastric walls, intraluminal foreign bodies and extraluminal masses.

Endoscopy frequently is preferred over radiographic studies in evaluating delayed gastric emptying and gastric outflow obstruction. Barium in the stomach can make endoscopy more difficult; therefore, endoscopy should be performed before administration of barium contrast media (Simpson, 2005).

Gastric emptying disorders may be suspected at the time of upper GI endoscopy. Food in the stomach after a 12- to 18-hour fast is good evidence of the condition (**Figure 54-2**). In some cases, endoscopic findings may be diagnostic. Chronic hypertrophic pyloric gastropathy, for example, has a typical endoscopic appearance, including hyperplastic mucosal folds surrounding the pylorus, protuberance of the pylorus and polyps (**Figure 54-3**) (Leib et al, 1993). In the case of antropyloric or proximal duodenal foreign bodies, endoscopy can be both diagnostic and curative.

Ultrasonography can be used to evaluate delayed gastric emptying. The rate of liquid- and solid-phase gastric emptying measured by ultrasonography is correlated closely with measurements by scintigraphy in people. Gastric contractions can be visualized in dogs using ultrasonography and prolonged retention of fluid in the stomach may indicate delayed gastric emptying. Studies suggest that ultrasonography may be a noninvasive method of evaluating liquid- and solid-phase gastric emptying in dogs (Wyse et al, 2003). Ultrasonography may be useful in the evaluation of pyloric masses and extraluminal sources of pyloric compression (Biller et al, 1994).

Fluoroscopy and nuclear scintigraphy can help assess gastric emptying rate. Radioscintigraphy is considered the gold standard method for evaluating gastric emptying. Correlation with results of radioscintigraphy is necessary to validate other methods of determining gastric motility (Wyse et al, 2003; Nelson et al, 2001). Other means of evaluating gastric motility include a variety of tracer studies and breath tests that have been developed for use in research settings (Wyse et al, 2001, 2003).

Risk Factors

Several breeds are associated with gastric motility disorders (Table 51-1). Congenital pyloric stenosis most often is encountered in brachycephalic dogs and Siamese cats. Chronic hypertrophic pyloric gastropathy usually affects small, purebred, middle-aged dogs, such as the Lhasa apso, Maltese, Shih Tzu and Pekingese (Matthieson and Walter, 1986; Simpson, 2005). Young animals are more at risk for gastric foreign bodies, whereas older pets are more likely to have neoplastic lesions that may obstruct gastric outflow. Young, large-breed dogs living in states bordering the Gulf of Mexico may be infected with *Pythium insidiosum*, resulting in gastric pythiosis and possible gastric outflow obstruction (Simpson, 2005, 2006; Grooters and Taboada, 2004).

Etiopathogenesis

Gastric motility disorders may arise from functional or mechanical obstruction of gastric outflow. Functional disorders of gastric emptying arise from abnormal or asynchronous gastric motility. Myenteric neuronal or gastric smooth muscle function or antropyloroduodenal coordination may be impaired.

A number of benign and malignant anatomic lesions of the stomach and proximal duodenum may result in mechanical gastric outflow obstruction (**Table 54-1**). The most common of these is chronic hypertrophic pyloric gastropathy, which refers to an acquired hypertrophic mucosal or muscular lesion of the pyloric antrum. In addition, congenital pyloric stenosis occurs in young dogs and cats as a consequence of benign muscular hypertrophy of the pylorus. Certain gastric and proximal duodenal neoplasms and granulomatous conditions (e.g., pythiosis, eosinophilic gastritis) can result in pyloric obstruction.

Table 54-1. Potential causes of gastric emptying disorders in dogs and cats.

Functional obstruction (primary motility defects)
Gastric ulcers
Idiopathic asynchronous motility
Idiopathic hypomotility
Infectious gastroenteritis
Postoperative ileus
Functional obstruction (secondary motility defects)
Drug therapy
Anticholinergics
Beta-adrenergic agonists
Narcotic analgesics
Electrolyte disturbances
Hypercalcemia
Hypocalcemia
Hypokalemia
Hypomagnesemia
Inflammation
Acute pancreatitis
Peritonitis
Metabolic disorders
Diabetes mellitus
Hepatic encephalopathy
Hypothyroidism
Mechanical obstruction
Congenital or acquired antral pyloric hypertrophy
Extraluminal compression
Gastric or duodenal foreign bodies
Gastric or duodenal granulomatous lesions
Gastric or duodenal neoplasia or polyps

Key Nutritional Factors

Key nutritional factors for patients with gastric motility and emptying disorders are listed in **Table 54-2** and discussed in detail below.

Water

Dehydration is a common problem in patients with persistent vomiting. Dehydration should be corrected with appropriate parenteral fluid therapy. Thereafter, water should be available free choice. Water should be offered between room and body temperature. Colder water delays gastric emptying.

Energy

Patients with chronic vomiting are often underweight due to longstanding inadequate caloric intake. The energy density of the food should be moderate to increased (4.0 to 4.5 kcal/g [16.7 to 18.8 kJ/g] [DM]) to ensure intake of sufficient energy with small amounts of food. Higher energy densities may help patients maintain or regain body weight and condition, but would require higher dietary fat levels. As discussed below, increased levels of dietary fat adversely affect gastric emptying and should be avoided.

Table 54-2. Key nutritional factors for foods for dogs and cats with gastric motility and emptying disorders.*

Factors	Recommended levels
Energy density	4.0 to 4.5 kcal/g (16.7 to 18.8 kJ/g)
Potassium	0.8 to 1.1%
Chloride	0.5 to 1.3%
Sodium	0.3 to 0.5%
Fat	≤15% for dogs ≤25% for cats
Crude fiber	≤5% crude fiber; avoid foods with gel-forming fiber sources such as pectins and gums (e.g., gum arabic, guar gum, carrageenan, psyllium gum, xanthan gum, carob gum, gum ghatti and gum tragacanth)
Food form consistency	Moist is best; initially liquid or semi-liquid
Food temperature	70 to 100°F (21 to 38°C)

*Nutrients expressed on a dry matter basis.

Electrolytes
Abnormalities in serum electrolyte concentrations, especially potassium, sodium and chloride, are common in patients with chronic vomiting and can adversely affect gastric motility and emptying. Initial abnormalities should be corrected with appropriate parenteral fluid therapy. Foods for patients with gastric motility should contain levels of potassium, chloride and sodium above the minimum allowances for normal dogs and cats. Recommended levels of these nutrients are 0.8 to 1.1% DM potassium, 0.5 to 1.3% DM chloride, and 0.3 to 0.5% DM sodium. Thereafter, the food should contain levels of minerals appropriate for the patient's lifestage.

Fat
Patients with chronic vomiting are often underweight due to longstanding inadequate caloric intake. The energy density of foods is related to dietary fat content and increasing dietary fat typically results in increased caloric intake. However, both solid and liquid foods containing increased fat levels generally are emptied more slowly from the stomach than similar foods with lower fat content. Fat in the duodenum stimulates release of cholecystokinin, which delays gastric emptying. Thus, foods for cats and dogs with gastric emptying or motility disorders should not provide excess fat. Foods with 15% or less (dogs) or 25% or less (cats) DM fat are probably appropriate for patients with gastric emptying or motility disorders.

Fiber
Many grocery brand moist foods contain gelling agents such as gums or hydrocolloids to enhance the aesthetic characteristics of the food. Foods containing gel-forming soluble fibers should be avoided in patients with gastric emptying and motility disorders because they increase the viscosity of ingesta and slow gastric emptying (Russell and Bass, 1985; Prove and Ehrlein, 1982; Sandhu et al, 1987; Burger et al, 2006). Such fibers include pectins and gums (e.g., gum arabic, guar gum, carrageenan, psyllium gum, xanthan gum, carob gum, gum ghatti and gum tragacanth). However, increased levels (>8% DM) of insoluble fiber (powdered cellulose) in dry foods fed to cats had no effect on gastric emptying (Armbrust et al, 2003). Other reports show that the ratio of slowly to rapidly fermentable fibers is important (Kritchevsky, 2001). Therefore, the crude fiber content of foods for patients with gastric motility or emptying disorders should be limited to no more than 5% DM.

Meal Size, Food Form and Food Temperature
In cats and probably dogs, larger meals are emptied more slowly from the stomach than smaller meals (Goggin et al, 1998). Liquids are emptied from the stomach more quickly than solids due to lower digesta osmolality. Water is emptied most quickly, whereas liquids containing nutrients are emptied more slowly. High-osmolality fluids are emptied more slowly than dilute fluids. Solids are the slowest to be emptied from the stomach (Fleming, 1997). A study in cats noted that dry foods emptied more slowly than moist foods (Goggin et al, 1998).

The ideal food form for patients with gastric emptying disorders has a liquid or semi-liquid consistency. Cold meals slow gastric emptying. Therefore, food should be offered between room and body temperature (70 to 100°F [21 to 38°C]).

FEEDING PLAN

Dehydration, electrolyte and acid-base abnormalities and gastric outflow obstruction should be corrected with appropriate fluid therapy and surgical intervention, respectively, before the feeding plan is initiated. For dogs or cats with functional gastric motility disorders, several prokinetic agents are available (Table 51-1) and should be considered if dietary management is insufficient to control clinical signs.

Assess and Select the Food
The form and levels of key nutritional factors should be assessed in the current food and compared with the recommendations outlined in the key nutritional factors section (**Table 54-2**). Most importantly, the food should be complete and balanced for the current lifestage of the patient. The food may not need to be altered for patients with mild disease or few clinical signs.

Tables 54-3 for dogs and **54-4** for cats provide information about key nutritional factor content of selected commercial veterinary therapeutic foods marketed for GI diseases and compares them to the recommended levels. Moist foods are preferred and partially or fully liquefying the food may help promote gastric emptying. These techniques should be used initially in patients with gastric motility or emptying disorders. Add water to a moist veterinary therapeutic food and hand mix or blend to produce a liquid or semi-liquid consistency. Alternatively, liquid enteral products with appropriate key nutritional factor content may be used.

Feed or offer buffering foods rather than foods that contain acidifying salts to most patients with acute or chronic vomiting. Hypochloremic metabolic alkalosis may occur in patients with

unrelenting vomiting secondary to gastric outflow obstruction. In such patients, oral consumption of food is not possible and intravenous fluid administration with electrolyte therapy should be used to correct this profound acid-base disturbance. A highly digestible food formulated for GI disease should be fed after the gastric outflow obstruction has been resolved by surgical or endoscopic means.

Foods with lower energy density require larger or more frequent meals to meet the patient's daily energy requirement. Larger meals may promote more vomiting and can slow gastric emptying. Optimal energy and fat levels should be determined according to the patient's ability to tolerate meal size and maintain optimal body condition.

Assess and Determine the Feeding Method

Patients with gastric motility disorders often require specialized feeding methods; the current feeding protocol is rarely appropriate. A thorough assessment includes verification of the feeding method currently used. Items to consider include feeding frequency, amount fed, how the food is offered, access to other food, relationship of feeding to exercise and who feeds the pet. All of this information should have been gathered when the history of the patient was obtained. If the patient has a normal body condition score (BCS of 2.5/5 to 3.5/5), the amount of food fed previously was probably appropriate.

Offer foods between room and body temperature (70 to 100°F [21 to 38°C]). Frequent small meals (at least three per day) are preferred. In some cases of complete pyloric outflow obstruction, parenteral nutritional support may be necessary to meet the patient's needs before surgical alleviation of the obstruction. This is indicated when the patient's body condition is poor (BCS of 1/5 or 2/5) and the patient is deemed at increased risk for postsurgical complications.

Late evening feedings are recommended for dogs with the so-called "bilious vomiting" syndrome. Gastroduodenal reflux in these patients probably arises secondarily to a gastric motility disorder. Late evening meals with or without prokinetic therapy may resolve clinical signs in affected dogs (Simpson, 2005).

Most patients can be fed using a feeding method similar to that used for normal pets, if normal gastric function is restored after surgery. The best feeding method will need to be individualized for each patient and determined by trial and error based on remaining gastric function.

REASSESSMENT

Body weight and condition should be assessed every two to four weeks. Document the presence or absence of vomiting. If vomiting continues, alter the food or feeding pattern. Dividing the daily food intake into additional meals also may increase GI tolerance. Use of prokinetic agents (e.g., metoclopramide, cisapride) should be considered if vomiting persists despite implementation of these therapeutic strategies.

Gradual attempts to normalize the feeding regimen can be made if the patient is doing well on the recommended therapy. Feeding more solid foods and larger, less frequent meals are more convenient for pet owners.

The prognosis for dogs and cats with gastric motility disorders varies with the underlying cause. Mechanical obstructions often can be managed effectively through surgical or endoscopic (e.g., foreign body retrieval) means, resulting in an excellent prognosis (Matthieson and Walter, 1986). Occasionally, dogs and cats with longstanding gastric outflow obstruction with gastric distention may have residual gastric motility abnormalities (Leib, 1997). These patients may benefit from the use of prokinetic agents.

Introduction to Small Intestinal Diseases

Deborah J. Davenport
Rebecca L. Remillard

"From the gut, comes the strut, and where hunger reigns, strength abstains."
Francois Rabelais

CLINICAL IMPORTANCE

Disorders of the small intestine are encountered frequently in veterinary practice. A number of acute and chronic enteropathies are recognized (**Tables 55-1** and **55-2** and **Boxes 55-1** through **55-3**) and must be distinguished from diseases of other organ systems resulting in gastrointestinal (GI) signs. Typical clinical manifestations of small intestinal disease include diarrhea, weight loss, poor body condition, vomiting, borborygmus and flatulence. **Table 55-3** lists breed-associated small intestinal disorders.

Diarrhea is defined as a change in the frequency, consistency or volume of bowel movements and stools. Diarrhea is the most common manifestation of small intestinal disease. The diarrhea associated with small intestinal conditions differs from that typically associated with large intestinal disorders (**Table 55-4**).

Chapters 56 through 60 include feeding plans for patients with small intestinal disorders. Tables in those chapters list the key nutritional factors for such patients as well as tables that include the levels of key nutritional factors of commercial foods marketed for patients with small intestinal diseases. For comparative purposes, these tables also include the recommended levels of key nutritional factors for patients with small intestinal diseases. Box 60-1 discusses the use of certain oligosaccharides in small intestinal disease.

MECHANISMS OF DIARRHEA

An understanding of normal gut physiology and the common pathophysiologic mechanisms responsible for diarrhea in companion animals allows for a rational approach to evaluation and treatment of patients with small intestinal disorders. There are four major mechanisms for diarrhea: 1) osmotic, 2) altered mucosal permeability, 3) abnormal motility and 4) secretory (Moon, 1978).

Osmotic Diarrhea

Osmotic diarrhea, also referred to as diarrhea of malabsorption, is the most common cause of diarrhea in dogs and cats (Moon,

1978). Osmotic diarrhea may occur in conjunction with other pathophysiologic processes. The presence of unabsorbed nutrients (solutes) in the bowel results in passive diffusion of water into the gut lumen (**Box 55-3**). This process continues until the osmolality of the intestinal chyme is approximately that of plasma. Osmotic diarrhea may occur as a result of maldigestion, malabsorption, administration of osmotic laxatives and overeating. Clinical manifestations of osmotic diarrhea include passage of large volumes of fluid or soft stools. Stools may appear greasy if steatorrhea is present. The diarrhea usually resolves following a 24- to 36-hour fast.

Diarrhea Due to Altered Mucosal Permeability

Altered mucosal permeability (i.e., exudative diarrhea) is another common cause of diarrhea in dogs and cats. The large or small bowel may be affected. The intestinal permeability barrier is composed of epithelial tight junctions, mucosal lymphatics and capillaries and the local immune system. Failure of any one of these components can result in diarrhea. Intestinal diseases that result in erosions, ulcerations and mucosal inflammation or infiltration are potential causes of gut permeability changes and diarrhea. Diarrhea associated with increased gut permeability may present as a protein-losing enteropathy (i.e., hypoproteinemia, hypoalbuminemia, weight loss). Fresh and/or melenic blood may be present in the stool. Fecal examination may reveal inflammatory cells. Often these diarrheas do not completely resolve if food is withheld.

Diarrhea Due to Abnormal GI Motility

Diarrhea may be associated with deranged intestinal motility. It is often difficult to determine whether abnormal GI motility is a primary entity or a consequence of another disorder. In general, deranged intestinal motility is not a common cause of small bowel diarrhea in dogs and cats. The most common motility

Key: APUD = amine precursor uptake and decarboxylation.

derangement is rapid intestinal transit associated with a decreased frequency of rhythmic segmental contractions, also termed ileus. The reduction in segmental contractions results in a "pipe" effect with little resistance to ingesta flow. Ileus may occur in conjunction with infiltrative diseases, severe abdominal pain, parvoviral enteritis or may develop postoperatively. In many cases, iatrogenic ileus complicates the management of patients treated inappropriately with anticholinergic agents. Increased frequency of peristaltic contractions is probably not an important cause of diarrhea in dogs and cats. However, it may play a role in the irritable bowel syndrome. A reduction in peristaltic or interdigestive motility may result in small intestinal bacterial overgrowth. Response to dietary manipulation is variable.

Secretory Diarrhea

Secretory diarrhea is relatively uncommon in companion animals vs. people (cholera is the prototypical example) and food animal species. Crypt epithelial cells produce intestinal fluid, whereas enterocytes lining the villous tips are responsible for absorption. Normally, absorption exceeds intestinal secretion. Most secretagogue effects are mediated via a second messenger (e.g., cyclic AMP, cyclic GMP, calmodulin). Secretagogues include GI hormones, bacterial enterotoxins, certain pharmacologic agents, deconjugated bile acids and hydroxy fatty acids. Clinical manifestations of secretory diarrhea are often extreme. Patients have large volumes of fluid diarrhea and often become dehydrated rapidly. Generally, fasting is not successful in alleviating clinical signs.

Box 55-1. Small Intestinal Neoplasia.

Lymphosarcoma, adenocarcinoma and mast cell tumors are the most common intestinal tumors recognized in cats, whereas adenocarcinomas and leiomyomas are more common in dogs. Adenocarcinomas occur most commonly in the jejunum and ileum of cats and in the duodenum and colon of dogs. Lymphosarcoma arising from gut-associated lymphoid tissue is the most common extranodal form. A number of other tumor types occur, including plasma cell tumors, leiomyosarcomas, hemangiosarcomas and carcinoid tumors, but are less common.

The diffuse nature of lymphosarcomas and mast cell tumors often results in maldigestion of carbohydrates and some proteins, malabsorption and subsequent malnutrition and provides the greatest opportunity for dietary therapy.

Nutritional support is of critical importance in managing patients with intestinal neoplasia. Providing optimal nutrition helps the clinician return the patient to ideal body condition, provides some protection against the toxic side effects of antineoplastic chemotherapy and improves the patient's quality of life (Chapter 30). As with many small bowel disorders, use of highly digestible foods is recommended with nutrient levels adjusted for each patient as tolerated.

In cases of intestinal neoplasia, assisted-feeding techniques (enteral or parenteral) may be required initially to meet nutritional, fluid and electrolyte needs as the patient recovers from surgery or receives chemotherapy. In particular, early nutritional support (i.e., parenteral or enteral) in debilitated cats is very advantageous in the initial management of gastrointestinal lymphosarcoma. Parenteral administration of nutrients can be added to oral intake to fully meet the patient's requirements. Reestablishing normal intestinal function and stimulating adaptation should begin as soon as the patient tolerates oral food intake.

Multiple (i.e., six to eight) small meals per day are recommended in a form best tolerated by the patient. Occasionally, a liquid form of the food may be necessary for patients undergoing various forms of treatment.

The Bibliography for **Box 55-1** can be found at www.markmorris.org.

Box 55-2. Wheat-Sensitive (Gluten-Sensitive) Enteropathy.

Wheat-sensitive enteropathy is a chronic small bowel disorder recognized primarily in Irish setter dogs. The condition is believed to have an autosomal recessive mode of inheritance. The condition, also termed gluten-sensitive enteropathy, is comparable in some ways to celiac disease of people. The disorder results from a hypersensitivity to gliadin, a glycoprotein found in many grains including wheat, barley, rye, buckwheat and oats. Gliadin is not found in rice, corn or potatoes.

Affected dogs usually develop clinical signs by six months of age, including weight loss, failure to thrive and chronic, intermittent small bowel diarrhea. Some dogs may outgrow the condition and fail to respond to wheat-gluten exposure as adults despite being affected as young dogs. There are no consistent laboratory findings in dogs with wheat-sensitive enteropathy. The results of intestinal function tests such as D-xylose absorption and serum folate/cobalamin concentrations are often normal. Intestinal biopsy can be a useful diagnostic aid. Typical histopathologic findings include partial villous atrophy and intraepithelial lymphocyte infiltration with inflammatory infiltrates within the lamina propria.

Diagnosis of this condition is usually based on signalment, history and response to a therapeutic food trial. Clinical signs usually resolve within two to four weeks after gliadin-containing grains are eliminated from the food. Definitive diagnosis can be made if the clinical signs recrudesce upon re-exposure to gliadin-containing foods or purified gluten.

The pathogenesis of gluten- or wheat-sensitive enteropathy is not completely understood. Hypersensitivity to gliadin has been theorized to develop in dogs due to an age-related delay in expression of a brush border peptidase (i.e., aminopeptidase N) or to increased intestinal permeability. Affected Irish setters have increased serum IgA levels and circulating CD4+ lymphocytes compared to normal dogs. Compared to celiac disease in man, there is no link to major histocompatibility genes (Chapter 31).

The feeding plan includes eliminating all sources of gliadin from the diet including commercial foods, homemade foods, table foods, commercial treats, supplements and chewable medications containing wheat, barley, rye, buckwheat or oats as ingredients. The carbohydrate portion of the food should be composed of potatoes, rice or corn.

Affected dogs should be fed to meet their daily energy requirement. Young growing dogs should be fed foods suitable for growth, whereas young adult and mature adult dogs should receive foods suitable for their lifestage and lifestyle.

The Bibliography for **Box 55-2** can be found at www.markmorris.org.

Box 55-3. Disaccharide Intolerance.

Lactose intolerance is the most common carbohydrate intolerance in people and possibly in dogs and cats. Lactose intolerance results from a relative or absolute deficiency of the enzyme lactase. If brush border lactase fails to hydrolyze lactose into galactose and glucose, the unabsorbed sugar will induce an osmotic diarrhea when it reaches the colon. In addition, colonic bacteria ferment lactose, producing volatile fatty acids, hydrogen and carbon dioxide, resulting in flatulence and pain.

The intestinal brush border mucosa and the disaccharidase enzymes that it contains (i.e., lactase, sucrase, maltase and α-dextrinase) are often lost due to enteritis from any cause. These enzymes are essential for digestion of disaccharides (i.e., lactose, sucrose, maltose and α-dextrins) and subsequent absorption of their constituent monosaccharides. As mentioned above, unabsorbed disaccharides result in a colonic osmotic diarrhea.

Often, one to two weeks are needed to fully restore intestinal lactase and sucrase brush border disaccharidase activity after the cause for their loss is corrected. Diarrhea may, therefore, occur during this period with the ingestion of carbohydrates requiring disaccharidase digestion. For example, jejunal and ileal lactase and sucrase activity were significantly less in piglets fed nothing per os; however, maltase activity in the jejunum and ileum was not different from that of enterally fed piglets after four weeks. Therefore, during and for several days after a diarrheic episode, foods containing maltodextrins should be fed but not those containing lactose and sucrose.

Inadequate intestinal disaccharidase activity is also the mechanism responsible for causing diarrhea after excessive milk consumption. Puppies and kittens normally have small but adequate amounts of intestinal lactase. After weaning age, lactase decreases to about 10% of peak activity in dogs and cats, and continued consumption of milk does not alter the decline in lactase activity. Diarrhea occurs if more lactose is consumed than the animal can digest. Bitch's milk contains only 3.1% lactose and queen's milk 4.2% vs. cow's and goat's milk (4.5 to 5%) as fed. This difference explains why puppies and kittens commonly have diarrhea when given cow's or goat's milk as a milk replacer.

Healthy adult dogs and cats may also develop diarrhea when fed milk. Adult dogs and cats have low levels of brush border lactase activity compared with levels present in pre-weaning animals and levels of other disaccharidases. Most newborn mammals have negligible maltase and sucrase activities, which develop during the first few weeks of life; however, lactase activity is high at birth and decreases with age. In one study, dogs developed diarrhea while consuming more than 1 g of lactose/kg body weight, an amount equivalent to about 20 ml milk/kg body weight or three-fourths cup of milk for a 10-kg dog. Thus, milk-based enteral diets and milk drinks for dogs and cats are commonly treated with enzymes (β-galactosidase) to hydrolyze lactase. However, this increases the osmolality of the product, which may cause diarrhea.

Altered intestinal disaccharidase activity also is hypothesized to be one of the factors responsible for diarrhea subsequent to rapid change in foods and feeding methods. Lactase and sucrase are food-inducible enzymes, whereas, maltase is not. Several days are required for intestinal disaccharidase enzyme activity to respond to a change in dietary carbohydrates.

Chapter
56

Acute Gastroenteritis and Enteritis

Deborah J. Davenport
Rebecca L. Remillard

"When the Humour falls upon the intestines, it produces a Diarrhea with a sense of heat, and sometimes a Griping...and sometimes with hot stools...so that most of the nutricious juices run off that way, which greatly wastes and sinks the patient."
Williams Hillary 1759, Observations on Changes of the Air

CLINICAL IMPORTANCE

Acute gastroenteritis (enteritis often accompanied by acute gastritis; called gastroenteritis) is one of the most common illnesses of dogs and cats. A number of infectious, toxic and dietary factors can trigger the sudden onset of diarrhea with or without vomiting (Table 55-1). This chapter addresses the diagnosis and management of dogs and cats with an acute onset of diarrhea with or without vomiting.

PATIENT ASSESSMENT

History and Physical Examination

Patients are usually presented for the sudden onset of diarrhea, vomiting or both. In many cases, the owner will report that the pet acts depressed and has a poor appetite. The number and character of the defecations should be assessed. Large fluid stools are typical of small bowel disorders. Melenic or hemorrhagic stools may indicate a potentially life-threatening disorder (**Table 56-1**).

The dietary history is critical. Food-induced diarrhea is relatively common; therefore, a recent change to a moist high-fat or meat-based food may be the source of the patient's diarrhea.[a,b] Often, it is possible to elicit a history of dietary indiscretion, feeding table foods over a holiday or access to garbage, carrion or abrasive materials. Cats that hunt birds may have been exposed to *Salmonella* spp. and dogs eating raw salmon are at risk for salmon poisoning (Scott, 1988; Hibler and Greene, 1986).

Feeding uncooked meat in homemade foods and racing greyhound rations is linked to bacterial enteritis (Chapter 11). Greyhound rations often contain raw ground beef and have been identified as fomites for salmonellosis and colibacillosis (Chengappa et al, 1993; Stone et al, 1993; Morley et al, 2006). Incorporation of raw poultry in foods has been linked to campylobacteriosis and salmonellosis (Davenport, 1989) (Chapter 11).

Other husbandry issues are also important. Records of vacci-

Table 56-1. Clinical signs associated with life-threatening acute gastroenteritis.

Abdominal pain	Fecal leukocytes
Dehydration	Fever
Depression	Melena or hematochezia

nations and anthelmintic treatments should be reviewed. Questions should be asked about the health of other pets and people in the household. A positive answer to these questions raises the likelihood that an infectious organism was involved.

Often, affected dogs and cats are depressed and dehydrated. Typically, the diarrhea is most consistent with small bowel disease (Table 55-4). Occasionally, patients may present with signs reflective of small and large bowel involvement. Abdominal discomfort may be recognized on palpation. Patients should be carefully evaluated for evidence of septic shock. Animals exhibiting systemic signs of illness such as fever and congested mucous membranes in addition to gastrointestinal (GI) signs should be treated more aggressively.

Laboratory and Other Clinical Information

Because there are many potential causes of acute gastroenteritis and enteritis, achieving a definitive diagnosis can be difficult. It is more important to determine whether the patient's condition is self-limiting or if it is potentially life-threatening. This decision, based on historical and physical findings, is critical. **Table 56-1** lists factors that suggest a potentially life-threatening condition. Cases of a serious nature should be pursued aggressively with the use of hematology, serum biochemistry profiles, urinalyses and fecal examinations for parasites and other infectious pathogens. Abdominal films or GI contrast radiographs are recommended to rule out obstruction. Self-limiting cases are usually approached more conservatively. Diagnostics are often limited to assessment of hydration status (i.e., packed cell volume, total protein concentration and body weight) and thorough examination of feces for evidence of parasites, bacterial pathogens (e.g., spores of *Clostridium* spp.), viruses (e.g., fecal ELISA for parvovirus) and enterotoxins (e.g., *C. difficile* fecal ELISA) (Chouicha and Marks, 2006).

Risk Factors

Risk factors for acute gastroenteritis and enteritis include age, breed, immune status and environment. Young animals are more susceptible to a variety of infectious pathogens including parasites, viruses and bacteria (De Santis-Kerr et al, 2006). Hemorrhagic gastroenteritis is reported most commonly in miniature schnauzers, dachshunds, toy poodles and other toy and small dogs (Guilford and Strombeck, 1996). Rottweilers, American pit bull terriers and Doberman pinschers appear to be at increased risk for parvoviral enteritis (Mantione and Otto, 2005; Houston et al, 1996).

Several canine breeds (e.g., Chinese Shar-Pei, German shepherd dog, beagle) may have IgA deficiency; therefore, these dogs may be more susceptible to develop a number of GI conditions, including giardiasis and small intestinal bacterial overgrowth (Table 55-1) (Batt et al, 1991; Whitbread et al, 1984). Likewise, immunocompromised animals are at risk for contracting viral and bacterial enteritides. For example, an outbreak of *C. difficile*-associated enteritis was reported in hospitalized dogs (Weese and Armstrong, 2003). Several conditions including cancer, diabetes mellitus, feline leukemia and feline immunodeficiency virus infections may result in deranged immune function.

Environment also plays an important role in exposure to pathogens. Dogs and cats kept in unsanitary or overcrowded conditions are much more likely to develop infectious enteropathies (De Santis-Kerr, 2006). In addition, animals kept in poorly controlled environments have higher risk for exposure to high-fat table foods, garbage containing spoiled food and toxins. Dogs in particular eat indiscriminately. Consumption of rotten garbage, decomposing carrion or abrasive materials (e.g., hair, bones, rocks, plastic, aluminum foil) can result in severe enteritis. Poor husbandry practices including inadequate parasite control and vaccination programs and overcrowding put pets at risk for acute gastroenteritis and enteritis.

Consumption of raw food diets has been associated with bacterial enteritides (Chengappa et al, 1993; Stone et al, 1993; Morley et al, 2006). Cultures of home-prepared and commercially available raw foods have demonstrated bacterial pathogens including *Salmonella* spp., *Campylobacter* spp., *Escherichia* spp. and *Yersinia* spp. (Weese, 2006; Strohmeyer et al, 2006). Dogs consuming such foods shed bacterial pathogens at a much higher rate than those consuming conventionally cooked commercial foods (Weese and Armstrong, 2006). A thorough dietary history should elicit details of potential exposure to raw meats.

Etiopathogenesis

In acute enteritis, diarrhea may occur as a result of any or all of the four mechanisms of diarrhea described in Chapter 55. Many viral organisms and cancer chemotherapeutic agents destroy intestinal villi. Consequently, diarrhea may occur due to altered gut permeability and/or osmotic mechanisms. Ileus may arise due to abdominal pain in patients with parvoviral enteritis. Finally, bacterial pathogens may elaborate enterotoxins that serve as potent secretogogues.

Small bowel atrophy begins within days in the absence of luminal stimulation. Atrophy, the small intestinal response to disuse, occurs in several species with simple stomachs, including foals (Oikawa et al, 1992), cats (Lippert et al, 1989), dogs (Remillard and Thatcher, 1989) and pigs (Schulman, 1988) and is similar morphologically. The hallmarks of small bowel atrophy are decreased villus height (about 50% in the jejunum and 25% in the ileum) with an overall reduced absorptive surface area and brush border enzyme activity (Remillard et al, 1998, 1998a; Levine et al, 1974).

Food in the lumen of the small bowel stimulates intestinal integrity (mass and function) by several mechanisms. Ingested nutrients mechanically and chemically stimulate the

Table 56-2. Key nutritional factors for dogs and cats with acute gastroenteritis or enteritis.*

Factors	Recommended levels
Sodium	0.3 to 0.5%
Chloride	0.5 to 1.3%
Potassium	0.8 to 1.1%
Fat	12 to 15% for dogs (highly digestible foods) 15 to 25% for cats (highly digestible foods) 8 to 12% for dogs (increased-fiber foods) 9 to 18% for cats (increased-fiber foods)
Energy density	4.0 to 4.5 kcal/g (16.7 to 18.8 kJ/g) (highly digestible foods) ≥3.2 kcal/g (≥13.4 kJ/g) for dogs and ≥3.4 kcal/g (≥14.2 kJ/g) for cats (increased-fiber foods)
Fiber	≤5% in highly digestible foods (mixed fiber sources are best) 7 to 15% in fiber-enhanced foods (insoluble fiber sources are best)
Digestibility	≥87% for protein and ≥90% for fat and carbohydrate (highly digestible foods) ≥80% for protein and fat and ≥90% for carbohydrate (fiber-enhanced foods)

*Nutrient levels are on a dry matter basis.

Table 56-3. Selected commercial oral rehydration solutions available for use in dogs and cats.

	Nutrient content (mEq/l)								
Products (manufacturers)	Na	K	Cl	Mg	Ca	P	Citrate	ME (kcal/l)	Comments

Enfamil Enfalyte (Mead Johnson)	50	25	45	–	–	–	34	126	mOsm/l = 167
Pedialyte Solution unflavored (Abbott Nutrition)	45	20	35	–	–	–	30	100	mOsm/l = 250-270
Rebound OES (Virbac)	52.2-65.2	20.5-25.6	10-20	–	–	–	–	253	–

Key: mEq/l = milliequivalents per liter, Na = sodium, K = potassium, Cl = chloride, Mg = magnesium, Ca = calcium, P = phosphorus, ME = metabolizable energy.

intestine, increasing intestinal secretory and endocrine activity. The type and amount of ingested nutrients mechanically alter the mucosal cell mass by affecting the rate of stem cell division and the rate of mucosal cell renewal. Gastric, duodenal and pancreato-biliary secretions, which normally accompany eating, digestion and absorption, promote mucosal structure and function (Yamada, 1985; Castillo et al, 1990). Refeeding the atrophied small bowel should consider altered function. Limited enteral feeding of milk (i.e., 2 ml/kg body weight, per os, twice daily) to piglets, providing only 10% of the resting energy requirement, resulted in significantly greater jejunal lactase and sucrase activities with taller villi and deeper crypts vs. findings in animals fed nothing per os (Remillard et al, 1998).

Glutamine is the preferred fuel for enterocytes. Glutamine is a conditionally essential amino acid necessary during intestinal recovery to stimulate enterocyte-DNA synthesis and increase enterocyte mucosal mass (Windmueller and Spaeth, 1974). In dogs, there is an increased intestinal requirement for glutamine during the immediate postoperative phase (i.e., less than seven days postsurgery). Glutamine uptake returns to normal later during the recovery phase (i.e., more than 10 days postsurgery) (Souba et al, 1990, 1987).

Key Nutritional Factors

Table 56-2 lists key nutritional factors for patients with acute gastroenteritis or enteritis, which are discussed in detail below.

Water

Water is the most important nutrient for patients with acute diarrhea with or without vomiting because of the potential for life-threatening dehydration due to excessive fluid loss and inability of the patient to replace those losses. Moderate to severe dehydration should be corrected with appropriate parenteral fluid therapy rather than using the oral route. Intraosseous fluid administration may be used in patients with limited venous access, but the subcutaneous route is not recommended in moderate to severely dehydrated patients.

Oral fluid therapy is typically reserved for non-vomiting patients with minor fluid deficits or to supply maintenance fluid requirements. Oral rehydration solutions have been used commonly in people and food production animals with acute diarrhea. Oral rehydration solutions have also been advocated for use in dogs and cats (Zenger and Willard, 1989). Oral rehydration solutions contain glucose, amino acids and electrolytes in addition to water. The physiologic basis for these solutions is the coupled transport of sodium and glucose and other active-

ly transported small organic molecules (Avery and Snyder, 1990). The maximum uptake of water and electrolytes occurs when the ratio of glucose to sodium approaches 1:1 (Avery and Snyder, 1990). An oral rehydration solution containing rice carbohydrate-based glucose polymers developed by the World Health Organization has been licensed for the small animal market (**Table 56-3**). Such solutions are most useful in secretory diarrheas, which are uncommon in small animals. However, oral rehydration solutions can be useful as an alternate fluid source, if readily consumed by the patient.

Electrolytes: Sodium, Chloride and Potassium

The electrolyte composition of intestinal (and gastric) secretions differs from that of extracellular fluids; therefore, loss of intestinal (and gastric) secretions may result in systemic electrolyte abnormalities. Dogs and cats with diarrhea and vomiting may have low, normal or high serum sodium, potassium and chloride concentrations. The derangement that predominates in a particular animal depends on the severity of the disease, nutritional status, site of the disease process, etc. For these reasons, serum electrolyte concentrations are helpful in tailoring the fluid therapy and nutritional management. Mild hypokalemia, hypochloremia and either hypernatremia or hyponatremia are the electrolyte abnormalities most commonly associated with acute diarrhea and vomiting.

Depletion of total body potassium is a predictable consequence of severe or chronic GI disease because the potassium concentration of gastric and intestinal secretions is high. Hypokalemia in association with GI disease will be particularly profound if losses are not matched by sufficient intake of dietary potassium.

Electrolyte disorders should be corrected initially with appropriate parenteral fluid and electrolyte therapy. Foods for patients with acute gastroenteritis should contain levels of sodium, chloride and potassium above the minimum allowances for normal dogs and cats. Recommended levels of these nutrients for dogs and cats are 0.30 to 0.5% dry matter (DM) sodium, 0.5 to 1.3% DM chloride and 0.8 to 1.1% DM potassium.

Fat and Energy Density

In comparison to processes involved with other macronutrients, fat digestion and absorption are relatively complex and may be disrupted in patients with GI disease. Ingestion of a fatty meal decreases gastroesophageal tone, slows gastric emptying and is a potent stimulus for pancreatic secretion.

On the other hand, dietary fat is a concentrated source of calories; higher fat foods allow smaller amounts of food to be ingested to meet the patient's daily energy requirement (DER). This is an important consideration in many patients because limiting the amount of food entering the GI tract helps control clinical signs. Fat also improves the palatability of food, which is important in patients with nausea.

For these reasons, foods for patients with acute gastroenteritis and many other GI diseases should contain moderate amounts of fat. Recommended dietary DM fat levels are 12 to 15% for dogs and 15 to 25% for cats. Dietary fat within these ranges should ensure the energy density of the food falls between 4.0 to 4.5 kcal/g (16.7 to 18.8 kJ/g) DM, thus providing sufficient energy with small amounts of food. Foods with higher energy densities may help restore or maintain body weight and condition in patients but would require higher dietary fat levels. Increased levels of dietary fat delay gastric emptying and therefore should usually be avoided. When feeding foods with increased fiber, the food's DM fat content will typically be lower (eight to 12% for dogs and nine to 18% for cats), as will energy density. Energy densities for these foods should be at least 3.2 kcal/g (13.4 kJ/g) DM for dogs and at least 3.4 kcal/g (14.2 kJ/g) DM for cats.

Fiber

Although dietary fiber predominantly affects the large bowel of dogs and cats, fiber can also affect gastric, small intestinal and pancreatic structure and function. Effects of dietary fiber include: 1) modifying gastric emptying, 2) normalizing intestinal motility and intestinal transport rate, 3) buffering toxins in the GI lumen, 4) binding or holding excess water, 5) supporting growth of normal GI microflora, 6) buffering gastric acid and 7) altering viscosity of GI luminal contents. Dietary fiber also adds indigestible bulk and decreases the DM digestibility of the food.

Various types and levels of dietary fiber have been advocated for patients with acute gastroenteritis. The traditional approach is to recommend low-fiber foods (≤5% DM mixed fiber) that are highly digestible and provide "low residue" in the GI tract. Mixed fibers include beet pulp, brans (rice, wheat or oat), pea, soy fibers, soy hulls and mixtures of soluble and insoluble fibers. Insoluble fibers include purified cellulose and peanut hulls. Soluble fiber sources include fruit pectins, guar gums and psyllium.

Another approach used by one of the authors (RLR) is to use foods containing insoluble fiber sources at levels between 7 to 15% DM. Each of these strategies can be successful in managing selected patients with acute gastroenteritis and enteritis.

Digestibility

The term "highly digestible" is not defined in a regulatory sense. However, the term has generally been reserved for products with protein digestibility ≥87%, and fat and carbohydrate digestibility ≥90%. Fiber-enhanced foods will typically have somewhat lower protein and fat digestibilities but carbohydrate should be about the same. Digestibility targets for fiber-enhanced foods are at least 80% for protein and fat and 90% or above for carbohydrate. The average digestibility coefficients for popular commercial dog and cat foods are 78 to 81%, 77 to 85% and 69 to 79% for crude protein, crude fat and digestible (soluble) carbohydrate, respectively (Kendall et al, 1982; Kendall, 1981). Veterinary therapeutic foods formulated for patients with GI disease usually contain meat and carbohydrate sources that have been highly refined to increase digestibility. Meat ingredients in many therapeutic foods are usually composed of muscle and organ sources rather than meat and bone meals. Typical meat/animal source ingredients in commercial GI foods include egg, cottage cheese, chicken,

low-ash poultry by-product meal and ground beef.

Carbohydrates make up the largest non-water fraction (i.e., 60 to 80% DM) of commercial and homemade foods formulated for managing patients with GI diseases. In pet foods, carbohydrate digestibility is influenced by source and processing. Dogs digest most properly cooked starches very well including corn, rice, barley and wheat (Walker et al, 1994; Bissett et al, 1998). Other starches (e.g., potato and tapioca) are less digestible, especially when inadequately cooked (Wolter, 1993; Schunemann et al, 1994; Baker and Czarnecki-Maulden, 1991; Kienzle, 1993; Morris et al, 1977). Cats, despite their obligate carnivorous nature, also efficiently digest carbohydrates. However, the opinion of some clinicians is that cats with small bowel disorders are less tolerant of dietary carbohydrate than dogs with similar causes of malassimilation (Buddington et al, 1991; Kienzle, 1993; Sherding, 1989; Washabau et al, 1986). More recently, a feeding trial in cats with diarrhea demonstrated no difference in response to foods containing moderate carbohydrate levels (31.7% DM) or low levels (15% DM) (Laflamme and Long, 2004).

A link has been established between particle size and carbohydrate digestibility in moist foods (Bissett et al, 1997). These findings support chopping or grinding carbohydrate ingredients (e.g., rice, corn, etc.) before they are incorporated into moist foods. These findings are probably not applicable to extruded dry products because the extrusion process allows for a more complete cook than the canning process. Studies have demonstrated almost complete ileal carbohydrate digestibility in normal dogs consuming extruded grains (Harmon et al, 1999).

In general, dietary fat is more digestible than digestible carbohydrates and protein. Depending on the fat source, the ap-

parent digestibility of fat by dogs can vary from approximately 81 to 95%; fats with higher levels of unsaturated fatty acids are more digestible (NRC, 2006). The apparent digestibility of dietary fat by cats is between 85 to 99%. Fat digestibility also depends on saturation of constituent fatty acids and age of cats. Older cats and kittens have lower fat digestibility (NRC, 2006). Digestibility of protein, carbohydrates and fat in foods for patients with acute GI disease should be high because normal digestion and absorption of nutrients are often compromised. Moderate amounts of fiber decrease the DM digestibility of the overall food; however, digestibility of the non-fiber macronutrients is usually unaffected (Harmon et al, 1999).

Other Nutritional Factors

Glutamine

The amino acid, glutamine, is considered a conditionally essential nutrient for pets with severe GI disorders. As the preferred energy substrate for enterocytes, glutamine is necessary for maintaining gut mucosal integrity (Windmueller and Spaeth, 1974, 1978). Commercial and homemade pet foods containing meat ingredients provide glutamine. Unfortunately, an analytical method for determining glutamine levels in foods is not widely available, making selection of foods based on glutamine content impractical (Kuhn et al, 1996). Glutamine intake can be increased by orally administering a 2% solution of glutamine in water; 0.5 g of glutamine per kg body weight should be provided daily. Many pets will readily consume a glutamine solution, or these solutions can be administered by dose syringe or indwelling feeding tubes. Such glutamine dosing regimens have been used for treating canine patients with parvoviral enteritis. Alternatively, commercial liquid or moist homogenized enteral foods (Chapter 25) enhanced with glutamine may be offered.

Acid Load

Acidemia is common in pets with diarrhea because fluid secreted in the caudal small intestine and large intestine contains bicarbonate concentrations higher than those in plasma and sodium in excess of chloride ions. The acidosis is compounded in some patients by development of hypovolemia (i.e., severe dehydration). Severe acid-base disorders are best corrected with appropriate parenteral fluid therapy. Foods for patients with acute diarrhea accompanied by vomiting should also avoid excess dietary acid load and preferably contain buffering salts (e.g., potassium gluconate and calcium carbonate). Ideally, foods that normally produce a urinary pH greater than 6.8 should be selected.

FEEDING PLAN

The first objective in managing acute gastroenteritis or enteritis should be to correct dehydration and electrolyte, glucose and acid-base imbalances, if present. Colloidal solutions or plasma transfusions may be necessary for those patients with hypoalbuminemia (Buriko and Otto, 2007). The dietary goals are to provide a food that meets the patient's nutrient requirements and allows normalization of intestinal motility and function. Medical therapy may include antibiotics, antidiarrheals, antiemetics, nonsteroidal antiinflammatory agents (e.g., flunixin meglumine), anti-endotoxin sera, analgesics, interferon and anthelmintics.

Assess and Select the Food

Levels of the key nutritional factors should be evaluated in foods currently fed to patients with acute gastroenteritis or enteritis and compared with recommended levels. Information from this aspect of assessment is essential for making any changes to foods currently provided. Changing to a more appropriate food is indicated if key nutritional factors in the current food do not match recommended levels.

There are several plausible dietary strategies for managing small bowel diarrhea after a 24- to 36-hour fast and they may be attempted in any order. The traditional approach is to first feed a highly digestible, low-residue food with moderate levels of fat. Small amounts of soluble or mixed fiber sources may be included in such foods. Including low levels of fiber does not usually impair digestibility or increase fecal volume. This approach can be accomplished by feeding commercial veterinary therapeutic

**Insoluble fiber sources are best in fiber-enhanced foods (see text).

foods formulated for GI disease (**Tables 56-4** and **56-5** for dogs and **56-6** and **56-7** for cats) or properly prepared homemade foods (Chapter 10). Foods for puppies and kittens with GI disease should also meet requirements for growth.

As mentioned above, dietary fiber content may be increased to normalize intestinal motility, water balance and GI microflora. Fiber has several physiologic characteristics that are beneficial in managing small bowel diarrhea. Moderate amounts of fiber (7 to 15% DM) add indigestible bulk, which buffers toxins, holds excess water and, perhaps more important, provides intraluminal stimuli to reestablish the coordinated actions of hormones, neurons, smooth muscles, enzyme delivery, digestion and absorption. Fiber normalizes transit time through the small bowel, which means fiber slows a hypermotile state, but also improves a hypomotile state to reestablish normal peristaltic action. **Tables 56-5** (dogs) and **56-7** (cats) list selected fiber-enhanced commercial veterinary therapeutic foods.

For cases in which protracted small bowel disuse (i.e., three to five days) is expected, a third strategy may be used. This involves providing early enteral nutrition intermittently by the oral route or continuously by a nasoesophageal tube. This strategy of feeding through vomiting and diarrhea rather than providing a period of bowel rest has been studied prospectively in dogs with parvoviral enteritis (Will et al, 2005; Mohr et al, 2003). The combination of an orally administered highly digestible food (previously incubated with pancreatic enzymes) every eight hours plus total parenteral feeding was compared to total parenteral feeding alone (Will et al, 2005). Dogs in the combined therapy group had a lower mortality rate than those receiving total parenteral nutrition alone, but the intermittent oral administration of food was complicated by marked nausea and vomiting in 90% of patients. The effect of early enteral nutrition using a polymeric enteral food administered continuously by a nasoesophageal tube was evaluated in dogs with parvoviral enteritis as compared to dogs held NPO (nothing per os) (Mohr et al, 2003). Early enteral nutrition resulted in a more rapid clinical improvement including increased body weight, resolution of vomiting and diarrhea and a lower mortality rate. The precise mechanisms responsible for these benefits are unknown but may include reduced protein/calorie mal-

nutrition, more rapid intestinal villous recovery, enhanced integrity of epithelial tight junctions, normalization of intestinal microflora and enhanced gut immunity (Mohr et al, 2003; Will et al, 2005).

For dogs held NPO for acute gastroenteritis, reintroduction to oral feeding may be accomplished by offering small amounts of a highly digestible food formulated for GI disease. Alternatively, initially feeding small amounts of a monomeric liquid food containing maltodextrins and glutamine may ease the transition to other foods (Chapter 25). Feeding puppies recovering from parvoviral enteritis a monomeric, iso-osmotic liquid food containing maltodextrins (no lactose) plus glutamine reduces nausea and vomiting, and subsequently eases the transition to feeding other commercial veterinary therapeutic foods.[c]

Assess and Determine the Feeding Method

A thorough assessment should include verification of the feeding method currently used. Items to consider include feeding frequency, amount fed, how the food is offered, access to other food and who feeds the pet. All of this information should have been gathered when the history of the patient was obtained. If the animal has a normal body condition score (2.5/5 to 3.5/5), the amount of food previously fed (energy basis) was probably appropriate.

Withholding oral intake of food and water for 24 to 48 hours is the first step in the feeding method for dogs and cats with acute gastroenteritis or enteritis. After this period, patients should be offered small amounts of water or ice cubes every few hours. If water is well tolerated, small amounts of food can be offered several times (i.e., six to eight times) a day. If the pet can eat food without episodes of diarrhea or vomiting, the amount fed can be increased over three to four days until the patient is receiving its estimated DER in two to three meals per day. During this period, if the patient begins to vomit, food should be withdrawn and offered again after several hours. As discussed above, continuous feeding can be used to deliver early enteral nutrition or monomeric liquid foods can be offered.

Persistent vomiting in some cases of parvoviral enteritis may complicate refeeding; some puppies develop gastroparesis and may require prokinetic drugs to facilitate feeding. In such cases, intravenous infusion of metoclopramide (at a rate of 1.0 mg/kg body weight/day) is recommended. Alternatively, metoclopramide can be administered to well-hydrated patients subcutaneously or intramuscularly at a dose of 0.5 mg/kg body weight q8h. Some patients may require partial parenteral or total parenteral feeding (Chapter 26).

REASSESSMENT

The prognosis for recovery in most cases of acute gastroenteritis and enteritis is good. Body weight should be recorded daily until recovery is complete. Changes in body weight from day to day usually reflect changes in hydration status rather than loss or gain of body tissue. Further diagnostic testing is warranted if severe diarrhea or vomiting persists. Acute worsening of clinical signs especially when accompanied by abdominal pain in a young dog with gastroenteritis may be a result of intestinal intussusception (Patsikas et al, 2003; Rallis et al, 2000). In such cases, abdominal radiography and/or ultrasonography are indicated.

Dogs and cats presenting with multiple or recurrent episodes of small bowel diarrhea require further diagnostic workup and, most probably, a combination of dietary and medical therapies. Parasitic causes, however, should be ruled out or treated empirically before pursuing further diagnostics. The diagnostic approach to patients with chronic small bowel diarrhea is beyond the scope of this book; readers are referred to internal medicine and gastroenterology texts for more information.

CASE 56-1

Acute Diarrhea in a Young Cat

Deborah J. Davenport, DVM, MS, Dipl. ACVIM (Internal Medicine)
Hill's Pet Nutrition Center
Topeka, Kansas, USA

Patient Assessment

A six-month-old intact male domestic shorthair kitten was examined for acute onset of vomiting, watery diarrhea, anorexia and lethargy. The kitten had been found as a stray two months previously and vaccination status was unknown. The kitten lived in a barn and the owners were concerned that it had been poisoned. A dog also lived in the house and there were several horses on the property. None of these animals were ill.

Physical examination revealed depression and dehydration. Excessive amounts of fluid and gas were palpable in the intestinal tract. Abdominal palpation stimulated vomiting; the vomitus was clear fluid with flecks of blood. Body weight was 2.5 kg and the kitten appeared thin (body condition score [BCS] 2/5).

Evaluation included a fecal flotation (negative), complete blood count (leukopenia) and serum biochemistry profile (normal except for changes associated with dehydration). A tentative diagnosis of panleukopenia due to feline parvovirus infection was made.

Treatment included aggressive intravenous fluid therapy to correct dehydration and systemic antibiotics. The kitten improved clinically within a few days and the leukocyte count returned to normal. The kitten began drinking water and eating small amounts of a moist homogenized recovery formula (Prescription Diet a/d Canine/Feline[a]). There was no further vomiting but diarrhea continued. The feces were no longer watery but were semi-formed and voluminous.

Assess the Food and Feeding Method

The kitten was fed a commercial dry grocery brand food formulated for growth (Purina Kitten Chow[b]). The food and water were available free choice in the barn. The kitten had access to other animal feed (commercial dry dog food, grain mixture for the horses) but had never been seen eating these foods.

Questions

1. What is the likely cause for the persistent diarrhea?
2. What are the key nutritional factors for this patient?
3. Outline a feeding plan for this kitten.

Answers and Discussion

1. Feline parvovirus infection destroys intestinal crypt cells in the jejunum and ileum. This results in shortened, blunt intestinal villi and also malabsorption. Villi will normally regrow very quickly after viremia resolves and crypt cells are reestablished. However, some cats have a prolonged recovery period with chronic enteritis and diarrhea. This may occur because villi are slow to recover or because of concurrent parasite, viral or bacterial infection. The recovery food may also contain excessive amounts of fat (29% dry matter [DM] fat) for the recovering gastrointestinal (GI) tract.
2. Key nutritional factors for patients with infectious enteritis include water, electrolytes, fat, energy, fiber and digestibility.

   Water. Water is the most important nutrient for patients with acute vomiting or diarrhea because of the potential for life-threatening dehydration due to excessive fluid loss and inability of the patient to replace losses. Oral fluid therapy is reserved for cats with minor fluid deficits or to supply maintenance fluid requirements.

   Electrolytes. Hypokalemia, hypochloremia and either hypernatremia or hyponatremia are the electrolyte abnormalities most commonly associated with acute vomiting and diarrhea. Electrolyte disorders should be corrected initially with appropriate parenteral fluid therapy. Foods for cats with acute gastroenteritis should contain levels of sodium, chloride and potassium above the minimum allowances for normal kittens and adult cats.

   Fat/energy density. Dietary fat is a concentrated source of calories; higher fat foods allow smaller amounts of food to be ingested to meet the cat's daily energy requirement (DER). This is important for many patients with GI disease because limiting the amount of food entering the GI tract helps control clinical signs. Fat also helps improve the palatability of food, which is important for patients with nausea. For these reasons, foods for cats with acute gastroenteritis should contain moderate amounts of fat (i.e., 15 to 25% DM).

   Fiber. Dietary fiber is beneficial because it: 1) modifies gastric emptying, 2) normalizes intestinal motility, 3) buffers toxins in the GI lumen, 4) binds or holds excess water, 5) supports growth of normal GI microflora, 6) buffers gastric acid and 7) alters viscosity of GI luminal contents. Cats with gastroenteritis may benefit from small amounts (i.e., crude fiber ≤5% DM) of a mixed (i.e., soluble/insoluble) fiber type in conjunction with a highly digestible food.

Digestibility. Digestibility of foods for cats with acute gastroenteritis should be high (fat and digestible carbohydrate ≥90% and protein ≥87%) because normal digestion and absorption of nutrients is often impaired.

3. Small amounts of water and food should be gradually reintroduced to the kitten. The food should reflect the nutrient profile discussed above. Veterinary therapeutic foods designed for patients with GI disease have appropriate nutrient levels and usually have high digestibility. Levels of nutrients in these products are also usually appropriate for growing cats. The DER should reflect the needs of a growing cat (i.e., at least 2.5 x resting energy requirement or 360 kcal [1.51 MJ]).

Progress Notes

Multiple fecal flotations were negative for intestinal parasites. A fecal culture was negative for bacterial pathogens. Tests for feline leukemia and feline immunodeficiency virus infection were negative. A commercial moist veterinary therapeutic food (Prescription Diet i/d Feline[a]) was mixed with the recovery food (approximately 50:50) and gradually introduced to the kitten. This food is highly digestible, contains a mixed fiber source and is formulated to meet the nutritional needs of kittens. The kitten readily ate this mixture for two days in the hospital and was sent home with the dry formula of i/d Feline (three-fourths cup daily to be increased as the cat grew and gained weight). Semi-formed feces persisted for several weeks but then gradually returned to normal. The food was changed to a commercial dry product appropriate for adult cats when the cat was neutered at nine months of age.

Chapter 57

Inflammatory Bowel Disease

Deborah J. Davenport
Albert E. Jergens
Rebecca L. Remillard

"With good digestion all can be turned to health."
George Herbert

CLINICAL IMPORTANCE

The term inflammatory bowel disease (IBD) refers to a group of chronic, idiopathic gastrointestinal (GI) disorders characterized by histopathologic lesions of mucosal inflammation. Each IBD variant is named by the predominant cellular infiltrate within the lamina propria. Currently, IBD is considered the most common cause of chronic diarrhea and vomiting in dogs and cats (Guilford, 1996; Jergens, 1999). The generic term, IBD, encompasses lymphoplasmacytic enteritis, lymphocytic gastroenterocolitis, eosinophilic gastroenterocolitis, segmental granulomatous enterocolitis (regional enteritis), suppurative enterocolitis and histiocytic colitis. The lymphoplasmacytic form is probably the most common type of IBD (Leib, 1997; Craven et al, 2004; Hall, 2005, Hall and German, 2005).

The severity of IBD varies from relatively mild clinical signs to life-threatening protein-losing enteropathies. In particular, the Basenji and Ludenhund breeds may present with a very severe variant that has been termed immunoproliferative small intestinal disease (Breitschwerdt, 1992; Flesja and Yri, 1977; Williams, 1997).

Inflammatory infiltrates may involve the stomach, small bowel and colon. In cats, the stomach and small bowel are affected most often. In dogs, IBD is common in both the small and large intestines. In many cases, multiple segments of the bowel are involved and clinical signs may be mixed, reflecting the broad distribution of mucosal lesions.

PATIENT ASSESSMENT

History and Physical Examination

The most common clinical signs in dogs and cats with IBD are chronic vomiting, diarrhea and weight loss. The predominant GI sign varies with the portion or portions of bowel affected. Vomiting tends to be the predominant clinical sign when the stomach and proximal duodenum are affected. Loose, fluid or steatorrheic stools are most common when the small intestine is involved. Diarrhea marked by tenesmus, mucus and small scanty stools is noted with colonic lesions. Clinical signs may be intermittent or persistent. Clinical signs tend to increase in frequency and intensity as IBD progresses temporally. The presence of systemic signs is also variable. Some animals present with a history of depression, malaise and inappetence. Others are alert and active at the time they are examined.

The frequency and character of the vomitus and stools are important features. At times, vomiting will be temporally related to food intake and the vomitus will contain food particles. In other cases, animals may vomit only fluid or froth. Owners should be questioned closely about the appearance of the vomited material. Dark black or coffee grounds material may indicate gastric ulceration or erosions. The diarrhea may be small or large bowel in origin. The color of the stools should be assessed to determine the presence of GI bleeding.

Physical examination findings in dogs and cats with IBD are variable. Many patients have no abnormalities. Others present

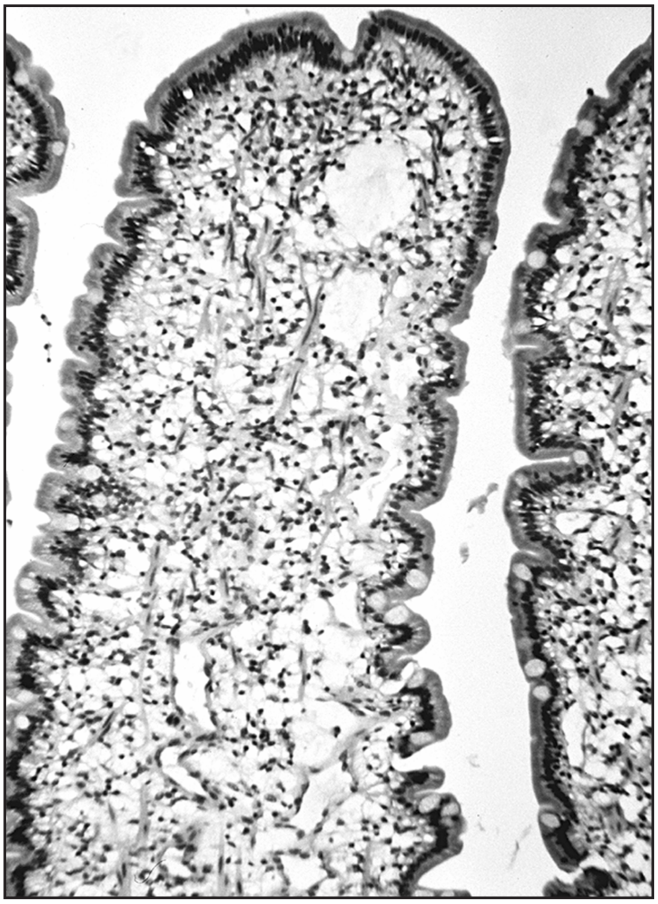

Figure 57-1. Photomicrograph of an intestinal villus showing typical monocellular infiltrates recognized in lymphoplasmacytic enteritis (original magnification 400X).

only with evidence of weight loss and poor body condition. Weight loss may be severe in longstanding cases. Mild peripheral lymphadenopathy may be detected in rare cases of IBD. This finding is most often recognized in cats with eosinophilic gastroenteritis and hypereosinophilic syndrome, which is characterized by multisystemic eosinophilic infiltrates (Moore, 1983).

Occasionally, thickened loops of bowel may be detected by abdominal palpation. This finding is more easily detected in cats. A segmental thickening of bowel may be suggestive of eosinophilic gastroenteritis in cats or granulomatous enteritis in dogs. This finding should also be distinguished from intestinal intussusceptions, foreign bodies, histoplasmosis and neoplastic lesions. Occasionally, pets with IBD present with abdominal pain, which suggests gastroduodenal ulceration (Jergens et al, 1992; Jergens, 1992).

Evidence of hemorrhage or hypoproteinemia may be noted in very severe cases. A vitamin K-dependent coagulopathy has been reported to occur in animals with marked steatorrhea but is rare. At times, IBD may cause protein-losing enteropathy. When severe, hypoalbuminemia and external manifestations of hypoproteinemia (i.e., pitting edema, ascites) may be present. Surprisingly, some animals with protein-losing enteropathy may present with only mild or no diarrhea.

Laboratory and Other Clinical Information

Laboratory findings in patients with IBD are often nonspecific. Hematologic findings are variable and may include blood loss anemia, anemia of chronic disease and/or eosinophilia. In cats with eosinophilic gastroenteritis and hypereosinophilic syndrome, eosinophil counts may exceed 100,000/µl (Moore, 1983). Patients with chronic diarrhea should be assessed with serum biochemistry profiles and urinalyses to determine the systemic effects of the GI disorder and to rule out concurrent disease. Electrolyte abnormalities, including hypokalemia, may be identified. Hypoproteinemia and hypoalbuminemia may be recognized in severe cases with protein-losing enteropathy. Prerenal azotemia may be present in dehydrated patients. In cats, IBD may be associated with pancreatitis and hepatitis, a syndrome that has been termed triaditis (Weiss et al, 1996; Steiner, 2007). In such cases, neutrophilia, increased hepatic enzyme activities, hyperbilirubinemia and increased serum pancreatic lipase immunoreactivity may be noted. IBD is often associated with a protein-losing nephropathy in soft-coated wheaten terriers. Varying degrees of azotemia and proteinuria are also common in these dogs (Vaden et al, 1998; Littman and Giger, 1990).

Fecal examinations are very important in the evaluation of patients with chronic diarrhea. Multiple fecal examinations using concentration techniques are necessary to rule out parasitism. Radiographic findings in IBD are usually nonspecific and nondiagnostic. Occasionally, thickened bowel loops with fluid and/or ingesta are observed on survey abdominal films. In addition, ultrasonographic examination may reveal enlarged mesenteric lymph nodes, focal thickening of the gut and poor definition of the intestinal wall (Baez et al, 1999).

Endoscopic abnormalities in IBD include mucosal granularity, hyperemia, friability and inability to visualize colonic submucosal blood vessels (Jergens et al, 1992). Multiple biopsy specimens should be collected from several bowel segments because histologic changes may be present despite a normal appearance (Jergens et al, 1992; Roth et al, 1990; Marks and LaFlamme, 1998).

The definitive diagnosis of IBD is based on histopathologic examination of biopsy specimens (**Figure 57-1**) collected by endoscopic or surgical techniques (Wilcock, 1992). Expected findings include lymphocytic and plasmacytic infiltrates within the lamina propria as well as architectural abnormalities such as crypt distortion and villous blunting. Histologic grading systems have been proposed to allow objective assessment of intestinal biopsy specimens and to reduce inter-observer variation (Jergens et al, 1992; Roth et al, 1990; Yamasaki et al, 1996; Willard et al, 2002). Despite the use of formal classification schemes, interpretation of histologic changes can be difficult when the lesions are mild or suggest lymphosarcoma (Roth et al, 1990; Wilcock, 1992; Willard et al, 2002; Evans et al, 2006). The latter finding is a serious concern in cases of lymphoplasmacytic enteritis and lymphocytic enteritis.

Quantification of mucosal inflammatory markers found in colonic lavage fluid (e.g., IgG, nitrite) has been suggested for evaluation of dogs with suspected IBD (Gunawardana et al,

1997). The use of a clinical scoring index for disease activity and measurement of C-reactive protein can provide value for assessing disease burden (Jergens et al, 2003; Garcia-Sancho et al, 2007).

Risk Factors

There does not appear to be an age or gender predisposition for IBD. The condition usually arises in adult dogs and cats, but has been diagnosed in puppies and kittens (i.e., less than six months of age). In people, there is a well-recognized familial tendency toward IBD (Fiocchi, 1998). A genetic influence has also been recognized in some dog breeds: 1) the German shepherd dog, Chinese Shar-Pei and soft-coated wheaten terrier for lymphoplasmacytic enteritis, 2) the German shepherd dog and Irish setter for eosinophilic gastroenteritis, 3) the boxer and French bulldog for ulcerative colitis and 4) the Basenji and Ludenhund for immunoproliferative enteropathy (Table 55-3).

The environment may also play an important role in IBD. Animals maintained in overcrowded, contaminated quarters are at risk for development of parasitic infections, viral and bacterial enteritis and small intestinal bacterial overgrowth, all of which are speculated to play a role in the pathogenesis of IBD. The role of parasites in the pathogenesis of IBD is poorly understood; however, occult parasitism has been suggested as a cause for these disorders. For example, in German shepherd dogs, visceral larval migrans has been linked to eosinophilic gastroenteritis (Hayden and van Kruiningen, 1973). In cats, feline infectious peritonitis has been associated with granulomatous and suppurative enterocolitis (Leib et al, 1986; Tebeau, 2007). In addition, small intestinal bacterial overgrowth has been reported in association with lymphoplasmacytic infiltrates and enteritis (Rutgers, 1996). Cats with IBD have been found to have higher fecal concentrations of *Desulfovibrio* spp. and lower numbers of *Bifidobacterium* spp. as compared to healthy cats (Inness et al, 2007).

Etiopathogenesis

Despite intensive study by veterinary and medical researchers, the pathophysiology of inflammatory bowel disorders is not fully understood (Fiocchi, 1998; Hanauer, 1996; German et al, 2003; Hall and German, 2005). The disorder is undoubtedly immune-mediated, yet the pathogenesis of the various forms of IBD is poorly defined. Increased populations of plasma cells producing IgA and IgG as well as T lymphocytes have been recognized in dogs with IBD as compared to normal dogs (Jergens, 1996 et al, 1999 et al; German et al, 2001). In addition, altered cytokine expression has been demonstrated in dogs with small and large intestinal IBD (German et al, 2001). Abnormal cytokine mRNA expression has been identified within intestinal biopsy specimens from cats with IBD (Nguyen Van et al, 2006).

The fundamental pathway for the development of IBD involves hypersensitivity. However, the underlying cause for hypersensitivity reactions is unknown. Two related theories have been proposed. The first speculates that IBD patients develop a defect in the intestinal mucosal barrier. This loss of mucosal integrity results in increased gut permeability and hypersensitivity responses to antigens that are normally tolerated (**Figure 57-2**) (Guilford, 1996). Alternatively, IBD may result from aberrant immunologic responses to luminal antigens. It has been hypothesized that defects in gut-associated lymphatic tissue (GALT) suppressor function may predispose patients to development of hypersensitivity to normally tolerated luminal antigens (**Figures 57-3** and 31-2 through 31-4) (Guilford, 1996). Parasites, pathogenic organisms, normal gut flora and dietary antigens may all serve as the trigger for these immunologic reactions. Both potential pathways culminate in release of inflammatory mediators. These substances may then further damage the intestinal mucosal surface and set up a vicious cycle of inflammation and loss of barrier function.

It is likely that the pathogenetic pathway is influenced by environmental (i.e., exposure to dietary antigens or GI parasites) and genetic factors that modulate disease expression (German et al, 2003). The predisposition for IBD in certain breeds (e.g., Basenjis, soft-coated wheaten terriers) suggests a likely role for genetic influences.

Mucosal inflammatory infiltrates and soluble factors are responsible for the clinical manifestations of IBD. Mucosal

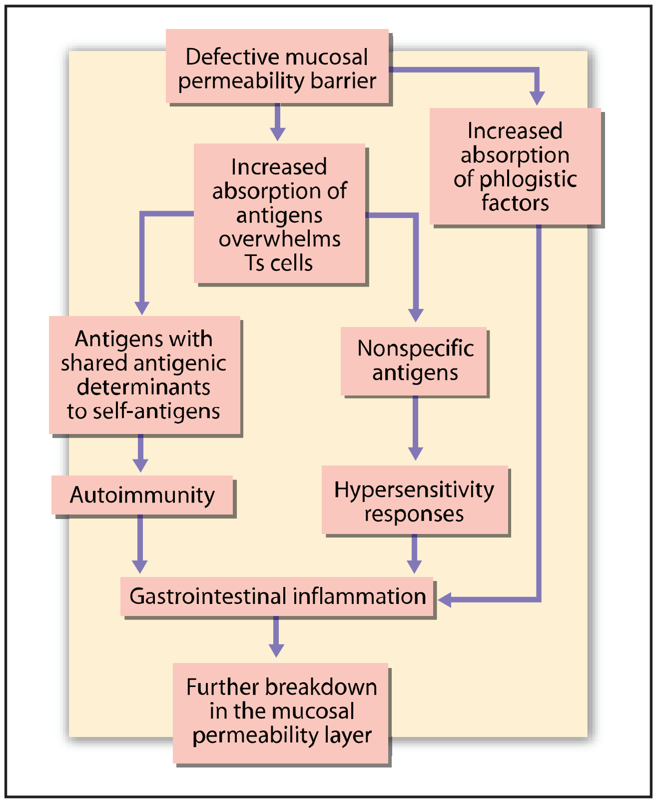

Figure 57-2. A proposed pathway for a defect in the mucosal permeability barrier as a cause of inflammatory bowel disease. (Adapted from Guilford WG. Idiopathic inflammatory bowel diseases. In: Guilford WG, Center SA, Strombeck DR, et al, eds. Strombeck's Small Animal Gastroenterology, 3rd ed. Philadelphia, PA: WB Saunders Co, 1996; 457.)

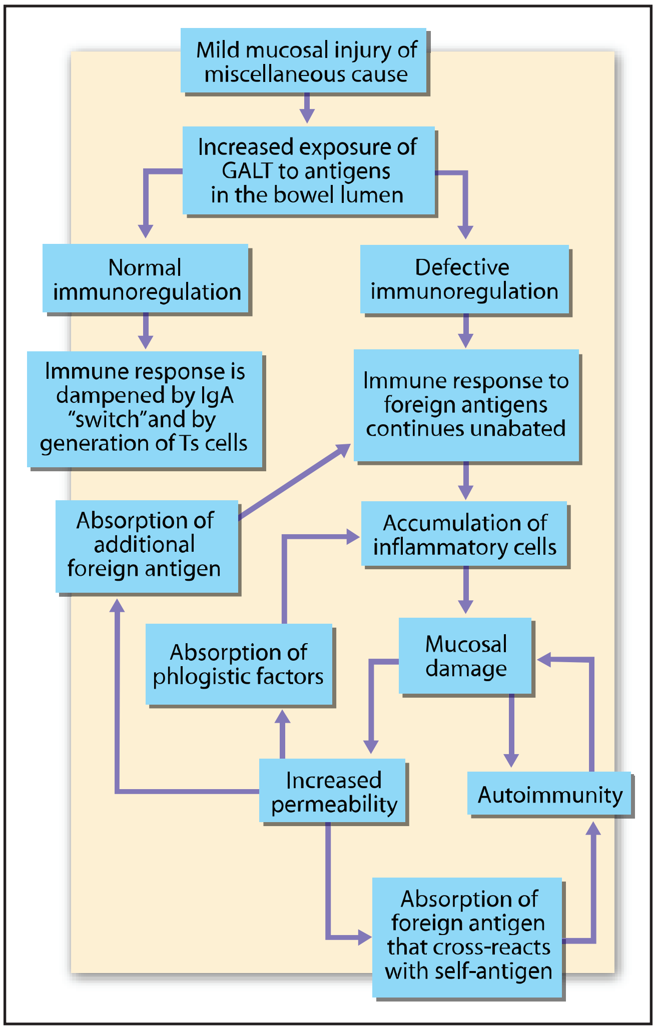

Figure 57-3. A proposed pathway for a defect in the suppressor function of the gut-associated lymphoid tissue (GALT) as a cause of inflammatory bowel disease. (Adapted from Guilford WG. Idiopathic inflammatory bowel diseases. In: Guilford WG, Center SA, Strombeck DR, et al, eds. Strombeck's Small Animal Gastroenterology, 3rd ed. Philadelphia, PA: WB Saunders Co, 1996; 453.)

inflammation disrupts normal absorptive processes resulting in malabsorption and osmotic diarrhea. Altered gut permeability can result in leakage of fluid, protein and blood into the gut lumen. Malabsorbed fats, carbohydrates and bile acids result in secretory diarrhea. Inflammatory mediators may also directly trigger intestinal secretion and mucus production by goblet cells. Mucosal inflammatory infiltrates may alter intestinal and colonic motility patterns, a mechanism attributed to the influence of prostaglandins and leukotrienes on smooth muscle. Inflammation of the proximal bowel (stomach and small bowel) may stimulate visceral afferent receptors that trigger vomiting. Delayed gastric emptying associated with gastroparesis or ileus may exacerbate vomiting.

Key Nutritional Factors

Key nutritional factors for patients with IBD are listed in **Table 57-1** and discussed in more detail below.

Water

Dehydration is a frequent problem in patients with IBD. Reduced water consumption is often aggravated by fluid losses from vomiting and/or diarrhea. Whenever possible, fluid balance should be maintained via oral consumption of fluids. However, dehydrated patients and those with persistent vomiting often need parenteral fluid administration.

Electrolytes

Serum electrolyte concentrations should be assessed regularly to allow early detection of abnormalities as vomiting and diarrhea persist. Hypokalemia is particularly common in patients with IBD. Thus, foods containing 0.8 to 1.1% dry matter (DM) potassium are preferred for dogs and cats with IBD. Initially, potassium levels should be restored with intravenous potassium supplementation. In addition, affected patients often lose large amounts of sodium through fluid feces; however, sodium deficits may be masked by dehydration.

Energy Density and Fat

Energy dense foods are preferred for managing patients with chronic enteropathies. Such foods allow the provision of smaller volumes of food, which minimizes GI distention and secretions. Unfortunately, energy dense foods are also high in fats. High-fat foods may contribute to osmotic diarrhea and GI protein losses, which complicate IBD. Thus, it is often advantageous to initially provide a food with moderate energy density (4.0 to 4.5 kcal/g [16.7 to 18.8 kJ/g] DM) for dogs and cats and fat levels of 12 to 15% for dogs and 15 to 25% for cats DM). Foods with higher fat levels can be offered if the patient tolerates them.

Fiber-enhanced foods typically have lower energy density levels than highly digestible foods because fiber-enhanced foods are usually lower in fat. The DM energy density of fiber-enhanced foods for IBD should be at least 3.2 kcal/g (13.4 kJ/g) for dog foods and at least 3.4 kcal/g (14.2 kJ/g) for cat foods. Fat content for fiber-enhanced foods for dogs and cats with IBD should be 8 to 12% and 9 to 18% DM, respectively.

There appears to be a difference in how dogs and cats are able to tolerate dietary fat in the face of GI disease. Normal cats can tolerate much higher concentrations of dietary fat than dogs (Lewis et al, 1979). Anecdotal information suggests that foods with increased fat content may actually benefit cats with small bowel disease (Guilford, 1996a). Recently, low-fat and high-fat foods were fed to cats with naturally occurring chronic diarrhea in a randomized six-week trial. Fecal scores in more than 65% of cats consuming both high- and low-fat foods improved over the course of the feeding period (Laflamme et al, 2007). The underlying cause of diarrhea in the cats was not investigated. More controlled evaluations are needed to confirm these observations.

Protein

Protein malnutrition may occur in dogs and cats with IBD due to fecal losses. High biologic value, highly digestible (≥87%) protein sources should be used. Protein should be provided at levels sufficient for the appropriate lifestage for patients not experienc-

Table 57-1. Key nutritional factors for dogs and cats with inflammatory bowel disease.*

Factors	Recommended levels
Potassium	0.8 to 1.1%
Energy density	4.0 to 4.5 kcal/g (16.7 to 18.8 kJ/g) for highly digestible foods for dogs and cats ≥3.2 kcal/g (≥13.4 kJ/g) for fiber-enhanced foods for dogs and ≥3.4 kcal/g (≥14.2 kJ/g) for cats
Fat	12 to 15% for dogs and 15 to 25% for cats for highly digestible foods For fiber-enhanced foods: 8 to 12% for dogs 9 to 18% for cats
Protein	≥25% for dogs ≥ 35% for cats If using a limited protein (elimination food) approach, restrict protein to one or two sources and use protein sources to which the patient has not been exposed previously or feed a protein hydrolysate (Chapter 31); also use lower protein levels (16 to 26% for dogs and 30 to 45% for cats)
Crude fiber	≤5% for highly digestible foods (mixed fiber) for dogs and cats 7 to 15% for increased-fiber foods (insoluble fibers are best) for dogs and cats
Digestibility	≥87% for protein and ≥90% for fat and digestible carbohydrate for highly digestible foods ≥80% for protein and fat and ≥90% for carbohydrate for fiber-enhanced foods

*Nutrients expressed on a dry matter basis.

ing excessive GI protein loss (at least 25% for adult dogs and 35% for adult cats [DM]). Suggested protein levels for patients being managed with "hypoallergenic foods" can be lower.

Because dietary antigens are suspected to play a role in the pathogenesis of IBD, "hypoallergenic" novel protein elimination foods or foods containing a protein hydrolysate are often recommended (Nelson et al, 1984; Nelson and Stookey, 1988; Davenport et al, 1987; Guilford, 1996a; Guilford et al, 2001). In some cases, elimination foods may be used successfully without pharmacologic intervention (Hall and German, 2005; Allenspach et al, 2006). Ideal elimination foods should: 1) avoid protein excess (16 to 26% for dogs and 30 to 45% for cats), 2) have high protein digestibility (≥87%) and 3) contain a limited number of novel protein sources to which the patient has never been exposed or contain a protein hydrolysate. Chapter 31 discusses elimination foods in detail. The suspected pathogenesis of IBD involves an increase in gut permeability; therefore, the use of "sacrificial" dietary antigens in the treatment of IBD has been also suggested, but proof of the concept using controlled dietary trials is lacking (Guilford, 1996) (**Box 57-1**).

The evidence regarding the efficacy of elimination foods in people with IBD is conflicting (Husain and Korzenik, 1998). Although specific foods provoking symptoms may be identified in as many as 80% of human patients with Crohn's disease, double-blinded rechallenges suggest that food hypersensitivity may be identified consistently in fewer than 10% (Husain and Korzenik, 1998). Similarly, positive reactions to food antigens applied topically to the gastric mucosa (i.e., gastroscopic food sensitivity test) have been recognized in canine patients with IBD (Vaden, 2000; Vaden et al, 1998a; Guilford et al, 1994; Elwood et al, 1994). Gastroscopic food sensitivity test findings, however, often do not correlate with the results of provocative food challenges or clinical responses (Guilford et al, 1994).[a] A protein hydrolysate-based elimination food has been used successfully in refractory canine IBD cases (Marks and LaFlamme, 1998; Hannah et al, 2000).

Box 57-1. Sacrificial Proteins in Inflammatory Bowel Disease.

Oral tolerance is difficult to maintain in the inflammatory milieu; therefore, animals with inflammatory bowel disease (IBD) are at risk for becoming rapidly sensitive to undigested food proteins entering the lamina propria. This theoretical concern has led to the concept of feeding a "sacrificial protein" source. The first novel protein fed to patients in the early phase of therapy is referred to as a sacrificial protein because it is being offered when the bowel is inflamed and the mucosal barrier porous. The dietary protein source is then changed after the first six weeks of therapy. For animals receiving concurrent prednisone therapy, this diet change is made just before the prednisone dose is decreased from the immunosuppressive to the antiinflammatory range, by which time it is hoped that the mucosal inflammation has been controlled and the mucosal barrier has markedly recovered. As a result, the second dietary protein source is less likely to result in acquired food hypersensitivity and delayed recovery from IBD. The potential benefit of this recommendation is currently under investigation. This type of nutritional management is likely to be of most value in those patients in which IBD has resulted from a transient injury to the gut-associated lymphoid tissue or the mucosal barrier (e.g., from a viral infection) rather than those in which IBD is due to an inherent (i.e., permanent) defect in these structures.

Fiber

It has been recommended that people with IBD eat small quantities of soluble or mixed fiber sources (Fiocchi, 1998). In fact, short-chain fatty acid and butyrate enemas induce clinical improvement in people with ulcerative colitis (Harig et al, 1989; Breuer et al, 1991). A number of substrates including beet pulp, soy fiber, inulin and fructooligosaccharides have been demonstrated by in vitro fermentation to produce volatile fatty acids that may be beneficial in IBD that involves the distal small intestine and colon (Sunvold et al, 1995, 1995a, 1995b; Jamikorn et al, 1999). In addition, these fermentable fibers may serve as prebiotics and foster the growth of beneficial bacterial organisms such as *Bifidobacterium* and *Lactobacillus* at the expense of more pathogenic microbes such as *Desulfovibrio* and *Clostridium* spp. (Chapter 5). These fibers are usually incorporated at rates of 1 to 5% DM in commercial products.

A second approach is to increase dietary fiber content to normalize intestinal motility, water balance and microflora. Fiber has several physiologic characteristics that are beneficial in managing small bowel diarrhea. Moderate levels (7 to 15% DM) of insoluble fiber (e.g., cellulose) add nondigestible bulk, which buffers toxins, holds excess water and, perhaps more important, provides intraluminal stimuli to reestablish the coordinated actions of hormones, neurons, smooth muscle, enzyme delivery, digestion and absorption. Fiber can help normalize transit time through the small bowel, which means slowing a hypermotile state, but also improving a hypomotile state to reestablish normal peristaltic action. However, this level of fiber reduces the energy density and digestibility of a food.

Digestibility

Feeding highly digestible (fat and digestible [soluble] carbohydrate at least 90% and protein at least 87%) foods provides several advantages in the management of dogs and cats with IBD. Nutrients from low-residue foods are more completely absorbed in the proximal gut. Furthermore, these highly digestible foods are associated with: 1) reduced osmotic diarrhea due to fat and carbohydrate malabsorption, 2) reduced production of intestinal gas due to carbohydrate malabsorption and 3) decreased antigen loads because smaller amounts of protein are absorbed intact. Ideal foods for IBD patients are free of lactose to avoid the complication of lactose intolerance. If fiber-enhanced foods are used, the digestibility will be reduced. Digestibility of protein, fat and carbohydrate of fiber-enhanced foods should be at least 80, 80 and 90%, respectively.

The use of monomeric liquid foods and total parenteral nutrition to provide a period of "bowel rest" for people and animals with IBD is controversial (Griffiths et al, 1995; Ling and Griffiths, 2000). Bowel rest has been recommended as a means of reducing or eliminating antigenic stimuli while minimizing GI secretions. The greatest benefit appears to be for human patients with Crohn's disease (Lewis and Fisher, 1994; Jeejeebhoy, 1995). Placebo controlled trials of monomeric foods have not been performed in people but response rates in clinical practice have been convincing (Ling and Griffiths, 2000). Monomeric feedings provide energy and nitrogen in a readily available, nonantigenic form. Monomeric liquid foods are also supplemented with glutamine. In pediatric human patients, a recent meta-analysis demonstrated that enteral nutritional support was as efficacious as corticosteroid therapy in acute Crohn's disease (Henschkel et al, 2000). Parenteral nutrition does not appear to provide any advantage over monomeric foods and is not recommended except in those patients unable to tolerate enteral feeding (Hanauer, 1996). Complete bowel rest may theoretically worsen GI mucosal lesions by depriving mucosal epithelial cells of nutrients such as glutamine and short-chain fatty acids (Husain and Korzenik, 1998). Veterinary experience with parenteral feeding and monomeric and hydrolysate-based foods in the management of IBD is limited (Marks and LaFlamme, 1998; Guilford, 1996a; Hannah et al, 2000). Most often, these therapies have been used in refractory cases in which other therapeutic modalities have failed.

Other Nutritional Factors

Vitamins

Adequate intake of water-soluble and fat-soluble vitamins is critical for patients with IBD. In many cases, the limited stores of water-soluble vitamins have been depleted by diarrheic losses and the large fluid flux through the animal. Thiamin deficiency, in particular, occurs commonly and can profoundly affect appetite. Cobalamin (vitamin B_{12}) deficiency has been recognized in dogs and cats with chronic enteropathies and can result in severe metabolic abnormalities including increased serum methylmalonic acid and disturbances in serum amino acid levels (Ruaux et al, 2001). Dogs and cats appear to more susceptible to cobalamin depletion than people because they have a more rapid cobalamin turnover as a consequence of biliary excretion of cobalamin (Simpson et al, 2001; Simpson, 2003). In addition, dogs and cats lack cobalamin binding protein TC1, which facilitates long-term cobalamin storage in people (Simpson, 2003). Hypocobalaminemia typically occurs when specific cobalamin receptors in the ileum are damaged as a consequence of inflammatory disease (Suchodolski and Steiner, 2003). Deficiency is accelerated by reduced cobalamin consumption and ongoing GI losses. A recent case control study demonstrated that parenteral cobalamin supplementation in cats with undetectable serum cobalamin values (<100 ng/l) normalized serum cobalamin and methylmalonic acid values and improved clinical indices such as body weight, vomiting and diarrhea (Ruaux et al, 2005). For that reason, serum cobalamin should be assessed in patients with chronic small intestinal disease and those with hypocobalaminemia (<300 ng/l) should receive weekly subcutaneous cobalamin therapy (250 μg in cats and 500 μg in dogs) for four to six weeks or until serum levels return to the normal range (Ruaux et al, 2005). Once or twice monthly therapy may be required for longer term maintenance. Disease of the proximal small intestine can inhibit absorption of dietary folate, which is present in foods in the polyglutamate form. Folate absorption requires the jejunal brush border enzyme, folate deconjugase, and specific folate monoglutamate carriers

(Suchodolski and Steiner, 2003). Chronic inflammatory disease of the small bowel can result in low serum folate values due to jejunal mucosal damage, reduced folate absorption and depletion of folate stores.

Loss of fat-soluble vitamins can be significant in patients with steatorrhea (e.g., vitamin K-deficient coagulopathies may occur in patients with IBD). Initially, parenteral administration of fat-soluble vitamins may be necessary. Administering 1 ml of a vitamin A, D and E solution,[b] divided into two intramuscular sites, is simple and cost effective. This should supply fat-soluble vitamins for approximately three months. Vitamin K_1 at a dosage of 0.5 to 1 mg/kg subcutaneously is recommended if a vitamin K-responsive coagulopathy is suspected. Dietary intake of vitamins is often sufficient when the disease responds to treatment and fat absorption is reestablished.

Zinc

Zinc deficiency is well recognized in people as a complication of IBD (Hendricks and Walker, 1988). The small intestine is the primary site of zinc homeostasis and there are several potential mechanisms for zinc deficiency in IBD (**Table 57-2**). In Crohn's disease, oral zinc supplementation improves clinical signs and normalizes intestinal permeability (Sturniolo et al, 2001). Zinc may provide benefits by enhancing brush border enzyme activity, water and electrolyte absorption and regeneration of the gut epithelial surface. Supplemental dietary zinc intake should be considered if dogs and cats with IBD have poor coat quality or dermatitis (Chapters 6 and 32).

Table 57-2. Potential causes of zinc deficiency in patients with inflammatory bowel disease.*

Decreased absorption
Intestinal inflammation
Supplemental iron and/or copper
Surgical resection of distal duodenum
Inadequate dietary intake
Anorexia
High fiber or phytate intake
Parenteral nutrition
Increased losses
Chronic blood loss
Increased metabolism
Increased requirements
Growth
Lactation
Pregnancy
Wound healing

Magnesium

Hypomagnesemia has been reported to occur in 30% of dogs and cats hospitalized for GI disorders (Martin, 1994; Toll et al, 2002). Anorexia and malabsorption complicated by the use of magnesium-free fluids are likely causes of low serum magnesium. Magnesium repletion can be accomplished via the use of intravenous fluids.

Omega-3 Fatty Acids

Omega-3 (n-3) fatty acids derived from fish oil or other sources have been hypothesized to have a beneficial effect in controlling mucosal inflammation in IBD. The rationale for the use of omega-3 fatty acids in inflammatory GI disorders first arose from the epidemiologic observation that Japanese and Eskimo populations consuming diets rich in fish sources of these fatty acids have a low prevalence of IBD (Ling and Griffiths, 2000). Some clinical evidence suggests that dietary supplementation with these fatty acids can modulate the generation and biologic activity of inflammatory mediators. More recently, it has been suggested that omega-3 fatty acids may act as competitive agonists of bacterial Toll-like receptor 4 (lipopolysaccharide receptor complex). Because aberrant immune responses to enteric flora have been speculated to play a role in the pathogenesis of IBD, this inhibitory effect may provide another rationale for the use of omega-3 fatty acids in IBD (Lee et al, 2003).

Foods supplemented with fish oil have been used in a limited number of human trials with mixed results (Belluzi et al, 1996, 2000; Mate et al, 1991; Lorenz-Meyer et al, 1996; Lorenz et al, 1989; Stenson et al, 1992). To date, there are no published therapeutic trials investigating the efficacy of omega-3 fatty acid supplementation in dogs or cats with IBD. Although use of omega-3 fatty acids warrants further consideration in veterinary gastroenterology, there is no well-established effective dose for dogs and cats. A reasonable starting dose estimated from human and animal trials is approximately 175 mg (range 50 to 300 mg) omega-3 fatty acids/kg body weight/day.

FEEDING PLAN

The justification for nutritional management of IBD is twofold. First, dietary factors may contribute to the initiation or perpetuation of the disease. Second, malnutrition is a common sequela to IBD due to anorexia, malabsorption and increased nutrient losses. Thus, dietary intervention should be aimed at controlling clinical signs while providing adequate nutrients to meet requirements and compensate for ongoing losses through the GI tract. Some dogs and cats with IBD may only require dietary manipulation (Hall and German, 2005; Allenspach et al, 2006). In other cases, dietary therapy is better used in concert with pharmacologic agents. Antibiotics (e.g., tylosin, tetracycline, enrofloxacin, metronidazole), anthelmintics (e.g., fenbendazole) and immunosuppressive agents (e.g., corticosteroids, budesonide, cyclosporine, azathioprine, cyclophosphamide) are often used for managing IBD.

Assess and Select the Food

Selection should focus on foods that reduce intestinal irritation/inflammation and normalize intestinal motility. Three types of foods may be useful in managing diarrhea associated with IBD: 1) highly digestible, low-residue foods formulated

for GI disease, 2) fiber-enhanced foods and 3) elimination foods. Unfortunately, no physical examination finding, laboratory test result or historical fact will dictate which method will be successful in any one patient. Dietary trials are often needed to find which food type works best.

The most commonly used strategy is to feed a highly digestible, low-residue GI food. There are several commercial veterinary therapeutic foods marketed for treatment of GI diseases. **Tables 57-3** and **57-5** list selected highly digestible foods for dogs and cats, respectively, and compare them to the recommended levels of key nutritional factors for IBD. When possible, choose the food that most closely matches the recommendations for key nutritional factors. Recipes for highly digestible homemade foods are also available (Table 10-6). Besides being the most common initial approach for dietary management of IBD, this strategy has also been effective in cats with chronic nonspecific diarrhea (Laflamme and Long, 2004).

A second approach is to increase dietary fiber content to normalize intestinal motility, water balance and microflora. **Tables 57-4** and **57-6** list selected fiber-enhanced commercial veterinary therapeutic foods for dogs and cats with IBD, respectively, and compare them to the recommended key nutritional factors for this approach. These foods typically have a lower energy density and IBD patients may have difficulty maintaining a normal body weight and body condition. Also, foods with 10 to 15% DM fiber usually have lower digestibility. The third dietary option in IBD cases is the use of an elimination food with a limited number of highly digestible, novel protein sources or one containing a protein hydrolysate. Commercial veterinary therapeutic foods (Tables 31-5 and 31-6) or homemade foods that contain novel protein sources often combine lamb, rabbit, venison, duck, fish or game meats with a highly digestible or novel carbohydrate source. All other possible dietary sources of protein and carbohydrate should be eliminated including treats, snacks, table foods, vitamin-mineral supplements and chewable/flavored medications. Clinical signs should abate within the first three weeks of strict dietary management (e.g., feeding only the novel ingredient or protein hydrolysate food). After signs abate, owners may add individual specific ingredients previously fed in an effort to identify the allergen. Clinical GI signs may recur within 12 hours after the offending ingredient is fed. In many cases, owners elect to continue feeding the elimination food if clinical signs abate.

Assess and Determine the Feeding Method

If the patient has a normal body condition score (BCS [2.5/5 to 3.5/5]), the amount of food previously fed (energy basis) was

probably appropriate. If the patient has a low BCS (1/5 or 2/5), the amount of food previously fed may have been inappropriate or significant malassimilation may be occurring due to IBD.

Initially, IBD patients should be fed multiple small meals per day as indicated by their acceptance and tolerance for the food. Meal size can be increased and meal frequency can be reduced as tolerated by the patient after the clinical signs have been successfully managed for several weeks.

REASSESSMENT

Regaining or maintaining optimal body weight and condition, normal levels of activity and alertness and absence of clinical signs are measures of successful dietary and medical management. Serial measurement of the clinical IBD activity index (CIBDAI) offers a more rigorous method of assessing response

to treatment (Jergens et al, 2003; Garcia-Sancho et al, 2007). Endoscopically obvious gastric and intestinal lesions often respond to therapy (Garcia-Sancho et al, 2007), but underlying histopathologic changes typically remain unchanged (Schreiner et al, 2005; Allenspach et al, 2006; Garcia-Sancho et al, 2007). Laboratory tests to assess serum cobalamin and folate levels are recommended for patients receiving parenteral cobalamin injections for hypocobalaminemia and/or have a history of low serum folate levels to assess the adequacy of and necessity for continued supplementation. The feeding method and amount fed can be adjusted as needed to maintain body weight and condition.

The prognosis for IBD varies with the specific entity present, severity of the condition at the time of presentation and owner compliance. The hypereosinophilic form of eosinophilic gastroenteritis in cats and segmental granulomatous enterocolitis (regional enteritis), immunoproliferative enteropathy and histiocytic colitis in dogs may be refractory to treatment (Breitschwerdt, 1992; Moore, 1983; van Kruiningen, 1967). Likewise, response to therapy may be poor when animals present late in the course of disease and with evidence of protein-losing enteropathy.

In most cases, judicious use of dietary and medical regimens controls the disease. Often, medical measures can be withdrawn after three to six months; thereafter, animals maintain remission with appropriate foods. In some cases, however, pharmacologic treatment may be required for the life of the patient.

The most common causes for failure to respond include noncompliance on the part of the owner and failure of the clinician to tailor a program incorporating dietary and pharmacologic measures for each patient (Guilford, 1996). Intercurrent illnesses such as triaditis in cats, small intestinal bacterial overgrowth or exocrine pancreatic insufficiency may also result in a poor response to treatment. Occasionally, treatment failures occur because of misdiagnosis of alimentary lymphosarcoma or progression of IBD to lymphosarcoma. This progression has been previously reported to occur in dogs (Breitschwerdt, 1982) and cats (Davenport, 1987, 1991).

CASE 57-1

Chronic Diarrhea in a Cat

Deborah J. Davenport, DVM, MS, Dipl. ACVIM (Internal Medicine)
Hill's Pet Nutrition Center
Topeka, Kansas, USA

Patient Assessment

A 10-year-old castrated male domestic shorthair cat was examined for a three-month history of intermittent diarrhea. The owner described the feces as being abnormal, three to five times per week; feces were usually fluid to semi-formed and occasionally black. No tenesmus or blood or mucus in the feces had been noted. The cat had not vomited although the owner felt that its appetite had decreased in the last few days. The cat lived in an apartment and no other pets were in the household.

Physical examination was normal except for mild accumulation of dental calculus and a somewhat "doughy" abdomen. Body weight was 4.4 kg with normal body condition (body condition score [BCS] 3/5). The medical record indicated that a body weight of 4.6 kg was recorded six months previously.

Diagnostic evaluation included a complete blood count (mild eosinophilia, 1,170/µl), serum biochemistry profile (normal), urinalysis (normal), serum T_4 concentration (normal), zinc sulfate fecal flotation (negative for *Giardia* cysts but positive for coccidia ova) and a Sudan black stain for fecal fat (positive). Two weeks of treatment with sulfadimethoxine for coccidiosis improved the diarrhea.

The owner returned with the cat six weeks after completion of sulfadimethoxine treatment because the diarrhea had worsened. The cat was thinner (BCS 2/5) and weighed 3.8 kg. Feces were soft and still positive for fat; however, fecal flotation was negative for coccidia and other parasites. A complete blood count revealed more severe eosinophilia (3,500/µl).

Endoscopic examination of the upper gastrointestinal (GI) tract revealed a normal esophagus and stomach but a coarse, granular, friable mucosa in the duodenum. Histopathologic examination of biopsy specimens collected during endoscopy revealed a normal esophagus, mild lymphoplasmacytic infiltration of the stomach and severe lymphoplasmacytic infiltration in the duodenum. Diagnosis was inflammatory bowel disease (IBD) (lymphoplasmacytic gastroenteritis).

Assess the Food and Feeding Method

The cat was fed a commercial dry grocery brand cat food. The food and water were offered free choice.

Questions

1. Outline a feeding plan for this cat.
2. What other medical therapy can be used in this patient?

Answers and Discussion

1. Several different types of foods may benefit patients with IBD. One strategy involves using a highly digestible, low residue food in conjunction with medical management to control inflammation. (See Answer 2.) Another strategy uses foods with mild to moderate levels of fiber to alter intestinal motility in conjunction with medical management. A third strategy uses an elimination ("hypoallergenic" or one containing a protein hydrolysate) food to decrease mucosal exposure to potential antigens. Although the etiopathogenesis of IBD is unknown, limiting exposure of the GI mucosa to potential antigens is considered an important part of the feeding plan. Use of an elimination food is often the first choice in these cases although a combination of various dietary strategies can also be tried. Access to table food and snacks should be avoided. Therapeutic trials with several different food types and careful monitoring are necessary for optimal case management. The food should be fed in an appropriate amount for the patient's body condition and activity level. For this cat, the daily energy requirement (DER) was estimated to be 1.4 x resting energy requirement for an ideal body weight of 4.5 kg (DER = 290 kcal [1.21 MJ]).
2. Medical therapy is indicated along with dietary management in most moderate to severe cases of IBD. Mild to moderate cases may respond to dietary management alone. Although clinical remission can be obtained in some cases without medical therapy, many gastroenterologists believe that remission will be more rapid, complete and prolonged if the patient is given a short course of antiinflammatory drugs. The rationale for this recommendation is that the more rapidly intestinal inflammation can be controlled, the more rapidly the intestinal permeability barrier will be restored and the less exposure the animal will have to intestinal luminal antigens, including the antigens in the new food. A large variety of medications have been used in cats with this condition including oral corticosteroids, parenteral corticosteroids (i.e., nonresponsive patients with severe disease), azathioprine, cyclophosphamide, metronidazole, tylosin, miscellaneous antibiotics and motility modifiers.

Progress Notes

The owner was offered several therapeutic options but elected to try an elimination food alone. The cat was started on a commercial moist veterinary therapeutic food (Prescription Diet Feline d/d[a]) that contained highly digestible ingredients (lamb and rice) to which the cat had not been exposed previously. The food was offered as two meals per day (one-fourth of a 14.25-oz. can twice daily). Four weeks later, the owner reported that the diarrhea had resolved completely and the cat weighed 4.2 kg. The feeding plan was continued.

The cat did well for more than a year; however, lethargy, vomiting and weight loss were noted 16 months after the initial diagnosis of IBD. Physical examination revealed a thin cat (body weight 3.5 kg, BCS 2/5) with palpably thickened bowel loops. Persistent eosinophilia and elevated liver enzyme activity were present. Evaluation of intestinal biopsy specimens obtained endoscopically revealed GI lymphosarcoma. The cat was euthanized at the owner's request.

Protein-Losing Enteropathies

Deborah J. Davenport
Albert E. Jergens
Rebecca L. Remillard

"Lymph, v.: to walk with a lisp."
From a Washington Post reader submission word contest

CLINICAL IMPORTANCE

Protein-losing enteropathy (PLE) is a broad term encompassing intestinal disorders characterized by gastrointestinal (GI) protein loss of such magnitude as to result in hypoalbuminemia. Lymphangiectasia is one form of PLE. Lymphangiectasia is characterized by abnormalities of the intestinal lymphatic system, which cause lymphatic hypertension. Lymphangiectasia may occur as a primary lymphatic defect or as a consequence of severe intestinal infiltrative disease (e.g., inflammatory bowel disease, alimentary lymphosarcoma, fungal enteritis). Lymphangiectasia is a common cause of PLE in dogs. PLE in cats is rare. Collectively, PLE is a relatively uncommon manifestation of diarrheic disorders in dogs and cats.

PATIENT ASSESSMENT

History and Physical Examination

Typically, signs of lymphangiectasia are insidious in onset and follow a waxing and waning course over several weeks to months before becoming overt. The clinical manifestations of lymphangiectasia are generally attributable to the loss of lymph constituents (i.e., albumin, lymphocytes, fat) or to the underlying enteric disease. Many patients present with chronic intermittent diarrhea or vomiting; however, not all have GI signs. Progressive weight loss, often in the face of a good appetite, is a consistent finding in longstanding cases. Excessive protein loss from leaky intestinal lymphatics results in hypoalbuminemia and loss of colloidal oncotic pressure. External manifestations of hypoalbuminemia may include pitting edema, ascites and pleural effusion. In some cases, chylous effusions of the abdomen, subcutis or thoracic cavity may occur in conjunction with primary or congenital lymphangiectasia (Fossum et al, 1987, 1990, 1992) Rarely, affected dogs may present with thromboembolic phenomena (e.g., pulmonary thromboembolism) as a consequence of antithrombin III deficiency. Severe hypocalcemia due to malabsorption in affected dogs can cause tetany and rarely seizures.

Physical examination findings may be unremarkable in dogs with PLE. Patients with severe hypoproteinemia may present with dyspnea and abdominal enlargement due to accumulation of fluid in the thoracic or abdominal cavities, respectively. Pitting edema of the limbs may be noted. Body condition

Figure 58-1. Endoscopic view of lymphangiectasia in the duodenum of a three-year-old Yorkshire terrier with diarrhea. Note the raised, white miliary structures along the mucosal surface. These structures are grossly dilated lacteals (intestinal lymphatics) filled with chylomicron-rich fluid. (Courtesy Dr. Chris Ludlow, Veterinary Internal Medicine Specialists of Kansas City, Kansas City, MO.)

assessment of body fat loss vs. muscle wasting should be performed because many patients are underweight at the time of presentation.

Laboratory and Other Clinical Information

There is a consistent pattern of laboratory results in many dogs with PLE. Panhypoproteinemia (i.e., hypoglobulinemia and hypoalbuminemia) and hypocholesterolemia are classic findings of lymphangiectasia and reflect the loss of lymphatic fluid into the gut lumen. A unique feature of PLE in Basenji dogs is an IgA-associated hyperglobulinemia. In lymphangiectasia, lymphopenia is an important finding that can be used to differentiate this condition from other causes of PLE (Tams and Twedt, 1981). Other laboratory findings may include anemia of chronic disease, a stress leukogram and hypocalcemia. Hypocalcemia is caused by malabsorption of calcium and/or vitamin D. Symptomatic hypocalcemia is rare; therefore, ionized calcium levels should be assessed before initiating intravenous calcium supplementation.

Fecal α-1-protease inhibitor assays have been developed for dogs and cats and offer a sensitive and specific technique for detection of increased intestinal protein loss (Melgarejo et al, 1998; Murphy et al, 2003). Fecal α-1-protease inhibitor is a plasma protein that is lost at the same rate as albumin. As a proteinase inhibitor, this protein is resistant to digestion and reaches the distal colon and rectum intact thus lending itself to a fecal immunoassay. Measuring fecal α-1-protease inhibitor is a particularly useful diagnostic tool for patients with PLE that do not have panhypoproteinemia.

Endoscopic examination in patients with PLE can be helpful to confirm a diagnosis. Mucosal granularity and glistening white patches, which indicate dilated lacteals may be noted (**Figure 58-1**). Feeding small amounts (10 to 20 ml) of corn oil or cream eight to 12 hours before endoscopy can enhance detection of dilated lacteals. Endoscopy also provides a noninvasive route for obtaining intestinal biopsy specimens. A definitive diagnosis of lymphangiectasia and other types of PLE is made through histologic demonstration of characteristic mucosal lesions. In lymphangiectasia, these lesions include dilated, chyle-engorged lacteals and submucosal lymphatics (**Figure 58-2**). Often, mucosal edema is present. In some cases, lipogranulomas may be identified adjacent to intestinal and mesenteric lymphatics. The pathogenesis of these lipogranulomas is unknown, but they are hypothesized to result from extravasation of chyle into perilymphatic tissue. Surgical techniques (e.g., laparoscopy) can be used to collect full-thickness intestinal biopsy specimens. The potential for surgical dehiscence should be considered before biopsy specimens are taken from patients with PLE. Full-thickness biopsy specimens should be obtained if a diagnosis cannot be made based on evaluation of endoscopic biopsy specimens. Care must be taken to use serosal patch grafts and to preserve abdominal fluid accumulation to reduce the potential for dehiscence and further decreases in total body albumin, respectively (Peterson and Willard, 2003).

Risk Factors

Several dog breeds appear to be at risk for development of PLE; Chinese Shar-Peis and rottweilers were identified as at risk at one university teaching hospital (Peterson and Willard, 2003). Primary lymphatic defects appear to be most common in Yorkshire terriers (Kimmel et al, 2000), poodles (Peterson and Willard, 2003), golden retrievers and dachshunds. Lymphangiectasia secondary to severe mucosal inflammatory infiltrates is a common sequela to immunoproliferative enteropathy in Basenjis and Lundenhunds (Breitschwerdt, 1992; Flesja and Yri, 1977; Williams, 1997). In one study, about 50% of the North American Lundenhund population had evidence of PLE (Berghoff et al, 2004). PLE may occur in conjunction with protein-losing nephropathy in soft-coated wheaten terriers; 10 to 15% of the population may be affected (Littman and Giger, 1990; Littman et al, 2000).

Etiopathogenesis

Normally, plasma proteins are lost into the GI lumen daily. This loss is attributed to protein leakage at the time of villous tip extrusion. Typically, these plasma proteins are re-assimilated through digestive and absorptive processes. Certain GI disorders can disturb protein balance. Intestinal protein loss can accelerate when the mucosal barrier is disrupted or disorders interfere with lymphatic drainage. Altered intestinal lymphatic drainage results in reflux of protein-rich lymph into the gut lumen. Excess protein can be lost through exudation or hemorrhage when the intestinal mucosa is damaged. Hypoproteinemia develops in either case after protein losses exceed compensatory synthesis.

Intestinal lymphangiectasia can arise as a primary disorder of the lymphatic system or secondary to chronic inflammatory bowel disease. Severe inflammatory infiltrates and lipogranulomas can obstruct lymphatic drainage. Normally, the intestinal lymphatics transport absorbed fats from enterocytes to the venous circulation via the thoracic duct. Lacteals become distended with chyle if lymphaticovenous flow is impaired. Overdistended lacteals rupture and release intestinal lymph (containing protein, lymphocytes, fat and cholesterol) into the lumen. In some patients with primary lymphangiectasia, the lymphatic defects are not limited to the GI tract. In these animals, abnormal lymph flow may result in chylothorax, chylous abdominal effusions and subcutaneous chyle accumulations (Fossum et al, 1987, 1990, 1992).

Key Nutritional Factors

Key nutritional factors for patients with lymphangiectasia and other types of PLE are listed in **Table 58-1** and discussed in detail below.

Energy Density and Fat

Controlling dietary fat intake is important in PLE patients. For many pet foods, most of the fat content is from long-chain triglycerides. After digestion and lymphatic absorption, reconstituted long-chain triglycerides in the form of chylomicrons provide a major stimulus for intestinal lymph flow (Chapter 5). The chylomicrons are transported from the mucosal epithelium via lacteals to the thoracic duct and into the systemic circulation. Long-chain triglyceride absorption increases lymph protein content and lymph flow two- to threefold for four to six hours postprandially (Simmonds, 1954). The protein content of lymph tends to increase with dietary fat intake (Simmonds, 1954). If lymphatic flow is impaired, lacteals become distended with lymph. These over-distended lacteals can rupture and release lymph into the intestinal lumen. This process can damage the intestinal mucosa and, as a result, even more protein is lost through exudation or hemorrhage into the small intestine. Limiting fat intake (i.e., <15% dry matter (DM) for dogs and cats) minimizes lymph flow, reduces lacteal and lymphatic distention and minimizes protein loss.

PLE patients may be cachectic and including medium-chain triglycerides (MCT) as a source of calories has been recommended (**Box 58-1** and **Table 58-2**). MCT are water-soluble, and readily and rapidly hydrolyzed. They were previously thought not to require micellarization for absorption so that they would be absorbed directly into the portal vasculature and thus would not affect lymph flow as do long-chain triglycerides. However, a study in dogs showed that some MCT absorption does occur via the lymphatics (Jensen et al, 1994). The oil is best used when it is incorporated into foods rather than as a supplement added to foods because MCT supplementation negatively affects palatability. Also, because MCT oils do not contain essential fatty acids, it is important to ensure adequate intake when MCT oils are supplemented for prolonged periods. In addition, supplemental use of MCT oils in cats has been linked to hepatic lipidosis (MacDonald et al, 1984).

From a dietary energy and fat perspective, the best option is to feed a balanced, highly digestible low-fat food (fat <15% DM for dogs and cats) with adequate energy density (>3.5 kcal/g [>14.6 kJ/g DM]). If MCT oils are used, they are best incorporated into the food.

Table 58-1. Key nutritional factors for foods for patients with lymphangiectasia/protein-losing enteropathy.*

Factors	Recommended levels
Energy density	>3.5 kcal/g (>14.6 kJ/g)
Fat**	<15% for dogs and cats
Protein	≥25% for dogs ≥35% for cats
Crude fiber	≤5%
Digestibility	≥87% for protein and ≥90% for fat and digestible carbohydrate

*Nutrients expressed on a dry matter basis.
**Inclusion of medium-chain triglycerides is desirable.

Protein

Foods for patients with PLE should contain enough high biologic value proteins to support hepatic protein synthesis and replace depleted tissue proteins. In general, food protein content should be at least 25% DM for canine patients and at least 35% DM for feline patients. Feeding high-protein or all-meat foods without other appropriate dietary alterations has not been successful (Finco et al, 1973; Matteeuws et al, 1974). If severe inflammatory bowel disease is the underlying cause of PLE, the use of a low-fat, elimination food containing lower levels (16 to 26% DM for dogs and 30 to 45% DM for cats) of highly digestible, novel protein sources or hydrolysate-based foods should be considered.

Fiber

Foods containing increased levels of insoluble fiber (>7%) are not routinely recommended for the dietary management of PLE. Fiber-containing foods do not seem to be directly detrimental for these patients. The assumption that the "rough" texture of fiber might mechanically traumatize the intestinal mucosa is not supported by clinical evidence (Guilford, 1996) and there are cases in the veterinary literature in which a high-fiber (20% DM) food was successfully fed because of the food's particularly low fat content (Tams and Twedt, 1981; Erickson,

Box 58-1. Medium-Chain Triglycerides.

Triacylglycerides (TAG) are the most common form of fat found in foods and stored in body fat depots. TAG are primarily composed of long-chain fatty acids (i.e., 16 to 24 carbons long). Medium-chain triglycerides (MCT) are eight to 10 carbons long and are typically minor constituents of a food. Increased levels of dietary MCT have theoretical advantages over long-chain triglycerides (LCT) for the treatment of some forms of gastrointestinal disease.

The most striking difference between MCT and LCT is the former are more water-soluble than the latter. MCT are normally absorbed by mechanisms independent of those used by LCT. MCT are hydrolyzed more rapidly and can rely on the small amount of intestinal lipase available, rather than on pancreatic lipase. The products of hydrolysis are easily dispersed and absorbed in the absence of bile acids. Like short-chain fatty acids, medium-chain fatty acids are absorbed at a faster rate, are not re-esterified with glycerol in enterocytes and are primarily transported from the gut via the portal vein directly to the liver. However, some MCT also appear to be incorporated in chylomicrons and transported to some degree in the thoracic duct.

MCT may have a place in the nutritional management of patients with defects in intraluminal hydrolysis of fat (e.g., decreased pancreatic lipase, decreased bile salts), fat malabsorption or defective lymphatic transport of fat (lymphangiectasia). MCT are prepared commercially by hydrolysis and fractionation of coconut oil to create an oil (MCT Oil[a]) that contains approximately 67% caprylic acid (C8) and 23% capric acid (C10). The oil provides 8.3 kcal/g (34.7 kJ/g); one tablespoon (15 ml) weighs 14 g and provides 115 kcal (481 kJ). The oil can be included in commercial foods, homemade recipes or used to supplement commercial foods. Empiric recommendations are to provide 25 to 30% of calories as MCT.

MCT are also available as part of a nutritionally complete formula for human infants and children (Portagen[a]). This dry powder is composed of corn syrup solids, MCT oil, casein, sucrose, corn oil, soy lecithin, vitamins and minerals. Caloric distribution is 14% protein, 40% fat and 46% carbohydrate. The fat content is 95% MCT. The powder is mixed with water to produce a solution providing 1 kcal (4.2 kJ) per ml. Alternatively, the powder can be included in a homemade food or mixed with a commercial pet food.

Potential side effects of using supplemental MCT in foods for patients with gastrointestinal disease include reduced palatability, vomiting and osmotic diarrhea. In cats, experimental MCT oil administration has been linked to hepatic lipidosis. MCT products are expensive and their use supplementally is generally reserved for those patients that are refractory to more traditional dietary approaches.

1988; Remillard, 1989; Sherding, 1987). Higher levels of dietary fiber bind digestive enzymes and bile acids, decrease pancreatic secretion of lipase and reduce pancreatic enzyme activity. Insoluble fiber, through these mechanisms, decreases intraluminal fat digestion and micelle formation, which selectively inhibits long-chain fatty acid absorption (Remillard, 1989). Therefore, fiber may play a secondary role in reducing long-chain fatty acid absorption and decreasing lymphatic flow and subsequent lymph fluid losses. However, increased levels of fiber (>10% DM) also reduce the caloric density and digestibility of a food; both factors are deemed important to the appropriate management of patients with PLE. Thus, lower fiber levels (≤5% DM), which support higher caloric density and improved digestibility are recommended for foods for these patients.

Digestibility

Feeding highly digestible (fat and digestible [soluble] carbohydrate ≥90% and protein ≥87%) foods provides several advantages for managing lymphangiectasia in dogs and cats. Nutrients (including the energy-supplying nutrients just mentioned) in highly digestible foods are more completely absorbed in the proximal gut. Furthermore, highly digestible foods are associated with: 1) reduced osmotic diarrhea related to fat and carbohydrate malabsorption, 2) reduced production of intestinal gas due to carbohydrate malabsorption and 3) decreased antigen loads because smaller amounts of protein are absorbed intact.

Other Nutritional Factors

Vitamins

Vitamin supplementation is rarely necessary when feeding commercially prepared foods. Dogs and cats usually have body stores of vitamins A, D, E and K to last several months. However, parenteral supplementation with fat-soluble vitamins may be needed if marked steatorrhea persists. Fat-soluble vitamin supplementation is warranted in cases of long-term fat malabsorption. It is simple and cost effective to administer 1 ml of a vitamin A, D and E solution,[a] divided into two intramuscular sites. This should supply fat-soluble vitamins for approximately three months. Patients with vitamin K deficiency should be treated appropriately. Vitamin K_1, at a dosage of 0.5 to 1 mg/kg, subcutaneously, is recommended if a vitamin K-responsive coagulopathy is suspected.

Minerals

Patients with fat malabsorption fed foods containing higher levels of fat may have increased divalent cation losses (i.e., calcium, magnesium, zinc and copper) because of intraluminal saponification. Calcium supplementation is generally not needed because serum calcium levels usually increase in conjunction with serum albumin concentrations. However, intravenous calcium supplementation should be instituted if hypocalcemic tetany develops. Hypomagnesemia has been reported to occur in Yorkshire terriers with lymphangiectasia (Kimmel et al,

Table 58-2. Summary of digestion and absorption of long- and medium-chain triglycerides.

Characteristics	Long-chain triglycerides	Medium-chain triglycerides
Digestion		
Hydrolysis by gastric lipase	Slow	Fast
Hydrolysis by pancreatic lipase	Fast	Very fast
Luminal transport		
Paracellular absorption	None	Some
Re-esterification and chylomicron formation	Yes	No
Requires bile acid micellarization	Yes	No
Transport route from gut	Lymphatics	Portal blood; some via lymphatics
Water solubility of essential fatty acids	Low	High

2000). Anorexia and malabsorption complicated by the use of magnesium-free fluids are likely causes of low serum magnesium levels in these dogs. If necessary, magnesium repletion can be accomplished by the use of appropriate intravenous fluids. Supplementation with other minerals should also be based on evidence of deficiency rather than given pro forma.

FEEDING PLAN

The goal of therapy for patients with lymphangiectasia or PLE is to decrease the enteric loss of plasma protein. In some cases, dietary manipulation alone is adequate. In others, concurrent medical management is necessary.

Assess and Select the Food

Levels of key nutritional factors in foods currently fed to patients with lymphangiectasia or PLE should be evaluated and compared with recommended levels (**Table 58-1**). Information from this aspect of assessment is essential for making any changes to foods currently fed. Changing to a more appropriate food is indicated if the key nutritional factors in the current food do not match recommended levels. However, it is unlikely that a suitable food is being fed if clinical signs are present. **Tables 58-3** and **58-4** list selected veterinary therapeutic foods marketed for lymphangiectasia or PLE for dogs and cats, respectively, and compare them to recommended levels. It is usually best to choose the food that most closely matches the key nutritional factor recommendations. Home-prepared foods (Chapter 10) can also be considered (Peterson and Willard, 2003).

If a patient cannot maintain normal body weight and condition when fed an appropriate food, supplemental MCT oil may be added to the food. This supplement, however, should be used with caution, introduced gradually and should not exceed 25% of the caloric requirement (<1 ml/lb [<0.5 ml/kg] body weight). **Box 58-1** provides more information about MCT, including potential problems with the use and misuse of supplemental MCT.

Some patients with PLE may require additional protein. Dogs may be fed a low-fat (<10% fat DM) cat food that has a higher protein (>35% DM) content (**Table 58-4**) than a comparable dog food. Protein may also be added in the form of cooked egg whites. Egg whites contain 90% of a very high biologic value protein, which can be a useful supplement for some patients with PLE to increase serum albumin levels. Provide a minimum of one to two cooked large egg whites per 10 kg body weight as needed to maintain serum albumin levels above 2 g/dl.

If severe inflammatory bowel disease is the underlying cause of PLE, a highly digestible, low-fat elimination food containing lower levels (16 to 26% DM for dogs and 30 to 45% DM for cats) of novel protein sources or hydrolysate-based foods should also be considered. Chapters 31 and 57 provide information about these foods.

Assess and Determine the Feeding Method

Initially, patients with lymphangiectasia or PLE should be fed multiple small meals per day as indicated by acceptance and tolerance of the food. Meal size can be increased as tolerated by the patient after the clinical signs have been successfully managed for several weeks. Anorectic patients can be fed by nasoesophageal or esophagostomy tube using liquid monomeric or polymeric foods. Longstanding hospitalized patients in poor body condition should be given a parenteral solution containing calories, protein and essential micronutrients (Chapter 26). Calories can also be easily administered peripherally to dogs and cats using an isomolar 20% lipid solution piggybacked with standard fluid therapy at volumes sufficient to meet the patient's resting energy requirement.[b]

CONCURRENT THERAPY

Immunosuppressive therapy as described for inflammatory bowel disease is indicated when lymphangiectasia or PLE occurs as a consequence of mucosal inflammatory infiltrates. Drugs with reported efficacy include glucocorticoids and cyclosporine. In addition to treating the underlying enteric lesions, corticosteroid therapy has the added advantage of controlling the inflammatory lesions of lymphangiectasia, lymphangitis and lipogranulomas.

When hypoalbuminemia is severe, plasma, concentrated human albumin, dextran or hetastarch infusions may be necessary to restore colloidal oncotic pressure. In general, aggressive nutritional support will be more successful than plasma transfusions for restoring normoalbuminemia. Plasma transfusions may, however, benefit those patients with hypercoagulability resulting from panhypoproteinemia; plasma serves as a rich source of coagulation factors and antithrombin III.

REASSESSMENT

Initially, patients with PLE should be reassessed weekly following discharge from the hospital. Each reexamination should include assessment of body weight and condition. Assessment of serum albumin and calcium concentrations and lymphocyte counts every two weeks is useful. In addition, serial radiography can be used to assess the resolution of abdominal or thoracic effusion.

If the patient's condition improves, dietary therapy should continue until the underlying enteropathy is resolved. Failing that, dietary management should continue for the lifetime of the pet. Over time, it may be possible to increase dietary fat intake; however, this should be done cautiously and only for patients having difficulty maintaining ideal body weight or those manifesting evidence of essential fatty acid deficiency (e.g., poor skin or coat quality).

Short Bowel Syndrome

Deborah J. Davenport

Chris L. Ludlow

Rebecca L. Remillard

"Who needs such a long intestine, anyway?"
Moshe Dayan

CLINICAL IMPORTANCE

Short bowel syndrome is a malabsorptive state that may develop after massive resection of the small intestine (Vanderhoof and Langnas, 1997). Short bowel syndrome is an important clinical entity in people but is uncommon in dogs and cats. This difference probably reflects the relative frequency with which predisposing conditions occur. In people, the most common reasons for extensive bowel resection are inflammatory and neoplastic conditions in which the residual bowel is often compromised. In dogs and cats, a number of intestinal conditions may warrant the removal of large segments of the bowel, including linear foreign bodies, intussusception, volvulus, infarction, neoplasia, entrapment, gastrointestinal (GI) surgical site dehiscence and fungal infections. In many of these conditions, the remaining intestine is healthy. The syndrome is characterized by malabsorption due to lack of gut surface area resulting in diarrhea, malnutrition and weight loss. Short bowel syndrome may occur whenever large segments of the small intestine (≥50%) are excised surgically (Gorman et al, 2006; Yanoff and Willard, 1989; Yanoff et al, 1992; Pawlusiow and McCarthy, 1994; Williams and Burrows, 1981; Joy and Patterson, 1978; Feldman et al, 1976; Uchiyama et al, 1996). However, one retrospective study was unable to correlate the percentage of resected bowel with the development of short bowel syndrome (Gorman et al, 2006).

PATIENT ASSESSMENT

History and Physical Examination

Dogs with short bowel syndrome typically develop diarrhea one or more days after a large portion of the small bowel is resected (Gorman et al, 2006; Yanoff et al, 1992). The diarrhea may be intermittent or persistent. Stools range from soft, cowpie consistency to explosive, watery diarrhea. In longstanding cases, the patient may have weight loss, polyphagia and evidence of malnutrition.

Occasionally, patients present weeks to months after surgery with small bowel diarrhea, flatulence and borborygmus. A delayed onset of clinical signs is associated with small intestinal bacterial overgrowth, which can develop as a sequela to resection of the ileocolic valve. Physical examination findings are usually unremarkable. Body condition assessment may demonstrate poor condition (body condition score 1/5 or 2/5). Most patients are bright, alert and active with an increased appetite.

Laboratory and Other Clinical Information

Hematologic and biochemical findings are variable, often reflecting the underlying condition that led to the bowel resection. Hypoproteinemia and hypoalbuminemia may be present in long-term cases. Mild, normocytic, normochromic nonregenerative anemia may be recognized as a consequence of chronic disease. Patients in which the ileum has been resected

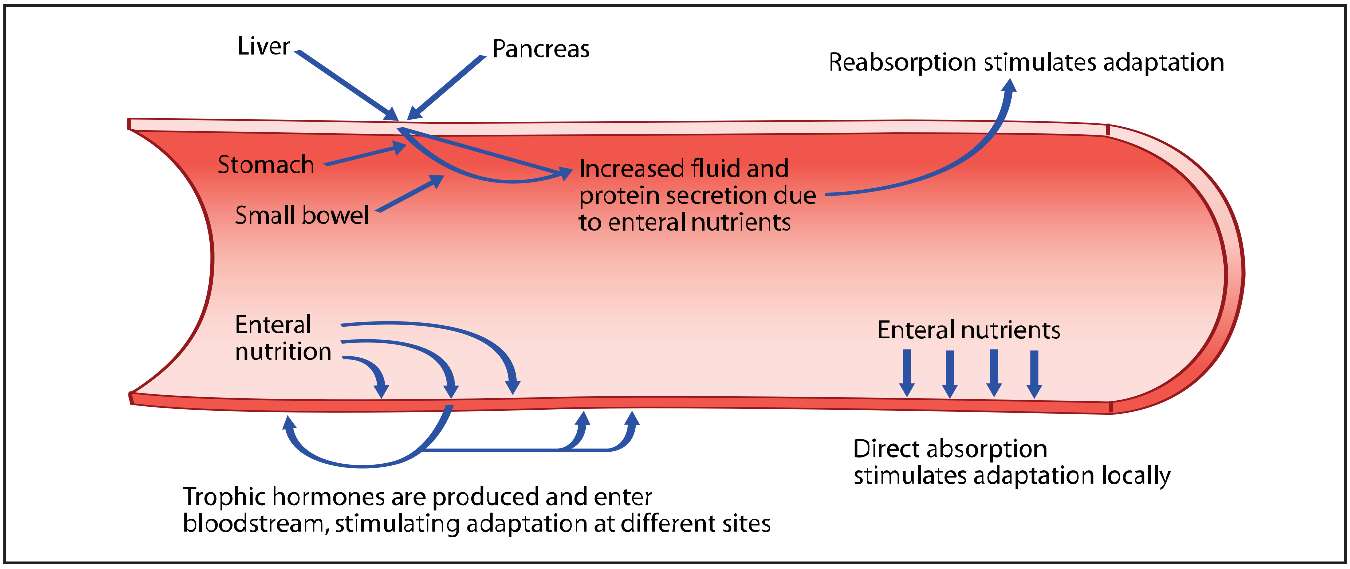

Figure 59-1. Schematic representation of the pathways by which enteral nutrients stimulate intestinal adaptation. (Adapted from Vanderhoff JA, Langnas AN. Short-bowel syndrome in children and adults. Gastroenterology 1997; 113: 1767-1778.)

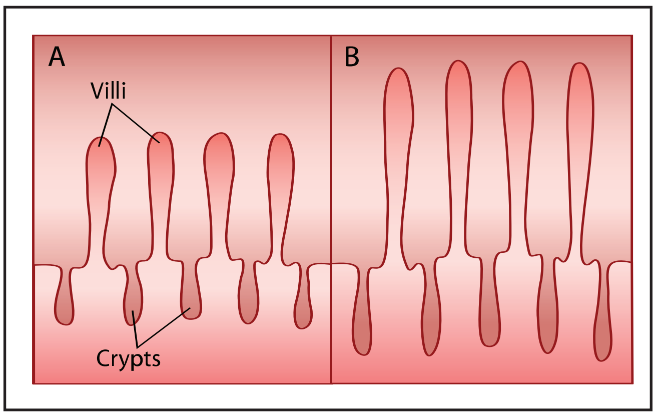

Figure 59-2. Diagrammatic comparison of normal (A) and adapted (B) gastrointestinal epithelium in patients with short bowel syndrome. Note the increased villous length and crypt depth. Increased muscle mass may also be observed. (Adapted from Vanderhoff JA, Langnas AN. Short-bowel syndrome in children and adults. Gastroenterology 1997; 113: 1767-1778.)

may have microcytic anemia consistent with that caused by cobalamin deficiency.

Radiographic findings are usually not helpful. Contrast films may demonstrate rapid transit of ingesta from the stomach to the colon. Contrast radiography can also be used to estimate the length of bowel remaining. In normal dogs, the small intestinal length is approximately four times the distance from the crown of the head to the rump. The percentage of small intestine remaining can be calculated by comparing the length of bowel remaining to this standard (Yanoff et al, 1992).

Risk Factors

Puppies and young adult dogs are most likely to suffer from GI conditions that may require extensive small bowel resection. Young cats, in particular, are at risk for linear foreign bodies (Gorman et al, 2006). GI conditions that may require resection include intestinal intussusception, volvulus, fungal infections (e.g., histoplasmosis), neoplasia and foreign bodies. Larger breeds, especially German shepherd dogs, are more likely to suffer from intussusception and mesenteric volvulus.

Etiopathogenesis

A surgeon may be faced with the need to resect a large portion of the small intestine in the management of a number of obstructive small intestinal diseases. Generally, as mentioned above, the potential for the syndrome exists any time 50% or more of the small bowel is resected. Remarkably, dogs with as little as 30 to 40 cm and cats with 18 to 20 cm of residual small intestine may achieve nutritional autonomy (Yanoff and Willard, 1989; Yanoff et al, 1992). Short bowel syndrome arises due to a lack of sufficient mucosal absorptive surface area. The reduced gut surface results in incomplete digestion and absorption of nutrients. Unabsorbed nutrients in the gut lumen lead to osmotic diarrhea. In addition, unabsorbed bile acids and fatty acids may result in secretory diarrhea in the large bowel.

Massive intestinal resection causes morphologic and functional adaptation in the remaining small bowel. Adaptation is stimulated by: 1) exposure to luminal nutrients, 2) endogenous GI secretions, 3) trophic effects of gut hormones, especially epidermal growth factor, enteroglucagon and gastrin, 4) intraluminal polyamines, 5) neural factors and 6) changes in blood flow to the remaining bowel (**Figure 59-1**) (Kouti et al, 2006; Chan and Klein, 1997). During adaptation, the intestine dilates and hyperplasia occurs in villi and crypts; however, the absorptive capacity of individual enterocytes does not change (Kouti et al, 2006; Williamson and Chir, 1978; Dowling, 1988). Therefore, the net increase in absorptive function in the remaining small bowel occurs because of increased total surface area.

In general, jejunal resections are tolerated better than removal of the ileum or the ileocolic valve. An intact ileum markedly enhances fluid, bile acid, cobalamin and electrolyte resorption. Loss of the ileocolic valve removes the physical barrier that sep-

arates the profuse bacterial flora of the colon from the relatively sparse population of the small bowel. Loss of the valve predisposes patients to development of small intestinal bacterial overgrowth or colonization of the remaining small bowel with bacterial pathogens.

Over time, the colon may begin to play an important role in maintaining nutritional homeostasis in patients with short bowel syndrome (Aghdassi et al, 1994; Nightingale et al, 1992). Following massive small bowel resection, colonic fermentation of malabsorbed carbohydrate may provide significant calories in the form of short-chain fatty acids. Short-chain fatty acids also promote mucosal hyperplasia. The mechanisms that lead to intestinal adaptation are not completely understood. However, a number of GI hormones including enteroglucagon, gastrin, cholecystokinin and secretin are involved, as are other pancreatobiliary secretions. Intraluminal foodstuffs including protein, protein hydrolysates, fats and glutamine stimulate release of these substances. Thus, intestinal adaptation appears to rely on exposure of the remnant bowel to intraluminal nutrients.

Intestinal adaptation is marked by enterocyte hyperplasia and increases in bowel diameter, villous height, crypt depth and number of enterocytes per length of the villous/crypt unit (**Figure 59-2**). Ideally, these physical changes will increase the bowel's absorptive capacity. Mucosal changes begin to occur within one to two days and can result in a fourfold increase in mucosal surface area within 14 days, if intraluminal nutrients are provided (Vanderhoof et al, 1992).

Key Nutritional Factors

Key nutritional factors for patients with short bowel syndrome are listed in **Table 59-1** and discussed in more detail below.

Table 59-1. Key nutritional factors for foods for dogs and cats with short bowel syndrome.*

Factors	Recommended levels
Digestibility	≥87% for protein and ≥90% for fat and digestible carbohydrate
Fat	12 to 15% for dogs 15 to 25% for cats
Fiber	≤5% (soluble or mixed fiber)
Carbohydrate	Lactose free
Food form	Dry foods are preferred due to slower gastric emptying vs. moist foods

*Nutrients expressed on a dry matter basis.

Digestibility

Because this is a malassimilative condition, highly digestible foods (fat and digestible [soluble] carbohydrate ≥90% and protein ≥87%) are recommended. The use of monomeric foods has been investigated in people with the syndrome; however, clinical evidence suggests that these foods are no more effective than polymeric foods (McIntyre et al, 1986). In addition, use of monomeric foods has been associated with villous atrophy (McIntyre et al, 1986; Levy et al, 1998). Polymeric foods are preferred because of their cost, palatability and trophic effects on the gut.

Fat

There are sound reasons for including fat in foods for dogs and cats with short bowel syndrome. Many patients with long-standing short bowel syndrome are underweight at the time of evaluation (Yanoff and Willard, 1989; Yanoff et al, 1992). Therefore, high-fat, energy-dense foods are recommended. Dogs and cats readily use most fats and oils of either animal or plant origin; therefore, fat should be included in the food for animals with short bowel syndrome up to the point of causing steatorrhea. Dietary fat levels of 12 to 15% dry matter (DM) in dogs and 15 to 25% DM in cats are often well tolerated. Intraluminal fat is probably the most influential nutrient in stimulating small bowel adaptation. Fat exerts profound effects on enterocyte growth, villous morphology, mucosal enzyme activity and segmental absorptive functions (Lentze, 1989). Fat also slows gastric emptying of digesta, which may better match the nutrient load to the compromised digestive capabilities of the shortened small bowel.

Replacing 50 to 75% of dietary fat with medium-chain triglycerides (MCT) has been reported to improve nutritional status in human patients with short bowel syndrome (Bochenek et al, 1970). Unfortunately, use of MCT in veterinary patients is limited due to cost, reduced palatability and poor GI tolerance. For these reasons, it is uncommon for MCT to be incorporated in excess of 30% of calories in homemade foods and 10% of calories in commercial foods. Whether MCT in foods are beneficial at these levels in veterinary patients is unknown.

Fiber

Although highly digestible foods are generally recommended for patients with short bowel syndrome, foods with moderate levels (10 to 15% DM) of insoluble fiber (e.g., cellulose) have been successfully used in refeeding patients with short bowel syndrome. Insoluble fiber included in foods at these levels is thought to help modulate intestinal motility and better control fecal water. Maintaining intraluminal bulk may stimulate the adaptive process through the release of GI trophic factors, including enteroglucagon, gastrin, cholecystokinin, secretin and other pancreatobiliary secretions.

Soluble fiber in foods may also benefit patients with short bowel syndrome by modulation of intestinal transit rate, absorption of intestinal water and production of short-chain fatty acids, which stimulate mucosal hyperplasia. Gel-forming fibers (e.g., pectins, gums) may slow gastric emptying rates (Russell and Bass, 1985; Prove and Ehrlein, 1982; Sandhu et al, 1987). Fermentable fiber supplementation (e.g., pectins, green banana) increases gut mass and colonic villous length, resulting in increased capacity for water reabsorption (Rabbini et al, 2001; Sales et al, 1998; Koruda et al, 1986). The most desirable approach is highly digestible, low-fiber foods with no more than 5% of a mixed fiber source DM. Mixed fiber sources include combinations of soluble (citrus and apple pectins and most gums) and insoluble (cellulose and peanut hulls) fiber

sources or mixed fiber sources (rice, oat and wheat brans; soy fibers; soy hulls and beet pulp). Patients that have undergone ileal resection do not absorb bile acids well, which may cause secretory diarrhea. In such cases, dietary intake of mixed fibers may bind bile salts. Several manufacturers include small amounts of a mixed fiber source in their highly digestible foods intended for GI diseases. This is the most desirable option if it can be done without negatively affecting digestibility. Lower levels of fiber (≤5% [DM]) are generally recommended and facilitate high digestibility and higher energy density while providing the benefits described above.

Digestible Carbohydrate

The digestible carbohydrate fraction of the selected food should be highly digestible (≥90%). Lactose-containing ingredients should be avoided because extensive small bowel resection results in loss of lactase and other brush border disaccharidases.

Food Form

Dry foods may be preferred because they may increase gastric retention time; it takes longer to lower the digesta osmolality of dry foods compared to moist foods.

Other Nutritional Factors

Prebiotic Fibers

Fructooligosaccharides and other prebiotic fibers have been proposed for use in the management of dogs with small intestinal bacterial overgrowth and, therefore, may be useful in cases of short bowel syndrome in which the ileocolic valve has been resected. However, clinical evidence to support use of these ingredients remains sparse in dogs and cats.

Vitamins

Fat-soluble vitamins are malabsorbed in many canine and feline patients with steatorrhea. Although commercial foods are supplemented with fat-soluble vitamins, fat-soluble vitamins may need to be administered by intramuscular or subcutaneous routes until intestinal adaptation occurs and diarrhea resolves. It is simple and cost effective to administer 1 ml of a vitamin A, D and E solution,[a] divided into two intramuscular sites. This should supply fat-soluble vitamins for approximately three months. Vitamin K_1 at a dosage of 0.5 to 1 mg/kg subcutaneously is recommended if a vitamin K-responsive coagulopathy is suspected.

If the distal ileum has been surgically removed, cobalamin

deficiency will develop because this portion of the bowel is solely responsible for B_{12} absorption. In such cases, parenteral supplementation of B_{12} is necessary. In dogs, cobalamin should be administered at 600 µg to 1 mg weekly for six weeks followed by injections every other week for six weeks then monthly doses until serum B_{12} levels normalize.[b] In cats, a dose of 250 µg weekly for four to six weeks is recommended. When short bowel syndrome is complicated by small intestinal bacterial overgrowth, bacterial uptake of vitamin B_{12} may exacerbate cobalamin deficiency.

Glutamine

Glutamine is the preferred fuel for enterocytes (Chan, 2006; Windmueller and Spaeth, 1974, 1978). Enteral administration of 2% glutamine solutions may benefit patients with short bowel syndrome (Frankel et al, 1993). Research in short-term (one-week) rat models has shown that adding glutamine to intravenous nutritional solutions reduces some aspects of disuse intestinal atrophy and enhances intestinal immune function (Burke et al, 1989; Alverdy et al, 1992; Jacobs et al, 1989). Glutamine administered intravenously for six to seven days prevents decreased intestinal weight, DNA content, villous height (O'Dwyer et al, 1989) and prevents decreased sucrase and lactase activities (Grant and Snyder, 1988) in adult rats fed parenterally. However, administering glutamine via foods (Vanderhoof et al, 1992a) and intravenous solutions (Remillard et al, 1998; Scott and Moellman, 1992) to research animals for more than one week was not shown to improve intestinal morphology. Glutamine may be a conditionally essential amino acid only during early periods of physiologic stress to stimulate DNA synthesis and increase mucosal mass early in recovery (Lacey and Wilmore, 1990). For example, rats undergoing abdominal radiation and fed glutamine orally the subsequent eight days had significant increases in jejunal villous numbers and height and an increase in the number of mitoses per crypt. Non-irradiated control rats fed the same glutamine-enriched food had no significant increase in mucosal cell activity (Klimberg et al, 1990). In one study performed in cats with methotrexate-induced intestinal injury, glutamine supplementation of a purified food failed to provide a benefit (Marks et al, 1996). Additional studies are needed to assess the benefits of glutamine supplementation in dogs and cats with GI disease including short bowel syndrome.

FEEDING PLAN

The goals of dietary and medical therapy for patients with short bowel syndrome are to provide adequate nutritional support during the period of intestinal adaptation and to stimulate adaptive changes that increase function in the remaining bowel segments. Diarrhea should be controlled as soon as possible because most pet owners will not tolerate persistent diarrhea. Changes required in the feeding management of short bowel syndrome are primarily determined by the function of the remaining small intestine. The feeding plan is often used in conjunction with medical therapy. (See below.)

Assess and Select the Food

Parenteral nutritional support is often required initially to meet nutritional, fluid and electrolyte needs as patients with short bowel syndrome recover from surgery. This is of particular benefit in situations in which the remaining intestine does not have normal function (e.g., infiltrative disease), in patients that have a low body condition score (1/5 to 2/5) at the time of surgery and in patients with complete or partial anorexia postoperatively. Reestablishing normal intestinal function and stimulating adaptation should begin as soon as the patient tolerates food enterally. Experimentally, intestinal adaptation did not occur in dogs with short bowel syndrome fed only parenterally (Feldman et al, 1976). Intestinal adaptation depends on using the remnant bowel, and not "bowel rest."

Parenteral administration of nutrients can be used in conjunction with enteral refeeding to meet the patient's requirements. The combination of continuous enteral nutrition through a feeding tube (nasoesophageal, esophageal, gastrostomy or enterostomy) and partial parenteral nutrition can be used in anorectic patients. A reduced fraction of the nutrient requirements (typically up to 30%) are given enterally, which provides nutrients and trophic factors for the adapting intestine. The remaining nutrient requirements are provided parenterally. This combination of feeding methods can be used in referral and primary care hospitals.

Continuous enteral nutrition consists of providing the calculated food volume at a constant rate over a prolonged period of time (12 to 24 hours). Studies in normal dogs and cats show that continuous enteral nutrition is well tolerated (Abood and Buffington, 1992; Chandler et al, 1996). Gravity drip, an intravenous infusion pump or an enteral feeding pump can be used to administer the food. The remaining nutrients are provided parenterally. Because only part of the patient's protein and caloric needs are being met parenterally, partial parenteral nutrition solutions are less hypertonic and may be administered through a peripheral vein (cephalic or saphenous) if less than 550 mOsm/l. This technique is less cumbersome and expensive than parenteral nutrition, which provides full caloric and protein needs, but requires central venous access. Partial parenteral nutrition may provide 30 to 70% of the patient's protein and caloric requirements assuming the remaining requirements are met through enteral nutrition. The solutions used in partial parenteral nutrition are similar to those used for parenteral nutrition, but more dilute glucose solutions are required. Providing 20% calories as glucose and 80% as lipid reduces the osmolality of the final solution and thus reduces endothelial irritation. Studies evaluating the use of partial parenteral nutrition demonstrate that complications are infrequent (Chan et al, 2002).

Refeeding should begin with a food that has the appropriate levels of key nutritional factors for patients with short bowel syndrome. **Tables 59-2** and **59-3**, provide the key nutritional factor content of selected veterinary therapeutic foods marketed for malabsorptive-type GI diseases in dogs and cats, respectively. These tables also include recommended levels of key nutritional factors for comparison. Appropriate formulations will be energy dense enough to meet the daily energy requirement of the patient in a reasonable volume of food and stimulate adaptation of remaining small bowel segments. Dry foods may be preferred because they may increase gastric retention time; it takes longer to lower the digesta osmolality of dry foods compared to moist foods (Chapter 54).

A liquid monomeric food containing glutamine and soluble fiber can be mixed with dry food during the first few days of recovery (Chapter 25). Such foods contain nutrients in readily absorbable forms and glutamine to fuel enterocyte hyperplasia.

Assess and Determine the Feeding Method

In contrast to feeding frequency commonly recommended for healthy animals (i.e., once or twice daily), patients with short bowel syndrome usually require multiple smaller meals per day to improve digestibility and prevent intestinal overload. Multiple (i.e., six to eight) small meals per day are recommended during the period of intestinal adaptation.

The amount of food may need to be increased to help animals regain or maintain ideal body condition. Aggressive nutritional support is recommended for patients with body condition scores less than 3/5. Additionally, supplemental parenteral feeding should be considered if the patient continues to lose weight despite consumption of what would normally be adequate calories. If parenteral support is used, infusion rates should be calculated to meet the patient's total caloric needs (Chapter 26). In some cases, total or partial parenteral nutritional support should be considered as an interim feeding method until the patient can meet its needs orally. Parenteral nutrition can be withdrawn gradually as intestinal function recovers and enteral feeding provides at least 70% of the patient's caloric needs. As mentioned above, intestinal adaptation did not occur in experimental dogs with short bowel syndrome when they were fed only parenterally (Feldman et al, 1976). Oral feedings or enteral infusions of glutamine-containing foods should continue throughout the parenteral feeding period to facilitate intestinal adaptation.

CONCURRENT MEDICAL THERAPY

Drugs commonly used in patients with short bowel syndrome include opiate antidiarrheal agents (e.g., loperamide, diphenoxylate), antibiotics (e.g., tetracycline, tylosin) and bile salt binding agents (e.g., cholestyramine, ursodeoxycholic acid). In addition, octreotide, a long-acting analogue of somatostatin (Nehra et al, 2001) has been recommended for use by some physicians in short bowel syndrome. This agent inhibits GI secretions and prolongs intestinal transit thus reducing diarrhea and fecal fluid loss. Glucagon-like peptide 2 has also been recommended due to its trophic effect on the GI mucosa (Jeppesen et al, 2001). The use of these compounds has not been investigated in veterinary patients with short bowel syndrome.

REASSESSMENT

Weekly determinations of body weight and condition and stool evaluations are useful for assessing dogs with short bowel syn-

drome. Medical therapies mentioned above should be considered if dietary therapy alone does not sufficiently improve stool quality and maintain body weight. Well-compensated patients should be evaluated immediately if a decline in body condition is noted. This presentation suggests concurrent GI disease or the onset of small intestinal bacterial overgrowth in dogs without an ileocolic valve.

The prognosis for recovery from short bowel syndrome is variable and cannot be based solely on the extent of resection (Gorman et al, 2006; Yanoff et al, 1992). The patient's preoperative condition, the functional integrity of the remnant bowel, degree of intestinal adaptation and the site of the resection are also important (Yanoff et al, 1992). For example, secondary complications (i.e., small intestinal bacterial overgrowth and large bowel diarrhea due to bile acid overload) may be avoided if the ileocolic valve can be preserved. In cases of surgical excision of intestinal neoplasia, adjuvant cytotoxic chemotherapy may be detrimental to remaining mucosa. In general, intestinal adaptation occurs in most dogs within one to two months and diarrhea may resolve in that time (Guilford and Strombeck, 1996). However, adaptation may continue for years; thus, stool quality may improve with time. In the meantime, the veterinarian and owner must work closely together to ensure optimal postoperative care.

CASE 59-1

Vomiting in a Labrador Retriever Crossbred Dog

Douglas Brum, DVM
Angell Memorial Animal Hospital
Boston, Massachusetts, USA

Patient Assessment

An 18-month-old neutered male Labrador retriever crossbred dog was examined for a 12-hour period of vomiting. The dog had no previous medical problems. The night before presentation, the dog ate a rawhide chew and began to vomit several hours later. The vomitus initially contained undigested food but then rapidly changed to a more liquid consistency. The dog weighed 22.3 kg (body condition score [BCS] 3/5) and was extremely depressed and weak. Rectal body temperature was 37.2°C (99°F). Mucous membranes were pale gray and the capillary refill time was three seconds. The heart rate was 180 beats/min. and femoral pulses were fair to poor. The dog's abdomen was tense and extremely painful. Significant clinical pathologic abnormalities included hyperglycemia (glucose 217 mg/dl, normal 65 to 110), thrombocytopenia (19.0 x 10^3/µl, normal 122 to 475) with clotting dysfunction (i.e., prolonged prothrombin time [8.7 sec., normal 4.5 to 7.6] and activated partial thromboplastin times [19.8 sec., normal 10.3 to 17.0]). Changes consistent with a small intestinal obstruction were apparent radiographically.

Exploratory celiotomy performed within two hours of presentation revealed a mesenteric volvulus involving the jejunum. Most of the jejunum was purple to black due to occlusion of mesenteric vessels. Resection of all questionable bowel was performed resulting in a final anastomosis of the remaining 10 cm of proximal jejunum to the ileum. The duodenum, pancreatic/bile duct, ileum and ileocecal junction were preserved.

Assess the Food and Feeding Method

The dog was normally fed a commercial dry grocery brand food (Purina Dog Chow[a]) once daily. Water was available free choice. Treats, snacks and table foods were given to the dog occasionally.

Questions

1. What preoperative, intraoperative and postoperative care is important for this dog?
2. What complications might occur subsequent to intestinal resection in this patient?
3. What are the key nutritional factors and feeding plan for this dog?

Answers and Discussion

1. Most dogs with mesenteric volvulus present in hypovolemic or endotoxic shock and therefore require immediate aggressive fluid therapy and broad-spectrum antibiotics preoperatively. Rapid surgical intervention is required in cases of small bowel obstruction. Intraoperative blood loss and hemorrhage due to coagulopathies may complicate recovery. Postoperative concerns include fluid losses, electrolyte imbalances, infection control and caloric intake. These problems can be addressed through aggressive fluid therapy, electrolyte replacement, continued broad-spectrum antibiotics and assisted feeding.
2. Short bowel syndrome often occurs when a large portion of the small intestine is removed, resulting in maldigestion and malabsorption causing diarrhea, steatorrhea, malnutrition and weight loss. The remaining length of small intestine will hypertrophy and absorptive capability will significantly increase; however, the functional capacity of the remaining intestine is difficult to predict and varies from case to case. Generally, complete adaptation takes months.
3. The key nutritional factors for this dog in the immediate postoperative days are water, electrolytes, energy (fat) and protein. Longer-term management of dogs with short bowel syndrome includes providing nutritional support to the patient until the intestine adapts, the diarrhea is controlled and weight can be maintained. A highly digestible food fed in small frequent feedings (i.e., six to eight meals/day) is recommended. Food characteristics should be individually modified to meet each patient's specific needs. Eventually, the patient may be fed its normal or similar food.

Progress Notes

The packed cell volume decreased to 19% during surgery; therefore, the dog was given one unit (500 ml) of packed red cells and one unit (50 ml) of fresh frozen plasma during surgery. Postoperatively, the dog had large amounts of bloody diarrhea, became hypoproteinemic and continued to have significant fluid losses through vomiting and diarrhea.

Crystalloid solutions supplemented with potassium were administered in quantities sufficient to meet fluid requirements and replace ongoing losses. The dog was given a parenteral mixture designed to meet daily fluid, electrolyte, resting energy and protein requirements. This mixture was administered via a peripheral catheter for the first five days after surgery (Chapter 26). After four days, the vomiting had resolved and a nasoesophageal tube (8 Fr.) was placed for a continuous infusion of a commercial liquid monomeric food (Peptamen[b]). This homogenized food contains protein, carbohydrates and fat in small, readily absorbable forms, has a caloric density of 1 kcal (4.2 kJ)/ml and contains glutamine. To meet the daily energy requirement of this dog, 720 ml of the monomeric food were infused via nasoesophageal tube continuously over 24 hours. This liquid food accounted for approximately 720 ml of the patient's daily water requirement, thus infusion of the intravenous crystalloid fluid was appropriately reduced.

After seven days in the hospital, the patient was discharged with instructions for the owner to feed a mixture of a commercial moist growth food (Science Diet Canine Growth[c]), the monomeric liquid food and small amounts of a moist high-fiber veterinary therapeutic food (Prescription Diet Feline r/d[c]). The moist growth food (521 kcal/can [2.18 MJ/can]) provided a nutrient-dense, highly digestible food to promote nutrient absorption and weight gain or maintenance. The monomeric food provided nutrients that were immediately absorbable with little or no digestion, and was to be used in decreasing amounts as the remaining small bowel adapted. Feline r/d (30% dry matter fiber) was used in small amounts to help control the diarrhea. Initially, the dog went home with instructions for the owner to feed 250 kcal (1.05 MJ) of the monomeric liquid food with each half can (260 kcal [1.09 MJ]) of the growth formula and to add 2 tbs of the high-fiber veterinary therapeutic food as needed to manage diarrhea. This mixture was offered every two to three hours for the first week and then less frequently as the dog tolerated larger meals. The proportions of these foods were varied over the next several weeks, depending on the dog's appetite, body weight and condition and stool quality.

The dog's body weight and condition declined initially; however, as stool quality gradually improved, the body weight and condition improved so that the dog was essentially normal eight weeks after surgery. The dog was fed the moist growth food only until its weight stabilized. After six months, the dog was fed a commercial dry maintenance-type food (Science Diet Canine Maintenance[c]) free choice. Four years postoperatively, the dog continued to do well, was maintaining a normal weight of 22.7 kg and body condition score (BCS 3/5) and had reasonably normal stools. The dog was fed two meals daily.

But many sanguine people hope to see him through a microscope."
Hilaire Belloc, More Beasts for Worse Children (1897)

CLINICAL IMPORTANCE

Small intestinal bacterial overgrowth (SIBO), a diarrheic disorder characterized by excessive numbers of small intestinal bacteria, has received much attention (Willard et al, 1994; Simpson, 1994; Johnston, 1999, 1999a; Davenport et al, 1994). Although the incidence of SIBO is unknown, some authors have suggested that it is present in up to 50% of dogs with chronic small bowel diarrhea (Rutgers et al, 1995), whereas others suggest that it occurs rarely in clinical practice (Johnston, 1999a; German et al, 2003). Controversy exists as to whether SIBO is a synonym for or a subset of a group of chronic enteropathies termed antibiotic- or tylosin-responsive diarrhea (Westermarck et al, 2005; Hall and Simpson, 2000).

PATIENT ASSESSMENT

History and Physical Examination

Affected dogs usually present with a history of weight loss and intermittent small bowel diarrhea. Borborygmus and flatulence are also common complaints. Physical examination findings are often unremarkable. Poor body condition (body condition score [1/5 or 2/5]) and unthriftiness may be present if the condition is longstanding.

Laboratory and Other Clinical Information

The gold standard for diagnosing SIBO is quantitative aerobic and anaerobic culture of undiluted duodenal juice. Samples can be collected via endoscopy or direct needle aspiration at surgery (Davenport, 1996; Papasouliotis et al, 1998; Johnston, 1999b). In dogs and cats, the small intestine normally contains a relatively sparse bacterial flora compared with the densely populated oral cavity and large bowel. Historically, the accepted upper limit for small intestinal bacterial flora has been 10^5 colony-forming units (CFU)/ml based on work done before 1984 (Batt and Needham, 1983). Subsequent studies have demonstrated that the small bowel of healthy dogs may contain bacteria in excess of 10^5 CFU/ml (Davenport et al, 1994, 1994a; Ludlow and

Box 60-1. Oligosaccharides.

Oligosaccharides are naturally-occurring carbohydrates found in some fruits, vegetables and grains. Structurally, oligosaccharides are sugar polymers that contain up to six sugars. Oligosaccharides containing fructose are termed fructooligosaccharides (FOS). Those that contain mannose are termed mannanoligosaccharides or MOS and so on. Typically found in low concentrations in foods, these complex carbohydrates can also be manufactured for commercial purposes using microbial or plant-derived enzymatic digestion of sugars.

Oligosaccharides resist digestion by mammalian digestive enzymes. Thus, they are classified as fibers or resistant starches. Because they resist digestion, oligosaccharides enter the large bowel in an intact form where they are readily fermented by certain colonic bacteria such as *Bifidobacterium* and *Bacteroides* spp. Based on in vitro studies, the fermentability of oligosaccharides is intermediate between that of cellulose and lactulose. Other organisms such as lactobacilli, eubacteria and clostridia do not readily use oligosaccharides. This preferential fermentation pattern suggests dietary supplementation with oligosaccharides may help foster beneficial gut bacteria.

The addition of oligosaccharides to pet foods has been studied with variable results. The inclusion of FOS at 0.75% (dry matter) did not influence the duodenal flora of healthy cats quantitatively or qualitatively. However, the fecal flora of cats was affected, resulting in increased numbers of lactobacilli and reduced numbers of *Escherichia coli*. Similar findings have been reported to occur in healthy cats consuming another oligosaccharide (i.e., lactosucrose). The clinical significance of these findings is unknown.

Investigators studied FOS supplementation in a group of healthy German shepherd dogs thought to have small intestinal bacterial overgrowth based on bacterial counts of specimens obtained by needle aspiration of the proximal small bowel at the time of surgery. In these dogs, the inclusion of FOS at 1.0% (as fed) was associated with changes in duodenal bacterial flora. However these changes were of less magnitude than normal dog variability for these parameters. Again, the clinical significance of these findings is unknown.

In some species, MOS derived from yeast cell walls binds to intestinal pathogens such as *Salmonella* spp. MOS inhibits attachment of salmonella to the intestinal mucosa by preferentially binding lectins. This effect has not been demonstrated to occur in companion animals to date.

The Bibliography for **Box 60-1** can be found at www.markmorris.org.

Davenport, 2000; Johnston, 1999a). Normal cats also have small intestinal bacterial counts in excess of 10^5 CFU/ml (Papasouliotis et al, 1998; Johnston et al, 1993). These findings suggest that laboratories should establish their own control or reference ranges for duodenal juice using their own sampling and microbiologic techniques. Furthermore, quantitative microbiology is cumbersome, invasive and not readily available to practitioners. Therefore, a number of other diagnostic modalities have been explored.

Other tests useful in diagnosing SIBO include serum folate and cobalamin concentrations, breath hydrogen measurements (with or without lactulose administration), serum total unconjugated bile acids and intestinal permeability tests. Determination of fasting serum folate and cobalamin concentrations is a rapid, noninvasive and simple method for evaluating dogs with suspected SIBO. Folate and cobalamin analyses have been useful in an experimental model of SIBO (Davenport, 1986) and in naturally occurring cases (Simpson, 1994; Batt and Morgan, 1982; Williams, 1991). However, these assays have low sensitivity and specificity (Rutgers, 1996; Simpson, 1994; German et al, 2003). Diet can influence serum folate and cobalamin concentrations. An analytical survey of commercial foods performed in 1994 revealed a wide range of dietary folate levels (Davenport et al, 1994a). Serum folate and cobalamin concentrations obtained from healthy dogs consuming foods containing high folate and cobalamin levels often exceed the upper limits of the reference ranges established for these vitamins (Davenport et al, 1994a; Williams, 1991). The influence of food on folate and cobalamin concentrations is responsible in part for the poor sensitivity of these assays for the diagnosis of SIBO.

Breath hydrogen testing has been used in human and veterinary medicine to diagnose SIBO. This technique is based on the fact that hydrogen is produced as a by-product of bacterial rather than mammalian metabolism. When given a carbohydrate substrate such as a sugar solution or ^{14}C-d-xylose, bacteria produce hydrogen, which can be measured in expired breath. Intestinal transit time can influence this technique; therefore, it is best considered a tool for assessment of carbohydrate assimilation (Johnston, 1999a). Recently, a ^{13}C-glycocholic acid blood test was validated for use in dogs. This test, which is based on the bacterial deconjugation of glycocholic acid, has the potential to recognize increased numbers of small intestinal bacteria through the early detection of ^{13}C-glycocholic acid (Suchodolski et al, 2005). Clinical data in affected animals, however, are lacking.

Intestinal permeability tests are nonspecific tools useful for evaluating animal patients with suspected small intestinal disease. These tests are most commonly available at referral centers and veterinary teaching hospitals.

Response to therapy with antibiotics should not be overlooked as an effective diagnostic tool. A therapeutic trial may be particularly useful in situations when quantitative cultures are not possible (Westermarck et al, 2005).

Risk Factors

A number of risk factors have been identified for SIBO. German shepherd dogs appear to be predisposed to this

enteropathy (Willard et al, 1994; Batt and Needham, 1983) possibly because of IgA deficiency (Batt et al, 1991; Whitbread et al, 1984; Willard et al, 1994). The recent development of fecal IgA assays has made detection of IgA deficiency more convenient as compared to measurement of IgA levels in intestinal biopsy samples (Tress et al, 2006; Littler et al, 2006).

Exocrine pancreatic insufficiency is also a predisposing factor for SIBO, and this condition can complicate management of exocrine pancreatic insufficiency (Williams et al, 1987).

Investigators have hypothesized that kenneled dogs (especially beagles) may be more likely to have duodenal fluid bacterial counts in excess of 10^5 CFU/ml (Batt et al, 1992).[a] Kennel-housed beagles, German shepherd dogs, Yorkshire terriers and poodles have subsequently been found to have increased counts (Willard et al, 1994; Davenport et al, 1994, 1994a). Quantitative counts in these apparently healthy dogs have ranged up to 10^8 CFU/ml. Potential causes for abnormal bacterial counts in kennel-housed dogs include environment (i.e., cleanliness), coprophagia and breed-specific characteristics (e.g., IgA deficiency). The bacterial flora of healthy colony cats, healthy pet cats and cats with gastrointestinal (GI) disease has been investigated (Johnston, 1996b). Both healthy colony and pet cats had small intestinal bacterial counts exceeding 10^5 CFU/ml duodenal fluid. Clinically abnormal cats had similar bacterial counts but had lower levels of anaerobic and microaerophilic bacteria.

Etiopathogenesis

SIBO can develop any time normal host defenses are impaired. Loss of gastric acid secretion, normal intestinal peristalsis, interdigestive ("housekeeper") motility, ileocolic valve function or local IgA production can result in SIBO. In people, intestinal stasis is the most common cause of SIBO; however, this particular underlying cause is far less common in dogs.

Key Nutritional Factors

Key nutritional factors for patients with SIBO are listed in **Table 60-1** and discussed in more detail below.

Digestibility

Feeding highly digestible (fat and digestible [soluble] carbohydrate ≥90% and protein ≥87%) foods provides several advantages for managing dogs with SIBO. Nutrients from these low-residue foods are more completely absorbed in the proximal gut. Highly digestible foods are also associated with reduced osmotic diarrhea due to fat and carbohydrate malabsorption and reduced production of intestinal gas due to carbohydrate malabsorption. The ideal food for SIBO patients is lactose free to avoid the complication of lactose intolerance due to loss of brush border disaccharidases.

Fat

Energy-dense foods are preferred for managing patients with chronic enteropathies. Calorie-dense products allow the clinician to provide smaller volumes of food at each meal, which minimizes GI stretch and secretions. Unfortunately, energy-dense foods tend to be high in fat. High-fat foods may contribute to osmotic diarrhea and GI protein losses, which complicate SIBO. Therefore, it is often advantageous to initially provide a food with moderate energy density (3.5 to 4 kcal/g [14.6 to 16.7 kJ/g] dry matter [DM]) that contains moderate levels of fat (12 to 15% DM for dogs and 15 to 25% DM for cats). Higher fat and more energy-dense foods can be offered if the patient tolerates these fat levels.

Table 60-1. Key nutritional factors for foods for dogs and cats with small intestinal bacterial overgrowth.*

Factors	Recommended levels
Digestibility	≥87% for protein and ≥90% for fat and digestible carbohydrate
Fat	12 to 15% for dogs 15 to 25% for cats

*Nutrients expressed on a dry matter basis.

Other Nutritional Factor

Prebiotic Fibers

Fructooligosaccharides (FOS) and other prebiotic resistant starches have been proposed for use in managing patients with SIBO. These indigestible sugars are thought to promote beneficial bacteria at the expense of bacterial pathogens (Fishbein et al, 1988; Hidaka et al, 1990; Hussein et al, 2005) (**Box 60-1**). When FOS was fed (1.0% as fed) to a group of German shepherd dogs with asymptomatic SIBO, total bacterial counts were reduced within the duodenum (Willard et al, 1994a). However, this reduction was smaller than the change in bacterial numbers demonstrated within the same dogs at different sampling intervals. Therefore, the clinical utility of FOS and other oligosaccharides in the treatment of SIBO remains unproven in dogs. In cats, feeding the non-digestible trisaccharide lactosucrose increased fecal counts of the favorable bacteria lactobacilli and bifidobacteria and decreased numbers of potential pathogens such as clostridia and Enterobacteriaceae (Terada et al, 1993).

FEEDING PLAN

The feeding plan is often used in conjunction with other medical therapy. Underlying causes of SIBO (e.g., partial intestinal obstruction) should be identified and treated before specific medical and dietary therapy is instituted. Antibiotic therapy is usually required for effective management of SIBO. Antibiotic selection should be based on culture and antimicrobial sensitivity testing of specific pathogens identified in duodenal aspirates. Tetracycline or tylosin should be used if no pathogen is isolated (Westermarck et al, 2005).

Assess and Select the Food

Levels of key nutritional factors should be evaluated in foods currently fed to patients with SIBO and compared with recommended levels (**Table 60-1**). Key nutritional factors include food digestibility and fat content. Information from this aspect

of assessment is essential for making any changes to foods currently provided. Changing to a more appropriate food is indicated if key nutritional factors in the current food do not match recommended levels.

Commercial veterinary therapeutic foods that are highly digestible and designed for patients with GI disease are recommended for patients with SIBO (**Tables 60-2** and **60-3** for dogs and cats, respectively). Many of these foods contain moderate levels of dietary fat. Young growing dogs and cats with SIBO should receive a food that meets the optimal levels of key nutritional factors for growth.

Assess and Determine the Feeding Method

Because the feeding method is often altered in patients with SIBO, a thorough assessment should include verification of the feeding method currently being used. Items to consider include feeding frequency, amount fed, how the food is offered, access to other food and who feeds the animal. All of this information should have been gathered when the history of the animal was obtained. If the animal has a normal body condition score (2.5/5 to 3.5/5), the amount of food previously fed was probably appropriate.

Ideally, patients with SIBO should be fed multiple small meals per day as indicated by animal acceptance and tolerance for the food. Meal size can be increased as tolerated by the patient after clinical signs have been successfully managed for several weeks.

REASSESSMENT

Owners of affected animals should be asked about frequency of diarrhea, borborygmi and flatus. Body weight and condition should be evaluated frequently to assess resolution of malabsorption. In general, SIBO can be managed effectively with a combination of medical (e.g., antibiotic) and nutritional therapies.

Introduction to Large Intestinal Diseases

Deborah J. Davenport

Rebecca L. Remillard

"Never ignore a gut feeling, but never believe that it's enough."
Robert Heller

CLINICAL IMPORTANCE

Disorders of the large intestine are frequently encountered in veterinary practice. A number of potential causes of acute and chronic large bowel diarrhea (**Tables 61-1** and **61-2**) must be distinguished from diseases of other organ systems resulting in gastrointestinal signs. Diarrhea associated with large intestinal conditions differs from that associated with small intestinal disorders (Table 55-4). Typical clinical manifestations of large bowel disease include frequent small scanty stools, tenesmus, dyschezia, urgency and passage of mucus and blood. **Table 61-3** lists breed-associated large intestinal disorders.

Chapters 62 through 65 include feeding plans for patients with large intestinal disorders including colitis, idiopathic (irritable) bowel syndrome, constipation/obstipation/megacolon and flatulence. Tables in those chapters list the key nutritional factors for such patients as well as tables that compare the levels of key nutritional factors of commercial foods marketed for patients with large intestinal diseases.

Chapter 62

Large Bowel Diarrhea: Colitis

Deborah J. Davenport
Rebecca L. Remillard
Maureen Carroll

"The physician strengthens nature, and employs food and medicine, for which nature makes use for the intended end."
Thomas Aquinas, Summa Theologica, 1270

CLINICAL IMPORTANCE

Colitis is a common disorder of dogs and cats. A number of infectious, toxic, inflammatory and dietary factors can trigger an episode of large bowel diarrhea (Tables 61-1 and 61-2). This chapter addresses the diagnosis and management of dogs and cats with acute and chronic colitis.

Currently, inflammatory bowel disease (IBD) is thought to be the most common cause of chronic large bowel diarrhea in dogs and cats (Guilford, 1996), although large bowel IBD appears to be more prevalent in dogs (Washabau, 2004). The generic term, IBD, encompasses lymphoplasmacytic enterocolitis, lymphocytic enterocolitis, eosinophilic enterocolitis, segmental granulomatous enterocolitis, suppurative enterocolitis and histiocytic colitis. Specific types are categorized based on the type of inflammatory cells found in the lamina propria. Lymphoplasmacytic colitis is thought to be the most common form of colitis (Leib, 1997, 2005). The severity of the condition varies from relatively mild clinical signs to life-threatening protein-losing enteropathy (PLE), although PLE is seen more commonly with severe small bowel disease. The boxer breed may present with an especially severe variant termed histiocytic or ulcerative colitis (Leib and Matz, 1995).

PATIENT ASSESSMENT

History and Physical Examination

The most common clinical sign in dogs and cats with acute or chronic colitis is large bowel diarrhea characterized by tenesmus, dyschezia, urgency and passage of mucus and blood (Table 55-4). Clinical signs may be intermittent or persistent. The clinical signs tend to increase in frequency and intensity as colitis progresses. The presence of systemic signs is also variable. Some patients present with a history of depression, malaise and inappetence; however, most are alert and active when examined. Hemorrhagic stools indicate a potentially life-threatening disorder (Table 56-1).

When evaluating colitis cases, careful attention should be paid to the dietary history. Food-induced diarrhea is common; a recent change to a moist high-fat or meat-based food may be

the source of the patient's diarrhea.[a,b] Often, it is possible to elicit a history of food change, indiscretion, feeding table foods over a holiday or access to garbage, carrion or abrasive materials, such as bones.

Other husbandry issues are also important; for example, records of anthelmintic treatments should be scrutinized. The likelihood that an infectious organism is involved is increased if other animals or people in the household are similarly affected.

Dogs and cats with acute colitis may act depressed and be dehydrated and may exhibit pain on abdominal palpation. Patients should be carefully evaluated for evidence of septic shock. Those patients with systemic signs of illness (i.e., fever and congested mucous membranes) in addition to gastrointestinal (GI) signs should be treated more aggressively.

Physical examination findings vary in dogs and cats with chronic colitis. Many patients have no abnormalities. Rarely, dogs and cats with colitis present with weight loss and poor body condition. In such cases, serious infiltrative colonic disorders (e.g., histoplasmosis, neoplasia, histiocytic colitis or large intestinal disease complicated by small intestinal disease) should be suspected.

Occasionally, thickened loops of bowel may be palpated, especially in cats. Segmental thickening of bowel is consistent with eosinophilic gastroenterocolitis in cats and granulomatous enteritis in dogs (Moore, 1983; Lecoindre et al, 2007). This finding should also be distinguished from intussusceptions, foreign bodies, histoplasmosis and neoplastic lesions.

Laboratory and Other Clinical Information

Because there are many potential causes of acute colitis, achieving a definitive diagnosis can be difficult. In acute cases, it is most important to determine whether the patient's condition is self-limiting or potentially life-threatening. This determination, based on historical and physical findings is critical. Some factors suggest a potentially life-threatening condition (Table 56-1). Cases of a serious nature should be pursued aggressively with diagnostics (i.e., hematology, serum biochemistry profiles, urinalyses and fecal examinations for parasites and other infectious pathogens such as *Giardia* and *Tritrichomonas foetus*) (Leib, 2002; Washabau, 2004a). An abundance of inflammatory cells in a fecal smear is an important finding and justifies a fecal culture. Self-limiting cases are usually approached more conservatively. Diagnostics are often limited to assessing hydration status (i.e., packed cell volume, total protein concentration and body weight) and a thorough examination of feces for parasites and bacterial pathogens (e.g., spores of *Clostridium* spp. or clostridial enterotoxins).

Laboratory findings in patients with chronic colitis are often nonspecific. Hematologic findings are variable and may include blood loss anemia, anemia of chronic disease, eosinophilia and lymphopenia. Serum biochemistry profiles and urinalyses should be performed on samples from patients with chronic diarrhea to assess the systemic affect of the GI disorder and to rule out concurrent disease. Decreased cholesterol values may be seen in patients with colitis. Electrolyte abnormalities, including hypokalemia and hypochloremia, may be identified. Acid-base derangements may occur with diarrhea, but are more common with small bowel disease. Hypoproteinemia and hypoalbuminemia may be recognized in severe cases of PLE. Dehydrated patients may have prerenal azotemia.

Fecal examinations are very important in the evaluation of patients with chronic large bowel diarrhea. Multiple fecal parasite examinations using concentration techniques are necessary to rule out parasitism and infection with organisms such as *Giardia* and *T. foetus.*

Endoscopic abnormalities in chronic colitis may include mucosal granularity, hyperemia, increased friability and inability to visualize colonic submucosal blood vessels (Jergens et al, 1992). Multiple biopsy specimens should be collected from multiple bowel segments. Even if these areas appear normal endoscopically, histologic changes may still be present (Jergens et al, 1992; Roth et al, 1990; Marks and LaFlamme, 1998). The definitive diagnosis of IBD is based on histopathologic examination of endoscopic or surgical biopsy specimens (Wilcock, 1992).

Risk Factors

The risk factors for acute colitis include age, breed, immune status and environment. Puppies and kittens are more susceptible to a variety of infectious pathogens including parasites (Gookin et al, 2004), viruses and bacteria. Likewise, immunocompromised dogs and cats are at risk for contracting viral and bacterial enteritides. Hospitalization and administration of cancer chemotherapeutic drugs are associated with nosocomial infection with *Clostridium* (Twedt, 1992) and *Campylobacter* (Davenport, 1989) spp.

Environment also plays an important role in exposure to pathogens. Dogs and cats kept in unsanitary or overcrowded conditions are much more likely to develop infectious enteropathies. In addition, pets kept in poorly controlled environments have a higher risk for exposure to high-fat table foods, garbage and toxins. Dogs in particular eat indiscriminately. Consumption of rotten garbage, decomposing carrion and abrasive materials (e.g., hair, bones, rocks, plastic, aluminum foil, etc.) can result in severe colitis. Poor husbandry practices including inadequate parasite control and overcrowding also put pets at risk for acute colitis. Feeding raw foods may predispose dogs and cats to infectious enteropathies (Chapter 11).

There does not appear to be an age or gender predisposition for any of the forms of IBD. Certain breeds appear to be at risk for specific colonic disorders (Table 61-3). For example, the boxer breed is linked to histiocytic colitis (van Kruiningen, 1967). Other breeds at risk for chronic inflammatory colonopathies include German shepherd dogs and French bulldogs (Guilford, 1996).

Etiopathogenesis

Chapter 55 describes four mechanisms of diarrhea. In acute colitis, diarrhea may occur as a result of altered gut permeability or osmotic mechanisms. Many of the bacterial pathogens elaborate enterotoxins that serve as potent secretogogues.

Despite intensive study by veterinary and medical researchers, the pathophysiology of IBD is not completely understood (Fiocchi, 1998; Hanauer, 1996). IBD may have a genetic origin in several animal species. Crohn's disease and ulcerative colitis are more common in certain human genotypes; a mutation leads to the development of colitis in mice (Watanabe et al, 2006). Genetic influences have not yet been identified in canine or feline IBD, but certain breeds (e.g., German shepherd dogs, boxers) appear to be at increased risk for the disease (Washabau, 2004) (Chapter 57).

Histiocytic colitis, also termed ulcerative or boxer colitis, is characterized by infiltration of the lamina propria with PAS-positive histiocytes. Some authors have suggested that the presence of these macrophages indicates an infectious etiology, especially in light of the occasional recognition of intralesional pathogens and the marked improvement many of these cases experience with fluoroquinolone therapy. However, to date no organisms have been consistently identified in tissues from affected canine and feline patients and immunohistochemical examination of samples from affected dogs suggests an immunologically-mediated pathogenesis for the disorder (Leib and Matz, 1995; German et al, 2000; Stokes et al, 2001).

Key Nutritional Factors

Key nutritional factors for acute and chronic colitis are listed in **Table 62-1** and discussed in more detail below.

Water

Water is the most important nutrient in patients with acute large bowel diarrhea because of the potential for life-threatening dehydration due to excessive fluid losses and inability of the patient to replace those losses. Moderate to severe dehydration should be corrected with appropriate parenteral fluid therapy rather than using the oral route.

Protein

Protein should be provided at levels sufficient for the appropriate lifestage of colitis patients unless PLE is present. Thus, dry matter (DM) protein levels in foods for adult dogs and cats should be between 15 to 30% and 30 to 45%, respectively (Chapters 13 and 20). Protein levels for growing puppies and kittens should be in the ranges of 22 to 32% and 35 to 50% DM, respectively (Chapters 17 and 24). High biologic value, highly digestible (≥87%) protein sources are preferred.

Some authors recommend the use of elimination foods because of the suspected role of dietary antigens in the pathogenesis of chronic colitis (Nelson et al, 1984; Nelson and Stookey, 1988; Guilford, 1997; German, 2006). In some cases, elimination foods may be used successfully without pharmacologic intervention. Mild to moderate lymphoplasmacytic and eosinophilic colitis are the forms most likely to respond to dietary management (Nelson and Stookey, 1988; Davenport et al, 1987). Chapter 31 discusses elimination foods and protein hydrolysates in more detail. The suspected pathogenesis of IBD involves an increase in gut permeability; therefore, the use of "sacrificial" dietary antigens has been suggested in the treatment of IBD (Box 57-1) (Guilford, 1996).

Table 62-1. Key nutritional factors for dogs and cats with colitis.*

Factors	**Recommended levels**
Protein	Adult dogs: 15 to 30% Growing puppies: 22 to 32% Adult cats: 30 to 45% Growing kittens: 35 to 50% Option: consider elimination foods or protein hydrolysates (Table 31-5 for dogs and Table 31-6 for cats)
Fat	Dogs: 8 to 15% Cats: 9 to 25%
Digestibility	Highly digestible foods: ≥87% for protein and ≥90% for fat and digestible carbohydrate Fiber-enhanced foods: ≥80% for protein and fat and ≥90% for digestible carbohydrate
Fiber	Highly digestible foods: ≤5% Fiber-enhanced foods: ≥7%
Electrolytes	Sodium: 0.3 to 0.5% Chloride: 0.5 to 1.3% Potassium: 0.8 to 1.1%

*All values expressed on a dry matter basis.

Fat

Compared with the processes involved with other macronutrients, fat digestion and absorption are relatively complex and may be disrupted in patients with GI disease. The action of bacterial flora on unabsorbed fats in the colon resulting in hydroxy fatty acid production is an important cause of large bowel diarrhea. Thus, foods indicated for patients with colitis and many other GI diseases often contain low to moderate amounts of fat (i.e., 8 to 15% DM for dogs and 9 to 25% DM for cats). However, dogs and cats digest fat very efficiently and the process is rarely disrupted except in malassimilative disorders. Therefore, colitis patients can be fed foods containing higher concentrations of fat when greater caloric density is required.

Digestibility

Feeding highly digestible (fat and digestible [soluble] carbohydrate ≥90% and protein ≥87%) foods provides several advantages for managing dogs and cats with longstanding inflammatory colitis. Nutrients from highly digestible, low-residue foods are more completely absorbed from the proximal gut. Low-residue foods are associated with: 1) reduced osmotic diarrhea due to fat and carbohydrate malabsorption, 2) reduced production of intestinal gas due to carbohydrate malabsorption and 3) decreased antigen loads because smaller amounts of protein are absorbed intact. Fiber-enhanced foods inherently have somewhat lower digestibility values. These foods should have protein and fat digestibilities of at least 80% and carbohydrate digestibility of at least 90%.

Fiber

Dietary fiber predominantly affects the large bowel of dogs and cats. Beneficial effects of dietary fiber include: 1) normalizing colonic motility and transit time, 2) buffering toxins (e.g., bile

acids and bacterial enterotoxins) in the GI lumen, 3) binding or holding excess water, 4) supporting growth of normal GI microflora, 5) providing fuel for colonocytes and 6) altering viscosity of GI luminal contents.

Fibers are often categorized as soluble, insoluble or mixed. Mixed fibers include beet pulp, brans (rice, wheat or oat), pea and soy fibers, soy hulls and mixtures of soluble and insoluble fibers. Insoluble fibers include purified cellulose and peanut hulls. Soluble fiber sources include fruit pectins, guar gums and psyllium.

Various types and levels of dietary fiber have been advocated for use in patients with colitis. Some veterinarians recommend low-fiber foods (≤5% DM crude fiber) to enhance DM digestibility and reduce quantities of ingesta presented to the colon. Other authors have had success using moderate levels (10 to 15% DM crude fiber) to high levels (>15% DM crude fiber) of insoluble fiber (Dennis et al, 1993). If a food with an increased fiber level is being considered, a crude fiber content of at least 7% DM is advisable. All three strategies have been used successfully in managing patients with colitis and each strategy is patient dependent.

Small amounts (1 to 5% DM fiber) of a mixed- (i.e., soluble/insoluble) fiber type can also be added to a highly digestible food. Some authors have suggested that feeding insoluble or slowly fermentable fibers is detrimental to the management of colonopathies; these suggestions are based on the results of a small, uncontrolled feeding trial comparing cellulose-containing foods with foods containing beet pulp (Reinhart et al, 1994). However, larger, controlled trials incorporating pre- and poststudy histopathology and electron microscopic examination of tissues have not identified any negative effects of slowly fermentable fiber on the colon (Campbell, 1993; Leib, 1992).[c] In fact, many clinicians select foods enhanced with insoluble fiber as their first food option in the management of acute and chronic colitis (Leib, 1989, 2000; Leib and Matz, 1995).[d]

Feeding soluble- or mixed-fiber sources in small quantities to human patients with chronic inflammatory colitis has been advocated (Fiocchi, 1998). Short-chain fatty acid and butyrate enemas induce clinical improvement in patients with ulcerative colitis (Harig et al, 1989; Breuer et al, 1991). Several substrates including beet pulp, soy fiber, inulin and fructooligosaccharides have been demonstrated by in vitro fermentation to produce volatile fatty acids that may be beneficial in inflammatory colonopathies (Sundvold et al, 1995, 1995a, 1995b; Jamikorn et al, 1999). Manufacturers of commercial products usually incorporate these fibers at 1 to 5% DM.

Electrolytes

Potassium depletion is a predictable consequence of severe and chronic enteric diseases because the potassium concentration of intestinal secretions is high. Hypokalemia in association with colitis will be particularly profound if losses are not matched by sufficient dietary intake of potassium.

Electrolyte disorders should be corrected initially with appropriate parenteral fluid and electrolyte therapy. Foods for patients with colitis should contain levels of sodium, chloride and potassium above the minimum allowances for normal dogs and cats. Recommended levels of these nutrients are 0.3 to 0.5% DM sodium, 0.5 to 1.3% DM chloride and 0.8 to 1.1% DM potassium.

Other Nutritional Factors

Acid Load

Acidemia (i.e., normal anion gap hyperchloremic acidosis) is common in patients with acute large bowel diarrhea because fluid secreted in the caudal small intestine and large intestine contains bicarbonate concentrations higher than those in plasma and sodium in excess of chloride ions. Hypovolemia (i.e., severe dehydration) compounds the acidosis in some patients. Severe acid-base disorders are best corrected with appropriate parenteral fluid therapy. Foods for patients with acute colitis should normally produce an alkaline urinary pH. These foods preferably contain buffering salts such as potassium gluconate and calcium carbonate.

Omega-3 Fatty Acids

Omega-3 (n-3) fatty acids derived from fish oil or other sources may have a beneficial effect in controlling mucosal inflammation in patients with chronic inflammatory colitis (Simopoulos, 2002; Barbosa et al, 2003). There is some clinical evidence that dietary omega-3 fatty acid supplementation may modulate the generation and biologic activity of inflammatory mediators. Chapter 57 provides more information.

Vitamins

Folic acid supplementation is recommended for patients receiving long-term sulfasalazine therapy (Linn and Peppercorn, 1992).

FEEDING PLAN

Initially, the objectives for managing acute colitis should be to correct dehydration and electrolyte, glucose and acid-base imbalances, if present. Medical therapy may include antibiotics, anthelmintics, motility modifying agents (e.g., loperamide) and immunosuppressant agents (e.g., corticosteroids and azathioprine). Local-acting antiinflammatory drugs such as sulfasalazine and olsalazine/mesalamine may also be used.

The feeding plan goal is to provide a food that meets the patient's nutrient requirements and allows normalization of colonic motility and function, and fecal water balance. In most cases of acute large bowel diarrhea, initial fasting for 24 to 48 hours, with access to water, either reduces or resolves the diarrhea by simply removing the effects of unabsorbed food and offending agents from the colon. Often, the patient's previous food can be gradually reintroduced over several days.

In chronic colitis, dietary intervention should be aimed at controlling clinical signs while providing adequate nutrients to meet requirements and compensate for ongoing losses through the GI tract. Optimal management of some dogs and cats with chronic colitis may require only dietary manipulation. In other cases, dietary therapy is better used in concert with appropriate

pharmacologic agents. Antibiotics (e.g., metronidazole, tylosin, fluoroquinolones [for histiocytic colitis]), anthelmintics, antiinflammatory agents (e.g., sulfasalazine) and immunosuppressive agents (e.g., prednisone, budesonide, azathioprine, cyclosporine) have all been used. Lifelong dietary therapy is often required to control clinical signs in longstanding colitis cases.

Assess and Select the Food

Levels of key nutritional factors in foods currently fed to patients with colitis should be evaluated and compared with recommended levels. Information from this aspect of assessment is essential for making any changes to foods currently provided. Changing to a more appropriate food is indicated if the current food does not match recommended levels.

Withholding food for one to two days and then reintroducing either a highly digestible or fiber-enhanced food is often palliative in managing acute colitis. After feeding the highly digestible or fiber-enhanced food for another three to four days, the pet's regular food may be reintroduced over another three-day period. Further workup is recommended if colitis recurs when the regular food is reintroduced.

Three types of food can be used to manage chronic colitis and they may be attempted in any order: 1) fiber-enhanced foods 2) highly digestible, low-residue foods formulated for GI disease and 3) elimination foods. Alternatively, fiber supplementation can be used in conjunction with the patient's original food. The optimal fiber level is determined by trial and error. There is no physical examination finding, laboratory test or historical fact to predict which method will be successful in any one patient. Dietary trials are often needed to determine which food type works best for individual patients. **Tables 62-2** through **62-5** list selected veterinary therapeutic foods for colitis management for dogs and cats, respectively. These tables compare the key nutritional content of selected veterinary therapeutic foods to the key nutritional factor target levels. Alternatively, homemade foods can be prepared. Foods for extended feeding of puppies and kittens with colitis should also meet the nutritional requirements for growth.

Another option in chronic colitis is to use an elimination food with a limited number of highly digestible, novel protein sources or a protein hydrolysate (Tables 31-5 and 31-6 for dogs and cats, respectively). Commercial veterinary therapeutic foods and homemade foods that contain novel protein sources are often formulated from lamb, rabbit, venison, duck or fish and a highly digestible or unusual carbohydrate source or protein hydrolysates. All other possible dietary sources of protein and carbohydrate should be eliminated including treats, snacks, table foods, vitamin-mineral supplements and chewable/flavored medications (Chapter 31).

Assess and Determine the Feeding Method

A thorough assessment should include verification of the feeding method currently being used. Considerations include feeding frequency, amount fed, how the food is offered, access to other

food and who feeds the pet. In cases in which colitis is caused by exposure to garbage or inappropriate amounts or types of foods, avoiding foods other than the pet's regular food is recommended and will often prevent further occurrences. If the animal has a normal body condition score (2.5/5 to 3.5/5), the amount of food previously fed (energy basis) was probably appropriate.

Initially, patients with acute colitis should have all food withheld for 24 to 48 hours. After this period, patients should be offered small amounts of food several times (i.e., six to eight times) a day. If the pet tolerates food without a recurrence of diarrhea, the amount fed can be increased over three to four days until the animal is receiving its estimated daily energy requirement in two to three meals per day.

Initially, chronic colitis patients should be fed multiple small meals per day as indicated by acceptance and tolerance of the food. Meal size can be increased and meal frequency can be decreased as tolerated by the patient after clinical signs have been successfully managed for several weeks.

REASSESSMENT

The prognosis for recovery in most cases of acute colitis is good. Bouts of acute colitis often resolve within two to four days with conservative medical and nutritional management. Body weight should be recorded daily until recovery is complete. Changes in body weight from day to day usually reflect changes in hydration status rather than loss or gain of lean or adipose tissue. Further diagnostic testing is warranted if severe large bowel diarrhea persists, or if clinical signs indicative of concurrent small bowel disease become apparent, such as vomiting, hypoalbuminemia and melena.

Weekly recordings of body weight and condition and stool evaluations are useful for assessing patients with chronic colitis. Regaining or maintaining optimal body weight and condition, normal level of activity and alertness and absence of clinical signs are measures of successful dietary and medical management. The feeding method and amount fed can be adjusted as needed to maintain body weight and condition. Additional medical therapies should be considered if dietary therapy alone fails to improve stool quality and maintain body weight.

Dogs and cats presenting with multiple or recurrent episodes of large bowel diarrhea require further diagnostic workup and, most probably, a combination of dietary and medical therapies; however, parasitic causes should be ruled out or treated empirically before pursuing further diagnostics.

CASE 62-1

Chronic Diarrhea in an Irish Setter

Michael S. Leib, DVM, MS, Dipl. ACVIM (Internal Medicine)
Virginia-Maryland Regional College of Veterinary Medicine
Blacksburg, Virginia, USA

Patient Assessment

A two-and-one-half-year-old neutered female Irish setter was examined for a five-month history of worsening diarrhea. Initially, the dog produced one abnormal stool every four or five days but now had two abnormal stools daily. Diarrhea was accompanied by tenesmus, hematochezia and excess fecal mucus. Hookworm ova were found in a fecal flotation; however, therapy with an appropriate anthelmintic did not improve the clinical signs. No other parasites or ova were identified in three additional fecal flotations. The owner reported no obvious weight loss.

The dog was obtained as a stray after being hit by a car more than a year ago. It sustained an acetabular fracture that was managed conservatively. Three other dogs and four cats housed with this dog were clinically normal. The dog lived inside and was well supervised in a fenced yard.

Physical examination was normal except for the healed pelvic fracture noted on rectal palpation. Rectal mucosa felt normal and there was no evidence of sublumbar lymphadomegaly or intraluminal masses. Body weight was 30 kg with normal body condition (body condition score [BCS] 3/5).

Assess the Food and Feeding Method

A commercial dry grocery brand food (Ken-L-Ration Biskit[a]) and a commercial dry veterinary therapeutic food (Prescription Diet Canine i/d[b]) had been fed during the previous five months. No difference in the diarrhea was noted when the dog ate either food. Table food and other snacks were not offered. Water was available free choice.

Questions

1. Prepare a list of differential diagnoses for this patient.
2. Outline a diagnostic plan for this dog.

Answers and Discussion

1. The following conditions should be strongly considered: lymphoplasmacytic colitis (inflammatory large bowel disease), irritable bowel syndrome, histiocytic ulcerative colitis, neoplasia and whipworm infection. Idiopathic colitis or inflammatory bowel disease involving the colon is a common diagnosis made after biopsy specimens are obtained from dogs with chronic large bowel diarrhea and examined microscopically. The cause is unknown. The causes of irritable bowel syndrome are poorly understood but the disorder may result from psychological influences on the colon resulting in abnormal motility and signs of large bowel diarrhea. This dog was introduced into the household as a stray. Although the dog seemed to interact well with the seven other household pets, group-related social factors may have caused stress that contributed to the diarrhea. Histiocytic ulcerative colitis has been seen most commonly in boxers but can occur in other breeds. It is much less common than lymphoplasmacytic colitis. Neoplasia would be uncommon in a dog of this age although colonic lymphosarcoma may occur in young dogs. Whipworm infection is still possible despite the negative fecal evaluations for parasites. Other causes of chronic large bowel diarrhea include *Giardia* infection, eosinophilic colitis, cecal inversion, bacterial infection (*Yersinia* spp., *Salmonella* spp., others), histoplasmosis, pythiosis and protothecosis. These disorders should only be considered after exclusion of the more likely diagnoses listed above.
2. The diagnostic plan for this dog should include the following: fecal flotation with zinc sulfate, complete blood count, serum biochemistry profile, urinalysis and colonoscopy with collection of multiple mucosal biopsy specimens. The laboratory database will evaluate the dog's anesthetic risk and identify systemic diseases that may produce chronic diarrhea. However, the history and physical examination make systemic disease unlikely. Flexible colonoscopy allows visualization and biopsy of the entire colonic mucosa. Although four routine fecal flotations only identified hookworm ova on one occasion, this procedure is not sensitive for identification of *Giardia* cysts. *Giardia* infection commonly produces small bowel diarrhea but can occasionally cause large bowel signs. Zinc sulfate flotation or formol-ether sedimentation is necessary to identify *Giardia* cysts in feces. Whipworms shed ova intermittently; therefore, infection may be present despite multiple negative fecal examinations.

Progress Notes

Two fecal flotations using zinc sulfate failed to identify *Giardia* cysts or other parasite ova. Results of the complete blood count, serum biochemistry profile and urinalysis were normal except for mild eosinophilia (2,200/μl). The cecum, ascending, transverse and majority of the descending colon were normal during endoscopic examination. A small 0.5-cm bleeding erosion was noted 15

cm from the anus. Biopsy specimens were obtained from the ascending and transverse colon, from three normal appearing areas in the descending colon and from the eroded area 15 cm from the anus. Microscopically, the eroded region had mucosal ulceration and moderate mucosal infiltration with plasma cells and lymphocytes. All other biopsy specimens had moderate lymphoplasmacytic infiltration into the mucosa. Final diagnosis was lymphoplasmacytic colitis.

Further Questions

1. Outline a feeding plan for this dog.
2. What other therapy should be considered for this patient?

Answers and Discussion

1. Several different types of foods can be used in patients with large bowel disease. One strategy involves using a highly digestible, low-residue food to minimize the amount of ingesta entering the colon. Another strategy uses foods with moderate levels of fiber to alter colonic motility, increase production of volatile fatty acids and control pathogen growth by helping maintain normal colonic pH. A third strategy uses an elimination ("hypoallergenic") food (or one containing a protein hydrolysate) to decrease the amount of potential antigens absorbed by the colon. Ideal elimination foods have moderate levels of protein (i.e., avoid protein excess); have reduced numbers of novel, highly digestible protein sources; and avoid excess food additives and biogenic amines. A combination of these dietary strategies can also be tried. Although the etiopathogenesis of lymphoplasmacytic colitis is unknown, limiting exposure of the colonic mucosa to potential antigens is considered an important part of the feeding plan. Use of an elimination food (or one containing a protein hydrolysate) is often the first choice in these cases. Access to table food, snacks and food for other household pets should be avoided. Therapeutic trials with several different food types and careful monitoring are necessary for optimal case management. The food should be fed in an appropriate amount for the animal's body condition and activity level. For this dog, the daily energy requirement was estimated to be 1.6 x resting energy requirement (1,550 kcal [6.49 MJ]).
2. Medical management of chronic colitis also includes antiinflammatory and immunosuppressive drugs (mesalamine, sulfasalazine [sulfapyridine and mesalamine], olsalazine, prednisone, azathioprine) and antimicrobial agents (metronidazole, sulfasalazine, tylosin, other antibiotics). Changing the environment to alleviate stressful situations may also benefit some patients in which irritable bowel syndrome is a complicating factor.

Progress Notes

The dog was fed a commercial dry veterinary therapeutic food, i.e., a novel protein food (Prescription Diet Canine d/d Rice and Duck[b]) for six weeks. The dog was fed two cups twice daily. The owner reported only two bouts of diarrhea during this period. The dog was eating the food readily and maintaining normal body weight and condition.

Flexible colonoscopy was again performed. Friable, granular mucosa was observed around the ileocolic junction and in the descending colon. Erosions were not seen. Histopathologic evaluation of biopsy specimens revealed moderate lymphoplasmacytic colitis with an increased eosinophilic component compared with specimens from previous biopsy sites. The feeding plan was not changed but therapy with sulfasalazine[c] (1 g, t.i.d.) was instituted. Although clinical signs were eliminated, tear production gradually decreased over the next six months. Keratoconjunctivitis sicca is a common side effect of prolonged therapy with sulfa drugs. The dose of sulfasalazine was tapered and increased tear production occurred but intermittent diarrhea also returned. Therapy with oral prednisone was initiated (40 mg every 24 hours) and the dose slowly tapered. Oral administration of 10 mg prednisone every 48 hours in conjunction with the feeding plan controlled most of the clinical signs. Stressful circumstances still caused intermittent diarrhea.

Dr. Bernhard Berliner (1938)

CLINICAL IMPORTANCE

Idiopathic (irritable) bowel syndrome (IBS) is a poorly defined functional bowel disorder of people and animals believed to be caused by gastrointestinal (GI) dysmotility. IBS is also called spastic colon, nervous colon, spastic colitis and mucous colitis. In people, IBS is a disease entity characterized by recurrent abdominal pain or discomfort associated with altered bowel movements (constipation and diarrhea), in which no obvious histopathologic lesion is identifiable (Halvorson et al, 2006). The postulated pathogenesis for IBS includes abnormalities of GI motility, visceral sensations, the brain and gut complex, personality and postepisodic infections in the colonic mucosa (Hongo and Sato, 2006). It is one of the most common GI complaints in human medicine with random population surveys indicating 12 to 15% of adults are affected (Jones and Lydeard, 1992; Talley et al, 1992; Camilleri and Choi, 1997). In veterinary medicine, IBS is a catchall term for a chronic large bowel disorder of presumed functional origin (Willard, 2003). This disorder is thought to occur far less commonly in pets than in people; however, it has been reported to account for 5 to 17% of large bowel disorders in dogs (Guilford, 1996; Henroteaux, 1990). IBS has not been recognized in cats.

PATIENT ASSESSMENT

History and Physical Examination

Dogs with IBS have chronic, intermittent bouts of diarrhea that are predominantly large bowel in character. Frequent, small-volume, fluid stools containing mucus are reported. Occasionally, explosive bouts of diarrhea and flatus may occur, often in association with abdominal pain. The intermittent diarrhea is often accompanied with varying signs of bloating, nausea, vomiting, dyschezia and tenesmus. Rarely, hematochezia may be seen. Some dogs have abdominal pain that is relieved by eating, eructation or defecation. Borborygmus, belching and flatus are frequent complaints in IBS. Typically, signs are variable and may change from bout to bout.

In some cases, GI signs can be linked to identifiable stressors. A thorough history may elicit such stress-causing variables as showing, work, boarding or changes in the home environment (e.g., owner anxiety, new spouse, child, pet, house or apartment).

Table 63-1. Diagnostic criteria for the irritable bowel syndrome in people.*

Abdominal pain or discomfort, relieved by defecation and/or associated with a change in stool frequency and/or consistency
Altered stool form
Altered stool frequency
Altered stool passage
An irregular pattern of defecation at least 25% of the time
Bloating or feeling of abdominal distention
Passage of mucus
Continuous or recurrent symptoms for at least three months
*Adapted from Thompson WG, Longstreth GF, Drossman DA. Functional bowel disorders and functional abdominal pain. In: Drossman DA, Corrazziara E., Talley NJ, et al, eds. The Functional Gastrointestinal Disorders: Diagnosis, Pathophysiology, and Treatment, 2nd ed. McLean, VA: Degnon, 2000; 351-375.

Table 63-2. Myoelectric and motility abnormalities prominent in people with irritable bowel syndrome.*

Clustered contractions in the small bowel
Delayed but prolonged colonic hypermotility in response to ingestion of food, particularly fats
Increased colonic motility and abdominal pain in response to cholecystokinin
Increased colonic motor activity in response to low concentrations of bile acids
Increased frequency of basal electrical rhythm
Lowered gastroesophageal sphincter pressure
Pronounced colonic hypermotility in response to cholinergic agents
Small bowel transit rate is faster when diarrhea is predominant
Small bowel transit rate is slower when constipation is predominant
Spastic response to rectal distention
*Adapted from Guilford WG. Motility disorders of the bowel. In: Guilford WG, Center SA, Strombeck DR, et al, eds. Strombeck's Small Animal Gastroenterology, 3rd ed. Philadelphia, PA: WB Saunders Co, 1996; 533.

Table 63-3. Key nutritional factors for foods for dogs with idiopathic bowel syndrome.*

Factors	Recommended levels
Soluble fiber**	1 to 5%
Mixed fiber**	5 to 10%
Insoluble fiber**	10 to 15%
Crude fiber***	≥8%

*All values are on a dry matter basis.
**Any one of the three types of fiber listed at the recommended levels can be effective, depending on patient response. See Chapter 5 and Figures 5-12 and 5-13 for more information about dietary fiber types and associated ingredient sources.
***Crude fiber is the only fiber value readily available for pet foods.

Generally, dogs with IBS are in good physical condition and do not exhibit weight loss or poor body condition as is often associated with organic GI disorders (e.g., inflammatory or infectious causes). Affected dogs may exhibit discomfort during abdominal palpation if examined during an acute episode of GI distress. Rectal examination may reveal mucoid feces.

Laboratory and Other Clinical Information

In IBS, colonic dysfunction exists in the absence of structural, biochemical or microbiologic lesions and therefore is a diagnosis of exclusion following an appropriate diagnostic workup (Leib, 2004). Results of routine laboratory tests are usually normal in dogs with IBS. Radiography and colonoscopy are rarely useful in the diagnosis of IBS other than as a tool to rule out organic disorders, because the findings are usually within normal limits. A consistent set of diagnostic criteria has been established for people based on numerous epidemiologic and pathophysiologic investigations (**Table 63-1**) (Zighelboim and Talley, 1993; Horwitz and Fisher, 2001). Clinical criteria have not been standardized in dogs. The diagnosis of IBS is applied to those dogs with the clinical signs and history in which other, more common organic causes have been ruled out.

Risk Factors

In people, IBS occurs three times as commonly in women than men and is often associated with diagnoses of other conditions such as fibromyalgia, interstitial cystitis and psychiatric disorders (Horwitz and Fisher, 2001). In veterinary patients, there is no known gender predilection for IBS. The condition is recognized most commonly in large working breeds (police and military dogs, drug- and bomb-sniffing dogs, search and rescue dogs and handicap assistance dogs) and small, nervous toy breeds. Any dog with a nervous, excitable temperament and/or a behavioral disorder such as separation anxiety seems predisposed to IBS. Abnormal personality traits, nervousness or stressors have been identified as preceding bouts of chronic idiopathic large bowel diarrhea in approximately 40% of IBS cases (Leib, 2000). The diagnosis of IBS should be strictly reserved for those cases in which no abnormalities have been found histologically. Intestinal biopsy specimens are normal in IBS patients (Tams, 2001).

Etiopathogenesis

The etiology of IBS is not defined; however, balloon distention, manometric and motility studies in people suggest disordered GI motility and visceral hyperresponsiveness to stimuli. Recent studies have suggested that neurotransmitter imbalances may be involved in IBS pathogenesis (Horwitz and Fisher, 2001). Additionally, IBS has been reported to occur as a sequelae to infectious enteritis (i.e., salmonellosis, dysentery) (Horwitz and Fisher, 2001). Comparable research has not been performed in dogs. The relationship of stress to the myoelectric and motility abnormalities present in IBS is not completely understood (**Table 63-2**). However, psychological stress can trigger hypermotility. In addition, the effect of central nervous system neuropeptides (e.g., cholecystokinin, serotonin, acetylcholine, vasoactive intestinal peptide and substance P) on GI motility and visceral sensitivity has been recognized (Tache et al, 1990). For example, cholecystokinin infusions promote colonic hypermotility and abdominal pain in patients with IBS.

Key Nutritional Factor: Fiber

Reports suggest that many canine and feline patients with IBS improved clinically when dietary fiber intake was increased

Box 63-1. Medical Therapy to be Considered for Concurrent Use with Appropriate Dietary Management for Dogs with Idiopathic Bowel Syndrome.

Most patients diagnosed with idiopathic bowel syndrome (IBS) respond favorably to increased intake of dietary fiber and can be managed successfully long term with appropriate food and intermittent pharmacotherapy. Medical treatment generally includes, either individually or in combination, antidiarrheal drugs, anticholinergics and tranquilizers.

Pharmacotherapy for diarrhea-predominant IBS includes use of motility-modifying drugs such as loperamide at 0.2 to 0.5 mg/lb, per os, or diphenoxylate at 0.1 to 0.22 mg/lb, per os, b.i.d. Loperamide is a potent antidiarrheal drug that decreases intestinal secretions, enhances absorption, stimulates rhythmic segmental contractions and increases anal sphincter tone. Stool consistency often improves significantly and pain and urgency abate after loperamide therapy. Although loperamide can be used safely on a long-term basis, several days to one to two weeks of therapy is often sufficient to normalize stools. After the first several days of therapy, it may be possible to decrease administration to once or twice daily.

Patients with signs of abdominal pain (e.g., cramping, bloating, assuming an arched-back stance, reluctance to move, loud abdominal gurgling sounds) or those with signs of general distress (e.g., pacing) can be treated with antispasmodics or combination antispasmodic-tranquilizer preparations. Antispasmodics reduce smooth muscle contractility. Abdominal pain can often be relieved by antispasmodic agents and the effects of stressors can be reduced by sedatives. Librax[a] contains the sedative chlordiazepoxide (5 mg) and an anticholinergic agent clidinium bromide (2.5 mg). The dose of Librax is 0.2 to 0.5 mg/lb of clidinium, per os, b.i.d. or t.i.d. Chlordiazepoxide is a benzodiazepine with peripheral smooth-muscle relaxant properties and central nervous system effects. This combination seems to be especially effective in relieving the discomfort that may be associated with increased colonic motor function. The drug can be given when the owner first notices that the patient has signs of abdominal pain or diarrhea or when stressful conditions are encountered and can usually be discontinued after a few days. Long-term use may be necessary (one to two doses daily) in patients affected by unpredictable flare-ups of abdominal distress.

Other anticholinergics such as propantheline (0.25 mg/kg, per os, b.i.d. or t.i.d.), hyoscyamine (0.003 to 0.006 mg/kg, per os, b.i.d. or t.i.d.) or dicyclomine (0.15 mg/kg, per os, b.i.d. or t.i.d.) have been suggested. Anticholinergics can decrease or inhibit gastrointestinal motility, which may worsen diarrhea. In people, side effects include xerostomia, urinary retention, blurred vision, headache, psychosis, nervousness and drowsiness.

Combination therapy (e.g., loperamide plus clidinium/chlordiazepoxide) may be necessary in some patients with diarrhea and abdominal pain. Sulfasalazine, especially when used in combination with loperamide or clidinium, sometimes provides symptomatic relief in patients with significant dyschezia and increased evacuation of small volumes of loose, mucoid stool. This response has been observed in patients in which multiple colon biopsy specimens and careful evaluation for pathogenic intestinal organisms have proved negative. Likewise, H_2-receptor blockers such as famotidine at dosages of 0.25 to 0.5 mg/lb, per os, every 24 hours, used in combination with clidinium or isopropamide, may provide better control of IBS-related nausea or vomiting than either drug alone.

The novel use of peppermint oil for the relief of pain in pediatric human patients with IBS has been reported. In randomized, placebo-controlled trials, enteric-coated peppermint oil capsules were found to relieve pain in 75% of affected patients. This treatment has not been evaluated in veterinary medicine.

ENDNOTE

(Leib, 1997, 2004; Guilford, 1996; Leib et al, 1997; Tams, 1992, 2001; Willard, 2003). Increasing dietary fiber alters fecal water content, colonic motility, intestinal transit time and gut microbial populations, all of which may benefit patients with IBS. Patients have been reported to respond to foods containing small amounts of soluble fiber (1 to 5% dry matter [DM]) or moderate amounts of insoluble fiber (10 to 15% DM) (Leib, 1997; Leib and Matz, 1995; Guilford, 1996; Leib et al, 1997; Tams, 2001; Willard, 2003). Foods with 5 to 10% DM mixed (insoluble and soluble) fiber sources are also recommended. However, from a practical matter, obtaining food content of the various fiber types is difficult. Typically, crude fiber values and ingredient lists are all that are available. Thus, it is recommended that foods for patients with IBS contain moderate amounts (≥8% DM) of crude fiber. Ingredient lists may provide information about the predominate type of fiber. Insoluble fiber sources include cellulose and peanut hulls. Soluble fiber sources include citrus and apple pectins, psyllium and gums. Rice bran, oat bran, wheat bran, soy fibers, soy hulls, pea fiber and beet pulp are sources of mixed fibers. Combinations of insoluble and soluble fiber sources would also be considered as mixed fibers. For a more detailed discussion of fiber types, see Chapter 5 and Figures 5-12 and 5-13. **Table 63-3** summarizes the recommended fiber types and levels for dogs with IBS.

FEEDING PLAN

Dietary management may not completely control IBS but is integral to comprehensive management of the condition. Appropriate dietary management can reduce the frequency and severity of clinical signs, either alone or in combination with medical treatment (psychotropic and GI antispasmodic drugs may be beneficial [**Box 63-1**]. Along with dietary and medical management, stressful events that trigger diarrheic episodes should be eliminated or reduced.

Table 63-4. Key nutritional factors in selected veterinary therapeutic foods for dogs with idiopathic bowel syndrome.*

Dry foods	Crude fiber (%)	Primary sources of fiber

Assess and Select the Food

The principle key nutritional factor for dogs with IBS is dietary fiber. **Table 63-4** lists selected veterinary therapeutic foods with increased levels of fiber that should be considered for dogs with IBS. Changing to a more appropriate food is indicated if the current food's level of fiber is low and/or the type of fiber it contains (i.e., soluble, insoluble or mixed) is unknown. In the event that the fiber content of the food currently being fed is within the recommended ranges, changing to a different food should still be considered. However, the most effective combination of fiber type and level cannot be predicted. These factors are determined by trial and error, on a patient-by-patient basis.

The veterinary therapeutic foods listed in **Table 63-4** include a variety of fiber types and concentrations. Clinicians should become familiar with several of these foods and work closely with the owner to determine the food composition that works best for each individual patient. One approach is to begin with a product containing mixed-fiber types (combination of insoluble and soluble fibers, e.g., brans, soy fibers, pea fiber, beet pulp). If the patient is unresponsive, other food choices should be considered with either soluble or insoluble types of fiber. Figures 5-12 and 5-13 provide information about the solubility of various fiber ingredients. Foods other than those determined to control the clinical signs should be strictly avoided for dogs in which recurring bouts are initiated by food changes, access to garbage or feeding table foods, treats or snacks.

If it is impractical to change the patient's food (e.g., pet owner bias) or if the food currently being fed is necessary for the management of concurrent medical conditions, fiber can be added to the current food. Moist foods are more suitable for fiber supplementation. Separation of fiber sources from kibbles of dry foods can be problematic. Moistening a fiber supplement before adding it to dry food or wetting a dry food before adding the fiber supplement may help. Excessively high levels of fiber added to a food may make the food unpalatable and/or unbalanced. Do not exceed recommended supplemental levels.

Soluble fiber supplementation can be achieved by adding psyllium-husk powder (e.g., Metamucil[a]) to the patient's regular food. The recommended daily starting dose is 1.3 g psyllium powder/kg body weight. This is equivalent to approximately 6 tsp of psyllium powder per 30 lb (13.9 kg) body weight/day (Leib, 2000, 2004). Soluble fiber improves stool quality and supports butyrate production for colonocyte health. However, soluble fiber may not sufficiently alter the underlying motility abnormalities thought to be involved in IBS. Exceeding more than 20%, or one part fiber supplement to five parts food, is not advisable.

High-fiber human breakfast cereals (e.g., Fiber One Bran Cereal[b]) can be used to increase the patient's insoluble fiber intake (Chapter 5, Case 5-1). The recommended starting dose of this fiber source is 0.5 g/kg body weight/day or 1 level tsp/30 lb (13.6 kg) body weight/day. Exceeding more than 5 tsp/30 lb body weight/day is not advisable. Insoluble fiber binds water, increases the bulk of the stool and improves intestinal motility.

Regardless of the supplemental fiber source, adding fiber should be done systematically based on a recommended fiber dose and the patient's response. The supplemental fiber source should be added in small amounts and increased by increments of 25% of the starting dose, every two weeks, until clinical signs improve or resolve. In some cases, the initial addition of a fiber supplement may increase the severity of clinical signs. If this happens, the fiber supplement should be discontinued immediately because clinical signs are unlikely to improve with time.

Assess and Determine the Feeding Method

When switching to a new food, do so gradually over a period of several days. When meal feeding, offering the food once or twice daily is usually sufficient; however, three to four meals per day may be necessary in some cases to minimize the amount of digesta passing into the large bowel at one time. If the patient has a normal body condition score (2.5/5 to 3.5/5), the amount of food previously fed (energy basis) was appropriate. Thus, the same amount of calories of the new food would be a good starting place for the amount to feed.

REASSESSMENT

Regular body weight and condition assessment and stool evaluations are useful for monitoring patients with IBS. Well-compensated patients should be evaluated immediately if a change or decline in condition is noted. Maintaining optimal body weight and condition, normal activity level and behavior and absence of clinical signs are measures of successful dietary and medical management. The feeding method and amount fed can be adjusted as needed to maintain body weight and condition. Additional medical therapy (**Box 63-1**) should be considered if dietary therapy alone is insufficient to improve stool quality and maintain body weight and condition. Finally, the patient's home life should be evaluated in an effort to identify the stressors, if any exist, and then these should be alleviated whenever possible. Clinicians are reminded that being available for communication and providing guidance to clients whose pets are afflicted by the unpredictable clinical signs of IBS are essential to successful management (Tams, 2001).

Chapter 64

Constipation/ Obstipation/Megacolon

Deborah J. Davenport

Rebecca L. Remillard

Maureen Carroll

"Austerity causes constipation; excess, diarrhea."
Mason Cooley, City Aphorisms, Twelfth Selection, New York, 1993

CLINICAL IMPORTANCE

The term constipation is applied to those patients that pass stools infrequently or exhibit tenesmus in association with defecation. Constipation is a clinical sign, not a disease, and may result from several disorders, separately or in combination. Constipation is not easily assessed in dogs and cats because it is often difficult to obtain accurate information about their defecation habits. However, constipation appears to be far less common in veterinary medicine than in human medicine. In people, it is the number one gastrointestinal (GI) complaint, accounting for more than 2 million physician visits each year in the United States (Sweeney, 1997; Lembo and Camilleri, 2003).

Obstipation is severe constipation that requires medical therapy in addition to dietary management for relief. The term megacolon refers to anatomic dilatation of the colon. Feline idiopathic megacolon is a frustrating, chronic, recurring problem that often results in euthanasia of affected patients. A similar condition occurs in dogs although it is relatively rare. Megacolon in dogs is usually seen as a consequence of severe chronic constipation resulting from obstruction (e.g., perineal hernias, stenosis of the pelvic canal or pelvic fracture malunion) and/or an underlying innervation defect. In cats, the pathogenesis of idiopathic megacolon remains unclear but appears to result from a generalized abnormality of colonic smooth muscle function (Washabau and Sammarco, 1996; Washabau et al, 2002; Byers et al, 2006).

PATIENT ASSESSMENT

History and Physical Examination

Dogs and cats with constipation typically exhibit tenesmus, dyschezia and abdominal pain. Chronically affected animals may present with systemic signs of illness including weight loss, inappetence, vomiting and depression.

Constipated cats are usually presented for reduced, absent or painful defecation for a period ranging from days to weeks or months. Some cats are observed making multiple, unproductive attempts to defecate in the litter box, whereas other cats may sit in the litter box for prolonged periods without assuming a defecation posture. Dry, hardened feces are seen inside and outside of the litter box. Occasionally, chronically constipated cats have

Table 64-1. Drugs associated with constipation.*

Antacids	Bismuth subsalicylate

Anticonvulsants (phenytoin)	Hematinics
Antidepressants	Opiates
Barium sulfate	Sucralfate

*Dimski DS. Constipation: Pathophysiology, diagnostic approach and treatment. Seminars in Veterinary Medicine and Surgery: Small Animal 1989; 4: 247-254.

intermittent episodes of hematochezia or diarrhea due to colonic mucosal irritation, which may give the owner the erroneous impression that diarrhea is the primary problem.

Cats with megacolon are usually presented for repeated episodes of constipation or obstipation. Although it is common for obese cats to present for constipation, chronically obstipated animals often exhibit weight loss and poor body condition. Prolonged inability to defecate may result in other systemic signs, including anorexia, lethargy, vomiting and poor coat quality (Washabau, 2001, 2005; Washabau and Holt, 1999; Bertoy, 2002). Owners of constipated pets should be questioned about medications their pet is receiving because a number of commonly used drugs are associated with constipation (**Table 64-1**). In addition, consumption of bones and raw foods has been associated with constipation and obstipation in dogs. Lastly, owners should be questioned regarding potential exposure to lead because lead poisoning can result in constipation. Consumption of lead-based paint chips and glazed ceramic food bowls are potential sources.

Depression and dehydration may be noted at physical examination of constipated animals. Abdominal palpation often reveals colonic distention and the presence of dry hard feces. Digital rectal examination may also confirm dry hard feces. Rectal examination may also reveal foreign bodies, rectal neoplasia or a reduction in the pelvic inlet due to a previous pelvic fracture. Anal sac disease, perianal fistulas and perineal hernias may be visualized upon examination of the perineum. In dysautonomia, constipation will be accompanied by other autonomic signs including mydriasis, distended urinary bladder, dysphagia, prolapsed nictitans and dry mucous membranes (Lyons, 1998).

Laboratory and Other Clinical Findings

Most constipated pets do not require diagnostic evaluation beyond a careful history and physical examination and the appropriate exclusion of systemic and GI causes. However, all obstipated and chronically constipated pets should have a workup that includes a complete blood count, biochemistry profile, urinalysis, thyroxine analysis and abdominal radiography. Further diagnostic evaluation may require abdominal ultrasound, GI contrast studies and/or colonoscopy.

Risk Factors

In cats, constipation occurs most commonly in middle-aged (mean = 5.8 years), male cats (70%) of domestic shorthair (46%), domestic longhair (15%) or Siamese (12%) breeding. A review of obstipation in cats (Washabau, 2001) revealed 62% of cases were due to idiopathic megacolon, 23% to pelvic canal stenosis and 6% to nerve injury with most related to Manx sacral spinal cord deformity. The remaining cases (4%) were due to complications of colopexy (1%), colonic neoplasia (1%) and suspected colonic hypo- or aganglionosis (2%). Inflammatory, pharmacologic and environmental/behavioral causes were not cited as predisposing factors in any of the original case reports in this review (Washabau, 2001). Endocrine factors including obesity were noted in several cases, but were not acknowledged as the etiology of megacolon. Although it is important to consider an extensive list of differential diagnoses in individual cats, it should be kept in mind that most cases are idiopathic, orthopedic or neurologic in origin.

The use of opioid narcotics for pain or control of GI transit time has long been recognized to cause constipation. The constipating effect of narcotic analgesics is well known but its mechanisms are poorly understood. Postulated mechanisms include decreased intestinal water, increased rhythmic segmentation and delayed colonic transit. Several other commonly used medications, including barium sulfate, bismuth subsalicylate and anticonvulsants, also have constipating effects.

Dietary indiscretion is frequently associated with constipation in dogs. Consumption of bones, rocks and clay may trigger an episode. Constipation and obstipation have been reported to occur in dogs consuming bones and raw food diets due to the large contribution bones make to such foods. Although not generally prone to dietary indiscretion, cats may develop constipation as a consequence of trichobezoar formation.

Perineal and perianal disorders (e.g., perineal hernias, perianal fistulas and anal sacculitis) often predispose pets to constipation because of the pain associated with defecation (**Box 64-1**). Suppression of defecation results in increased fecal retention time, increased water absorption and inspissated feces. Orthopedic disorders may have a similar effect if the animal experiences pain when it assumes the defecation stance. Improperly healed pelvic fractures may reduce the size of the pelvic inlet and impinge on the rectal lumen.

Lastly, lead exposure may lead to constipation in affected animals presumably due to autonomic nervous system damage.

Etiopathogenesis

It is important to consider an extensive list of differential diagnoses (e.g., neuromuscular, mechanical, inflammatory, metabolic/endocrine, pharmacologic, environmental and behavioral causes) for the obstipated patient (Byers et al, 2006; Bertoy, 2002; Washabu and Holt, 1999). The parasympathetic nervous system and intrinsic myenteric and submucosal plexuses innervate the colon. Destruction or damage to either pathway results in reduced colonic motility and potentiates constipation. Normal colonic motility involves both propulsive and non-propulsive patterns. Ingesta, digesta and associated somatic activity stimulate propulsive contractions, which serve to move colonic contents distally. Non-propulsive motility, also termed rhythmic segmentation, mixes colonic contents and promotes absorption of water and electrolytes.

Box 64-1. Dietary Management of Perianal Fistulas in Dogs.

The perianal fistula syndrome (anal furunculosis) is a frustrating problem for pet owners and veterinarians. Although uncommon in the general canine population, it is commonly seen in the German shepherd dog. This condition is often recurrent or refractory to treatment and may lead to elective euthanasia. The etiology of perianal fistulas is unknown, although it is suspected to be immune-mediated. Immunohistochemical studies of tissues from affected dogs support this concept. These tissues had T-helper cell cytokine mRNA profiles and increased expression of matrix metalloproteinases 9 and 13, which are primarily produced in macrophages. Reports of the successful use of immunosuppressive drugs, including prednisone and cyclosporine, and elimination foods in affected dogs lend credence to the idea that the condition is immune mediated. Concurrent lymphoplasmacytic colitis is found in the majority of dogs with perianal fistulas, although it is unknown if these conditions are causally linked.

Dietary treatments for perianal fistula patients are highly case specific and dependent on the degree of diarrhea, constipation, tenesmus and rectal stricture that may be present. Success with dietary therapy can be unpredictable, and it is often trial and error to discover which dietary maneuver will succeed in a particular patient. The feeding plan is used in conjunction with immunosuppressive agents and stool softeners, depending on the degree of rectal stricture. The preferred therapy for perianal fistula is immunosuppressive therapy, with the greatest success occurring with cyclosporine therapy. This is the preferred therapy in severe disease and when rectal stricture is present. Other options include systemic prednisone and azathioprine or topical tacrolimus administration. The reader is referred to medical texts for more information. When medical management is not successful or there are residual fistulas, surgical resection of necrotic, inflamed tracts is necessary. The most successful surgical procedures involve cryotherapy or the use of the Nd:YAG laser; other surgical techniques have high complication and recurrence rates. Interested readers are referred to surgical texts for more information.

The signs of large bowel diarrhea associated with perianal fistula are sometimes managed successfully by increasing the insoluble fiber content of the food. If the current food contains less than 5% dry matter (DM) crude fiber, insoluble fiber is the first treatment of choice because it increases fecal bulk and improves transit time. However, it is prudent to increase the DM fiber concentration in increments of 5% per week until clinical signs resolve; increasing fiber intake too rapidly may result in pain and obstipation. This can be done by mixing the patient's current food with a high-fiber food, in a manner recommended for a gradual transition from one food to another. Another successful approach, especially when rectal stricture is present, is to use a lower residue food containing a mixed-fiber source. Low-residue foods may contain either little or no (<2% DM) crude fiber or use predominately soluble or fermentable fiber (<5% DM total dietary fiber).

Novel antigen diets have been suggested for managing dogs with perianal fistulas. This approach was used successfully in 18 of 27 (67%) dogs also receiving immunosuppressive doses of corticosteroids. Chapter 31 discusses elimination foods.

Some investigators have speculated that omega-3 (n-3) fatty acids derived from fish oil or other sources may have a beneficial effect in controlling inflammation associated with perianal fistulas. Chapter 57 provides more information about omega-3 fatty acids.

Some dogs with perianal fistulas may benefit from small, frequent meals in conjunction with exercise to encourage more frequent defecation.

Body weight and condition determinations and stool evaluations are useful for assessing patients with perianal fistulas. Patients should be evaluated immediately if a change or decline in body weight or condition is noted. Regaining or maintaining optimal body weight and condition, normal activity level, normal behavior and absence of clinical signs are measures of successful management. Feeding method and amount fed, as tolerated by the patient, can be adjusted as needed to maintain body weight and condition. If dietary therapy alone is insufficient to improve stool quality and maintain body weight, additional medical or surgical therapy should be considered. Unfortunately, recurrence is common and prolonged medical therapy and multiple surgeries may be necessary. Many affected dogs are eventually euthanized because of client frustration with repeated bouts of the disease or the cost of continuous medical therapy.

The Bibliography for **Box 64-1** can be found at www.markmorris.org.

The pathogenesis of feline idiopathic megacolon has been variably attributed to primary neurogenic or degenerative neuromuscular disorders. Although a small number of cases (11%) result from neurologic disease, the vast majority (>60%) of cases have no evidence of neurologic disease (Washabau, 2001; Washabau and Holt, 1999). These cases may involve disturbances of colonic smooth muscle; in vitro studies suggest that colonic smooth muscle function is impaired in cats affected with idiopathic megacolon (Washabau and Sammarco, 1996; Washabau et al, 2002).

Isometric stress measurements (in vitro) were performed on colonic smooth muscle segments obtained from cats suffering from idiopathic dilated megacolon. Megacolonic smooth muscle developed less isometric stress in response to neurotransmitters (acetylcholine, substance P, cholecystokinin), membrane depolarization (potassium chloride) and electrical field stimulation, when compared to muscle from healthy controls. These differences were observed in longitudinal and circular smooth muscle from both the ascending and descending colon. No significant abnormalities of smooth muscle cells or of myenteric neurons were observed histologically. These studies suggested that feline idiopathic megacolon is a generalized dysfunction of colonic smooth muscle, and that treatments aimed at stimulating colonic smooth muscle contraction might improve colonic motility (Washabau and Sammarco, 1996).

Dehydration and electrolyte imbalances may induce constipation. Dehydration enhances colonic water absorption and leaves a dry, hard fecal mass. For example, cats with chronic

Table 64-2. Key nutritional factors and their recommended levels for foods for patients with chronic constipation or obstipation.*

Factors	Recommended levels
Water	>75% for cats and dogs with constipation or obstipation (moist foods)
Fiber	≥7% crude fiber (insoluble or mixed is best) for cats and dogs with chronic constipation and intermittent obstipation ≤5% for cats with chronic obstipation (megacolon)
Digestibility	Highly digestibility for cats with chronic obstipation (megacolon) (fat and digestible carbohydrate ≥90% and protein ≥87%)
Energy density	≥4 kcal/g for cats with chronic obstipation (megacolon)

*All values are on a dry matter basis except water; to convert kcal to kJ, multiply kcal by 4.184.

kidney disease may have intermittent constipation associated with dehydration. Electrolyte disturbances (e.g., hyponatremia, hypokalemia, hypocalcemia and hypercalcemia) may alter colonic muscular activity resulting in constipation.

Mechanical obstruction may result in constipation due to intraluminal or extraluminal masses, rectal strictures and narrow pelvic outlets (e.g., improperly healed pelvic fractures). Additionally, a number of neurologic disorders may result in reduced colonic motility. These include cauda equina syndrome, dysautonomia (Key-Gaskell syndrome) and diabetic or hypothyroid polyneuropathy.

Key Nutritional Factors

Key nutritional factors for chronic constipation differ from key nutritional factors for obstipation. **Table 64-2** summarizes key nutritional factors for constipation and obstipation.

Water

Maintaining normal hydration status is important for managing patients with chronic constipation or obstipation. Water is a key nutrient and its intake is often overlooked. A variety of methods should be used to encourage water intake. These include providing multiple bowls of potable water in prominent locations in the pet's environment, feeding moist (>75% water) rather than dry forms of foods, adding small amounts of flavoring substances such as bouillon or broth to water sources and offering ice cubes as treats or snacks. Addition of canned pumpkin and/or sweet potato to the current food has been successfully used in some cases of constipation.[a] These canned vegetables consist primarily of water (90%), which adds a significant quantity of water to the digesta. Beneficial effects resulting from canned pumpkin or sweet potato are likely the result of an increase in total daily water consumption, although fiber intake is also increased.

Fiber

Many patients with constipation improve clinically when the fiber content of their food is increased. Dietary fibers are poorly digestible polysaccharides, derived from a variety of sources. Fiber sources typically used in commercial pet foods include sugar beet pulp, cereal grains, cellulose, soy hulls, peanut hulls and pea fiber. Increasing fiber intake usually increases fecal water content, colonic motility and intestinal transit rate, all of which may benefit patients with constipation. Both fermentable and non-fermentable fiber sources have been advocated for the management of constipation (Dimski, 1989; Zoran, 1999). Fiber acts as a bulk-forming laxative. Insoluble (poorly fermentable) fibers (e.g., purified cellulose, peanut hulls) normalize colonic motility by distending the colonic lumen, increasing colonic water content, diluting luminal toxins (e.g., bile acids, ammonia and ingested toxins) and increasing the rate of passage of digesta. This change in colonic transit time reduces colonocyte exposure to toxins while softening the stool and increasing the frequency of defecation. Several gel-forming fibers have been recommended as an aid in managing constipation in people (Wald, 1998) and animals (Dimski, 1989). Soluble (fermentable) fibers (fruit pectins, guar gum, psyllium) are readily fermented by bacteria, producing short-chain fatty acids, which benefit colonic health. These fibers, whether added to or incorporated into food, are reported to swell to form emollient gels and facilitate passage of fecal matter (Dimkski, 1989; Lembo and Camilleri, 2003). However, fermentable fibers may not be as laxative as insoluble or mixed fibers because they have little ability to increase fecal bulk or dilute luminal toxins (Washabau, 2005a). Flatulence, diarrhea and abdominal cramping are potential side effects to fermentable, gel-forming fibers. These side effects can be reduced by a gradual transition to fiber supplementation, slowly increasing the level of added fermentable fiber until efficacy is achieved with minimal side effects. Such fibers should be added at no more than 5% of the total food because soluble fibers can significantly reduce the availability of minerals, including zinc, calcium, iron and phosphorus (Wedekind et al, 1995, 1996, 1996a) (Chapter 5).

Ingredients such as beet pulp, brans (rice, wheat or oat), pea fiber, soy fibers, soy hulls or mixtures of soluble and insoluble fiber sources are intermediate in their fermentability and have moderate attributes of both fermentable and poorly fermentable fibers (Figure 5-13). They are referred to as mixed fibers.

For patients with chronic constipation that still have some level of colonic motility, the crude fiber content of a food should be at least 7% dry matter (DM) initially and the fiber source should be insoluble or mixed.

Fiber sources can be added to a patient's current food (**Box 64-2**), but it is generally better to switch to a fiber-enhanced food. Feeding additional dietary fiber is preferable to the use of laxative medications alone. Dietary fiber is more physiologic, better tolerated and often more effective than non-fiber laxatives.

The motility patterns of patients with obstipation are completely abolished (e.g., severe endstage megacolon in cats). In these patients, fiber-enhanced foods and fiber supplements are no longer effective stimulants of colonic motility and, worse, can contribute to obstipation. Foods for patients with megacolon should have no more than 5% DM crude fiber.

Box 64-2. A Safe and Practical Method for Providing Supplemental Fiber to a Patient's Current Food and Limitations of Using Canned Pumpkin as a Supplemental Fiber Source.

Adding fiber supplements is the least desirable approach for increasing fiber intake in patients with chronic constipation. In most constipation cases, dietary fiber intake can be increased by switching to a balanced food with the desired fiber content (**Tables 64-3** and **64-4**) or a mixture of two balanced foods can be fed using the Pearson square method to determine the amounts of constituent foods in the mixture (Chapter 1). If fiber supplements are used, they should be added to moist foods to ensure the fiber is mixed with the food and doesn't settle out in the bowl.

For this method, a practical source of fiber is Fiber One Bran Cereal[a] breakfast cereal. Although it is a human breakfast cereal and is not nutritionally balanced for dogs and cats, it does contain carbohydrate, protein, minerals and vitamins. Thus, relative to other readily available fiber supplements such as psyllium, wheat bran or canned pumpkin, Fiber One breakfast cereal is a more balanced source of fiber. It is somewhat palatable (depending on the individual patient's preferences and amount used) and contains a good amount of insoluble fiber (almost 50% dry matter [DM] crude fiber). **Table 1** provides a dose schedule for moist food.

Use the Pearson square method for determining how much Fiber One to add to a dry pet food to achieve a specific crude fiber level. Variability in the weight density per 8-oz. measuring cup makes it difficult to create a similar reliable table for dry pet foods.

Besides not being a balanced food, canned pumpkin as a fiber source has an important volume limitation. Canned pumpkin contains 90% water and on an as fed basis has only a fraction of the crude fiber of Fiber One cereal. As noted below, to obtain a fiber level of 10 to 11%, 2 tsp of Fiber One breakfast cereal are added to an 8-oz. cup of moist food. To achieve the same amount of fiber, more than 8 oz. of canned pumpkin would have to be added to the 8 oz. of moist food, more than doubling the amount of food the patient would have to eat to ingest the same amount of crude fiber.

ENDNOTE

a. Fiber One Bran Cereal. General Mills Cereals, LLC, Minneapolis, MN, USA.

Table 1. Dose schedule for Fiber One Bran Cereal to add to a typical moist food* and resultant crude fiber level.

Added Fiber One	Total crude fiber in mixture (DM)
1 tsp	7 to 8%
2 tsp	10 to 11%
3 tsp	13 to 14%
4 tsp	16 to 17%
5 tsp	18 to 19%

Key: tsp = rounded teaspoon (~5 g).
*8 volume oz. measuring cup of a typical moist food; assumed crude fiber content of approximately 3% DM, before Fiber One cereal is added. To improve acceptance by the patient and allow the colon and colonic microflora to adapt to the increase in fiber intake, gradually increase the amount of fiber added.

Digestibility and Caloric Density

For patients suffering from obstipation (including feline megacolon), in which colonic motility patterns are completely abolished, feeding a highly digestible food (fat and digestible [soluble] carbohydrate ≥90% and protein ≥87%) with an increased energy density (≥4.0 kcal/g [≥16.7 kJ/g] DM) will provide adequate nutrition and markedly reduce the fecal mass. A food's energy density and digestibility are inversely related to its fiber content. Reducing fiber results in increased caloric density, which helps meet the patient's requirements in a small volume of food. Calorically dense foods can markedly reduce the burden of home management (i.e., administering stool softeners and enemas) for pet owners. In such cases, fecal production is reduced to such an extent that owners can generally remove feces by cleansing enemas once or twice weekly. In many cases, this food transition is made as the owner considers the surgical option of subtotal colectomy.

The energy density and digestibility of a food are less important in constipated patients.

FEEDING PLAN

Initial management of chronic constipation includes owner education, encouraging increased water intake, appropriate dietary changes and judicious use of laxatives and enemas. If the affected animal is overweight, a weight-reduction program should be considered. Obstipation often requires multiple cleansing enemas with or without mechanical removal of impacted feces before dietary changes are instituted.

Assess and Select the Food

The key nutritional factor content of the food currently being fed should be evaluated in patients with constipation. Information from this aspect of assessment is essential for making any changes to foods currently provided. Changing to a more appropriate food is indicated if levels of key nutritional factors of the current food do not closely match recommended levels. **Tables 64-3** and **64-4** list selected commercial veterinary therapeutic foods for dogs and cats, respectively, affected with chronic constipation and compare the key nutritional content of these foods to recommended levels.

Many constipated cats respond favorably when fed a fiber-enhanced food, particularly if it is a moist food. Cats should be well hydrated before increasing fiber intake to maximize the therapeutic effect of fiber and to minimize the potential for fiber impaction in the constipated colon (Scherk, 2003; Washabau and Sammarco, 1996). Also, it is prudent to increase the fiber concentration gradually (e.g., 5%, 10%, 15%, 20%) over several weeks until clinical signs improve or resolve.

While less convenient, the fiber intake can also be increased by adding a higher fiber food to the current food. Most commercial grocery and specialty brand pet foods contain less than 5% DM crude fiber. Fiber-enhanced foods contain between 8

(Adapted from Washabau RJ, Sammarco J. Alterations in colonic smooth muscle function in cats with idiopathic megacolon. American Journal of Veterinary Research 1996; 57: 580-587. Scherk MA. Feline megacolon. In: Proceedings. 21st Annual American College of Veterinary Internal Medicine Forum 2003, Charlotte, NC: 911-913.)

and 25% DM crude fiber. The source of fiber may be determined by reviewing the ingredient list (Chapter 9). Almost any intermediate fiber concentration can be achieved by combining foods (dry or moist) that have different levels of fiber. The amounts of the constituent foods for the mixture can be determined using the Pearson square (Chapter 1). When making this calculation, be sure to use the same method of expressing the foods' fiber content (i.e., as fed or DM basis).

Adding fiber supplements such as psyllium, coarse wheat bran, bran cereals and canned pumpkin to the pet's regular food is another method of increasing the fiber intake of constipated patients. However, this is a less desirable approach. Fiber supplements can be awkward to use, may make the food unpalatable and in some instances can significantly reduce mineral bioavailability and create an unbalanced food. Fiber supplements work best when added to moist foods. **Box 64-2** provides a safe method for increasing the fiber content of a moist pet food by using a high-fiber human breakfast cereal as the fiber source.

Obstipated patients that have lost colonic motility should be fed foods that are highly digestible and have increased energy density. **Table 64-5** lists the key nutritional factor contents for foods for feline patients with chronic obstipation (megacolon) and compares them to recommended levels. Patients with severe megacolon may need veterinary therapeutic foods for stress/recovery (Tables 25-8 and 25-9) or homemade foods.

Assess and Determine the Feeding Method

Because the feeding method may be altered in patients with constipation, a thorough assessment should include verification of the feeding method currently being used, including feeding frequency, amount fed and access to other food.

In some cases, smaller more frequent meals may aid colonic motility patterns. Dogs should be walked immediately after feeding; both mild exercise and the gastrocolic reflex will often result in defecation during the immediate postprandial period. Feeding three to four meals per day also minimizes the amount of ingesta entering the large bowel at one time. As discussed above, water intake should be encouraged and drinking water should be readily available (i.e., multiple locations in the pet's environment) at all times.

ADJUNCTIVE MEDICAL THERAPY

The specific therapeutic plan will depend upon the severity of constipation and the underlying cause (**Figure 64-1**). First epi-

Table 64-6. Non-dietary medical therapies.

Emollient/lubricant laxatives/stool softeners
Dioctyl sodium succinate (Colace, Regulax SS, Surfak)
Dioctyl calcium sulfosuccinate (Sufax)
Mineral oil (Fleet mineral oil)
Hyperosmolar laxatives
Glycerin
Lactulose (Cephulac, Chronulac, Duphalac)
Polyethylene glycol (Miralax) (toxic to cats)
Polyethylene glycol with electrolytes (Colyte, GoLYTELY, NuLYTELY)
Sugar alcohols
Sorbitol (potentially toxic to small dogs and cats)
Mannitol
Saline laxatives
Magnesium citrate (Evac-Q-Mag)
Magnesium hydroxide (Phillip's Milk of Magnesia)
Magnesium sulfate
Sodium phosphate (Fleet enema, Fleet Phospho-Soda, Visicol)
Stimulant laxatives
Aloe
Anthraquinones
Cascara sagrada (Colamin, Sagrada-lax)
Senna (Senokot, Ex-Lax)
Castor oil (Purge, Neoloid, Emulsoil)
Diphenylmethanes
Phenolphthalein
Bisacodyl (Dulcolax, Correctol)
Sodium picosulfate (Lubrilax, Sur-Lax)
GI prokinetic therapy
Cisapride
Prucalopride (Resolor) (not approved in the U.S.)
New applications of existing drug classifications
Acetylcholinesterase inhibitors (ranitidine, nizatidine, neostigmine)
Erythromycin
Metoclopramide
Prostaglandin E_1 analogues (misoprostol)

sodes are often transient and resolve without medical therapy. Mild to moderate or recurrent episodes of constipation usually require medical intervention. In addition to dietary management, these cases may be managed, often on an outpatient basis, with water enemas, oral or suppository laxatives, and/or colonic prokinetic agents. Obstipation usually requires hospital admittance to correct metabolic abnormalities and to evacuate impacted feces using water enemas, manual extraction of retained feces, or both. Followup therapy in such cases is directed at correcting predisposing factors and preventing recurrence (Washabau and Sammarco, 1996). Medical therapies for mild to moderate constipation include enemas, stool softeners, laxatives (**Table 64-6**) and colonic motility modifiers (e.g., cisapride[b], 0.25 mg/kg body weight, t.i.d. to q.i.d.). A number of poorly absorbed carbohydrates may prove useful as laxatives. These sugars, including polyethylene glycol, sorbitol, lactulose and lactitol are hydrolyzed to fatty acids by the colonic microflora. The metabolites of these sugars exert osmotic pressure and draw fluid into the colon lumen. Additionally, laxative therapy may occasionally be needed to promote fecal hydration and lubrication.

Cats suffering from bouts of obstipation or idiopathic dilated megacolon are, by definition, unresponsive to medical therapy. Surgery (subtotal colectomy) may become necessary to remove the affected portion of the bowel in cases of idiopathic megacolon. In most cases, subtotal colectomy with ileorectal or cecocolic-rectal anastomosis is the treatment of choice.

REASSESSMENT

Body weight and condition assessments and stool evaluations are useful for monitoring patients with constipation. Well-compensated patients should be evaluated immediately if a change or decline in condition is noted. Regaining or maintaining optimal body weight and condition, normal activity level, normal behavior and absence of clinical signs are measures of successful dietary management. The feeding method and amount fed can be adjusted as needed to maintain body weight and condition. Additional medical therapies should be considered if dietary management alone is insufficient to improve stool quality and maintain body weight. Although treatment is highly case specific, many cases can eventually be managed with diet alone after initial medical therapies are gradually discontinued.

Occasionally, a patient may develop constipation, obstipation or flatulence while being fed moderate- (8 to 15% DM fiber) or high-fiber (>15% DM fiber) foods. The prudent recommendation in such cases is to decrease the fiber content by one-half, reevaluate the patient in one week and decrease the fiber content again if necessary. This situation occurs more commonly in older overweight and obese cats consuming dry, high-fiber, low-calorie foods for weight control than in cats being treated for constipation with fiber.

CASE 64-1

Constipation in a Domestic Shorthair Cat

Deborah J. Davenport, DVM, MS, Dipl. ACVIM (Internal Medicine)
Hill's Science and Technology Center
Topeka, Kansas, USA

Patient Assessment

A six-year-old, neutered male exclusively indoor domestic shorthair cat was examined for tenesmus and apparent constipation. The owners had noticed the cat making multiple unproductive attempts to defecate in the litter box. The cat was also seen sitting in the litter box for prolonged periods without making attempts to urinate or defecate. Two other cats in the household were normal. The owners cleaned the litter box daily and noticed both normal and dry, hardened feces. Because the cat had been constipated in the past, the owners were giving a flavored petrolatum product (Laxatone[a]) each day by mouth.

Physical examination revealed a normal-appearing, overweight, 5.5-kg cat. The cat's body condition score (BCS) was 4/5. Abdominal palpation elicited a painful response and the entire colon was distended with firm feces.

Warm tap water and mineral oil enemas were given to the cat; some of the fecal material was subsequently passed. The cat was anesthetized and warm tap water was infused into the colon while the remaining fecal material was manually expressed by abdominal palpation. The cat was discharged the same day with instructions for the owners to increase the amount of flavored petrolatum given each day.

Ten days later, the cat was reexamined for similar problems. Abdominal radiographs revealed a markedly distended colon impacted with feces. No foreign material, mass lesions, healed pelvic fractures or spinal abnormalities were noted radiographically. The fecal material was removed by enemas and manual extraction. A tentative diagnosis of chronic constipation and possible megacolon was made.

Assess the Food and Feeding Method

All of the cats in the house were fed a commercial dry specialty brand adult cat food free choice. Canned tuna or a variety of commercial moist grocery brand foods were offered once or twice weekly as a treat. Water was available free choice although all three cats liked to drink from faucets and toilet bowls.

Questions

1. What are the key nutritional factors to consider for this patient?
2. Outline an appropriate feeding plan (foods and feeding method) for this cat.
3. What other therapy can be used in conjunction with the feeding plan?

Answers and Discussion

1. The key nutritional factors for this patient are water and fiber intake. Fiber is classified as a bulk-forming laxative although it has many other properties. Fiber's beneficial effects in treating animals with constipation include increasing fecal water content, increasing intestinal motility, altering intestinal transit rate and increasing frequency of defecation. Feeding more moist food and less dry food would also increase water intake.
2. Fiber supplements such as psyllium husk fiber, wheat bran or pumpkin can be added to the moist foods. Alternatively, commercial, fiber-enhanced moist foods can make up part or all of a patient's diet. This cat will need to be fed separately from other cats in the household. Several smaller meals during the day rather than one large meal may be beneficial and will be similar to the free-choice feeding method used previously.
3. Therapy for chronic constipation includes: 1) removing impacted feces, 2) administering laxatives, 3) assessing the diet and 4) administering prokinetic agents. Laxatives are classified as emollient (dioctyl sodium sulfosuccinate), lubricant (mineral oil, petrolatum), hyperosmotic (lactulose, magnesium salts, polyethylene glycols) and stimulant (bisacodyl). All these may be used in cats with mild to moderate constipation, but they should be avoided in cases with functional or mechanical bowel obstruction (obstipation). Studies suggest that stimulating colonic smooth muscle contraction may improve colonic motility in cats with idiopathic dilated megacolon. In vitro studies have shown that cisapride[b] stimulates propulsive motility in the colon, and anecdotal experience suggests that cisapride also effectively stimulates colonic propulsive motility in cats with mild to moderate idiopathic constipation. Cats with longstanding obstipation and megacolon are not likely to improve with dietary, laxative and prokinetic therapy alone. Subtotal colectomy should be considered in these cases.

Progress Notes

Metamucil[c] (0.5 tsp) was added to the moist food (1-1/4 5.5-oz. cans) and offered to the cat daily in addition to the regular commercial dry food fed free choice. The moist food plus fiber supplement made up approximately half of the daily food intake. Little improvement was noted after one month. The cat was then exclusively fed a commercial moist veterinary therapeutic food (Prescription Diet w/d Feline[d]) with moderate fiber levels (9.3% dry matter crude fiber). One 5.5-oz. can was divided into three meals per day for slow weight loss. There was some improvement after one month (i.e., increased frequency of defecation and moister feces). However, constipation remained an intermittent problem. Cisapride, 2.5 mg, two to three times daily per os, was added to the therapeutic protocol and, subsequently, the cat had only occasional problems with constipation.

Chapter 65

Flatulence

Philip Roudebush
Deborah J. Davenport
Rebecca L. Remillard

"He couldn't ad-lib a fart after a baked-bean dinner."
Johnny Carson

CLINICAL IMPORTANCE

Flatulence is excessive formation of gases in the stomach or intestine, but the term is often used incorrectly. Excessive flatulence is usually associated with noticeable flatus, belching, borborygmus or a combination of these signs. Flatus, rather than flatulence, is gas expelled through the anus. Belching is the noisy voiding of gas from the stomach through the mouth. Borborygmus is a rumbling noise caused by the propulsion of gas through the intestines.

Excessive flatus is a chronic objectionable problem that occurs often in dogs and less commonly in cats. Although belching and borborygmus are rarely chief complaints of pet owners, routine questioning may elicit their presence. Flatus, belching and borborygmus occur in normal pets but often develop as a consequence of small intestinal or colonic disorders. At times, flatus is the primary reason pet owners seek veterinary advice.

PATIENT ASSESSMENT

History and Physical Examination

Pet owners often describe an increase in frequency of belching, audible flatus or an objectionable odor associated with flatus (Jones et al, 1998). At times, it may be possible to elicit a history of dietary change or dietary indiscretion in association with flatus. Occasionally, belching and flatus develop in conjunction with other gastrointestinal (GI) signs including weight loss, diarrhea and steatorrhea. This type of history is very suggestive of an underlying small intestinal disorder.

In most cases, physical examination findings are unremarkable in dogs and cats with flatulence, although abdominal distention is sometimes noted in cats. Intestinal gas can often be detected during abdominal palpation; however, it is difficult to assess the quantity of gas by palpation alone. Animals having poor body condition and objectionable flatus may have an underlying GI condition.

Laboratory testing is usually not indicated. However, further evaluation is in order if concomitant GI signs are present. Readers are referred to earlier chapters involving small and large bowel disorders for further information.

Risk Factors

Excessive aerophagia is a risk factor for flatulence and is seen with brachycephalic, working and sporting canine breeds and pets with aggressive and competitive eating behaviors. Dietary indiscretion and ingestion of certain pet food ingredients may be risk factors for certain individuals.

Etiopathogenesis

Gas in the GI tract is normal and may be derived from three sources: air swallowing, intraluminal gas production and diffu-

sion of gas from the blood to the GI tract.

Regarding flatus, the rate of excretion of gas per rectum varies greatly in people and animals. Excretion rates in people range from 400 to 1,500 ml/day (mean 705 ml/day). People, eating their usual foods, passed gas per rectum an average of eight to 10 times per day with an upper normal limit of 20 times per day (Strocchi and Levitt, 1997). Swallowed air is thought to contribute the most to gas in the digestive tract. This may be the cause of flatus commonly seen in many brachycephalic breeds. Vigorous exercise and rapid and competitive eating situations may exacerbate aerophagia. Studies using ultrafast computed tomography in people show that a mean of 17 ml of air accompanies the swallowing of 10 ml of water. In people, air introduced into the stomach can result in flatus within 15 to 35 minutes and it has been estimated that gases can move 10 cm/second through the GI tract (Levitt, 1980). In a study using an in vivo methodology of flatulence assessment in dogs, flatus developed as soon as two hours post-feeding (Yamka et al, 2006).

A large amount of gas is formed from colonic bacterial fermentation of poorly digestible carbohydrates and certain fibers. Fiber-containing foods contribute to flatus indirectly through reduced dry matter (DM) digestibility. Certain fibers (soluble or fermentable) used in pet foods are fermented by colonic microflora and may contribute to flatus directly. Foods that contain large amounts of nonabsorbable oligosaccharides (e.g., raffinose, stachyose and verbascose) are likely to produce large amounts of intestinal gas (Levitt, 1980). Dogs and cats lack the digestive enzymes needed to split these sugars into absorbable monosaccharides. Therefore, bacteria in the colon ferment these sugars producing hydrogen and carbon dioxide. Soybeans, beans and peas contain large quantities of nonabsorbable oligosaccharides (Yamka et al, 2003, 2006). Soybean meal is commonly used in pet foods as a protein source. The stachyose and raffinose content of soybean meal is variable ranging from 32 to 112 g/kg and 6 to 14 g/kg DM, respectively, which could contribute to flatulence if they compose more than 22 g/kg of food DM (Yamka et al, 2006).

Diseases that cause maldigestion or malabsorption are often associated with excessive flatus because excessive amounts of malassimilated substrates are delivered to the colon where bacterial fermentation occurs. Flatus may be present in animals with lactose intolerance.

The interaction between hydrochloric acid and alkaline food and saliva produces carbon dioxide in the stomach. The reaction between gastric acid and pancreatic bicarbonate in the duodenum also generates carbon dioxide. In addition, carbon dioxide enters the GI tract via diffusion from the blood. Belched gas is largely swallowed air (nitrogen and oxygen) plus variable quantities of carbon dioxide.

Odorless gases (i.e., nitrogen, oxygen, carbon dioxide, hydrogen and methane) compose as much as 99% of flatus (Strocchi and Levitt, 1997). The residual 1% is composed of odoriferous gases that contain sulfur, such as hydrogen sulfide, methanethiol and dimethylsulfide (Roudebush, 2001; Collins et al, 2001). These gases contribute the objectionable odors associated with flatus. Excessive quantities of odorless gases provide a vehicle for the odoriferous gases and volatiles and probably worsen objectionable flatus. Onions, nuts, spices, cruciferous vegetables (e.g., broccoli, cabbage, cauliflower, Brussels sprouts) and high protein ingredients often increase production of odiferous gases.

Key Nutritional Factors

Table 65-1 summarizes the key nutritional factors, discussed below, for foods for dogs and cats with objectionable excessive flatulence.

Digestibility

Digestibility, especially of the carbohydrate fraction of food, is an important nutritional factor in patients with excessive flatulence. Feeding a highly digestible food reduces the residues available for bacterial fermentation in the large intestine. Thus, foods with high digestibility (fat and digestible [soluble] carbohydrate ≥90% and protein ≥87%) are recommended for patients with objectionable flatus).

Carbohydrate

Certain carbohydrate sources may affect flatus production in individual patients. Changing the source of carbohydrate in the food may benefit some animals (Suarez et al, 1999). Anecdotal reports in people suggest that a food in which all carbohydrate is supplied by white rice reduces flatus output. Studies in dogs have also shown that foods containing rice as a carbohydrate source result in less intestinal gas formation than foods containing wheat or corn (Washabau et al, 1986). This suggests that animals with flatus may benefit from foods with rice as the sole or predominant carbohydrate source.

Protein

Dietary protein sources and amount may affect flatus odor. Changing the sources of protein in the food may benefit some patients (Suarez et al, 1999). Ammonia and volatile amines are odorous and could result from microbial fermentation of food protein residues reaching the large intestine. Therefore, protein digestibility (discussed above) and amount should be considered if flatus is a problem. Dietary protein should probably not exceed 30% for dogs and 40% for cats DM. Leguminous protein sources such as soybean meal should be avoided in pets with excessive flatulence.

Fiber

Soluble or fermentable fiber-enhanced foods may contribute to excessive flatus in some patients. Soluble fibers including fruit pectins and gums (e.g., guar gum, carrageenan) are readily fermentable by gut microbes resulting in gas production (Chapter 5). Even some mixed fibers in adequate amounts (brans, soy fiber, soy hulls, pea fiber and beet pulp) can be a source of flatulence. Some of these sources of fiber also contain non-fiber ingredients that can contribute to objectionable flatus (e.g., soy hulls and pea fiber). For patients with excessive flatus, the amount of fiber should probably be limited to no more than 5% DM.

Table 65-1. Key nutritional factors for foods, treats and snacks for dogs and cats with excessive flatulence.*

Factors	Recommendations
Digestibility	Increased digestibility Fat and carbohydrate digestibility ≥90% Protein digestibility ≥87%
Carbohydrate	Change source: rice is preferred
Protein	Avoid high-protein foods Adult dogs: limit to ≤30% or less Adult cats: limit to ≤40% or less Avoid legumes (see below)
Fiber	Dogs and cats: limit to ≤5% fiber (most important aspect regarding fiber) Avoid high-fiber foods, especially soluble/fermentable and mixed fibers (soy fiber, soybean hulls, pea fiber, psyllium, pectin, carrageenan, guar gum, bran and beet pulp)
Legumes	Avoid all beans (including soybeans), peas, lentils, peanuts
Lactose sources	Avoid milk, ice cream, cheese, yogurt
Sulfur-containing vegetables	Avoid broccoli, cauliflower, Brussels sprouts, cabbage
Onions	Avoid
Nuts	Avoid
Spices	Avoid
Fructose	Avoid fruits and high-fructose corn syrup
Vitamin-mineral supplements	Avoid; unnecessary with most commercial foods

*Nutrient values are on a dry matter basis.

Food Ingredients

As discussed above, certain protein, carbohydrate and fiber ingredients or levels may affect flatus production in individual animals. Of the numerous foods alleged to enhance flatus in people, baked beans is the only natural food that has been carefully studied. A diet regimen deriving half of its calories from pork and beans increased flatus elimination in people from a basal level of 15 to 176 ml/hour (Steggarda, 1968).

Changing the sources of protein or carbohydrate in the food may benefit some animals (Suarez et al, 1999). For example, changing from a commercial dry food that contains corn, chicken meal and soybean meal to a dry food that contains lamb meal, rice and barley may be helpful. Vegetarian-based foods can be problematic because they often include potentially odiferous sulfur-containing vegetables and legumes. The lactose content of foods and treats (e.g., cheese, ice cream, milk) may be a factor in adult dogs and cats, especially those with lactase deficiency or in animals with underlying GI disease. A series of dietary trials is often successful in finding a food that lessens flatulence in individual pets. **Table 65-1** lists several categories of human foods and food ingredients to avoid or limit.

FEEDING PLAN

Dietary management of flatulence is primarily concerned with decreasing intestinal gas production by bacterial fermentation of undigested food. Changes in the feeding plan can be used in conjunction with other therapy. Recently, commercial products have been introduced that claim to reduce flatulence (**Box 65-1**).

Assess and Select the Food

Obtaining a thorough dietary history is of paramount importance in evaluating patients with excessive flatulence. Specific foods, major food ingredients, treats, supplements and opportunities for dietary indiscretion should be evaluated.

In general, pets with excessive flatulence will benefit from highly digestible foods. Consumption of such foods may reduce the amount of residue reaching the large intestine, thereby decreasing substrate availability for bacterial fermentation and subsequent gas production. Commercial foods and treats fed to pets that have excessive flatulence should also be evaluated for specific ingredients that might be further contributing to the problem. To accomplish this, compare the food's ingredient list on the package or label (Chapter 9) to the ingredients recommended to avoid or limit as listed in **Table 65-1**. If a food's major ingredients are potentially offensive, change to a food that has a nutrient profile and ingredient list that more closely compares to the recommendations in **Table 65-1**. Several veterinary therapeutic foods marketed for GI diseases or adverse food reactions are often suitable for feeding to patients with excessive flatulence (**Tables 65-2** and **65-3**, for dogs and cats, respectively). Most of these foods are complete and balanced for long-term feeding. Dietary trials may be necessary to select a food that reduces flatus. **Table 65-1** also lists human foods to avoid as treats or snacks or as ingredients for homemade foods for patients that have a history of excessive flatulence.

Assess and Determine the Feeding Method

A thorough assessment should include verification of the feeding method currently being used. Considerations include feeding frequency, amount fed, how the food is offered, access to other food, relationship of feeding to exercise and who feeds the animal. All of this information should have been gathered when the history of the animal was obtained. If the animal has a normal body condition score (2.5/5 to 3.5/5), the amount of food previously fed (energy basis) was probably appropriate.

Reducing aerophagia is important in the control of flatulence in dogs, especially in brachycephalic breeds. Feed several small

Box 65-1. Carminatives.

INTRODUCTION
Carminatives are medicines or preparations that relieve flatulence. Various herbal and botanical preparations have been used for thousands of years as carminatives. More recently, commercial products have been introduced that claim to reduce or control flatulence. These products can be used in conjunction with changes in the feeding plan and usually contain activated charcoal, bismuth subsalicylate (BSS), zinc acetate, simethicone, *Yucca schidigera* preparations, α-galactosidase, pancreatic enzyme supplements and various herbal preparations. Nonabsorbable antibiotics such as neomycin reduce flatulence and the number of flatus episodes in healthy people and dogs. However, routine use of nonabsorbable antibiotics in otherwise healthy pet animals with flatulence is not indicated.

ACTIVATED CHARCOAL
Dry activated charcoal adsorbs virtually all odoriferous gases when mixed directly with human feces and flatus gas. However, ingestion of activated charcoal by human subjects has been ineffective in reducing the number of flatus events, volume of intestinal gas released, odor of feces or breath hydrogen excretion after bean ingestion. In vitro studies suggest that the failure of ingested charcoal to reduce liberation of volatile sulfur compounds is due to the saturation of charcoal binding sites during passage through the gut. Wetting activated charcoal slows uptake of sulfur-containing gases considerably. Activated charcoal is found in a number of commercial canine treats purported to control flatulence.

BISMUTH SUBSALICYLATE
BSS reduces fecal and flatus odor in people when given frequently (four times daily). Bismuth is the active ingredient and avidly adsorbs hydrogen sulfide, forming insoluble bismuth sulfide. Bismuth sulfide imparts a characteristic black color to feces. Bismuth also has antibacterial activity, which may account for some of its effects. BSS contains 50% bismuth by weight and is found in various commercial veterinary antidiarrheal-adsorbent products and in over-the-counter antidiarrheal products for human use (e.g., Pepto-Bismol). There appears to be a striking dose-dependent response with BSS in that a dose of 400 mg of BSS/100 g of dry food completely suppresses cecal hydrogen sulfide release in rats, whereas one-fifth this concentration has no demonstrable effect. BSS may be effective in controlling objectionable flatus in pet animals but probably needs to be given multiple times per day, which precludes its practical, long-term use. BSS should be used with caution in cats because of concerns with salicylate toxicosis.

ZINC ACETATE
Similar to bismuth, zinc acetate binds sulfhydryl compounds and reduces volatile sulfur compounds when exposed directly to gas from human flatus. Addition of zinc acetate to food (1%) decreased fecal hydrogen sulfide concentrations and improved flatus odor in rats. One report showed that an oral treat containing zinc acetate, activated charcoal and *Yucca schidigera* extract reduced highly odoriferous episodes of flatus in dogs.

SIMETHICONE
Simethicone (dimethylpolysiloxane) is an antifoaming agent that reduces surface tension of gas bubbles and is found in commercial veterinary products and over-the-counter products for human use. Why simethicone would be beneficial in patients with flatulence is not obvious; however, one could speculate that altered gas bubbles might be more effectively eliminated. A few controlled trials of treatment with simethicone have been conducted in people. In general, simethicone had no effect on total daily flatus volume, number of

*Protein and crude fiber levels are on a dry matter basis.

flatus episodes or average volume per flatus event in people. Simethicone may help reduce gastric accumulation of gas and alleviate upper gastrointestinal (GI) signs. The effectiveness of simethicone in controlling flatulence in pet animals is unknown. It would not be expected to control objectionable flatus odors.

Yucca schidigera

Extracts of the *Yucca schidigera* plant have been used to control fecal malodor in animal waste lagoon systems and may help decrease fecal aroma. The mechanisms of action are poorly understood and may include "binding" ammonia or altering microbial activity. In the United States, *Yucca* preparations are only approved as flavoring agents in pet foods and it is unknown whether they effectively control flatulence or objectionable flatus odors when ingested by pet animals. An oral treat containing *Yucca schidigera* extract, activated charcoal and zinc acetate reduced highly odoriferous episodes of flatus in dogs.

α-GALACTOSIDASE and β-MANNANASE

Products containing α-galactosidase are available as human (Beano) and veterinary (CurTail) products. They reduce flatus volume by improving digestion of nonabsorbable oligosaccharides found in soybeans, beans, peas and other legumes. These products would not be expected to improve excessive flatus due to other causes (e.g., aerophagia) or improve the odor of flatus. Anecdotal reports suggest that these products may be beneficial in some animals. β-mannanase is another enzyme that may improve digestion of nonabsorbable oligosaccharides in legumes. β-mannanase has been used to increase feed conversion and dry matter digestibility of soy-based diets in poultry and swine. In dogs, however, supplemental β-mannanase was not shown to increase digestibility of food or reduce flatulence.

PANCREATIC ENZYMES

Pancreatic enzyme supplementation decreases abnormal intestinal gas production in dogs with exocrine pancreatic insufficiency. Pancreatic enzyme preparations have also been widely used for bloating and abdominal distention in people. Because ingestion of these preparations should add little to the enzyme output of the pancreas in otherwise normal individuals, no solid rationale exists for their use in flatulent patients without pancreatic disease. Nevertheless, a recent study in people showed that a microencapsulated pancreatic enzyme preparation significantly reduced postprandial symptoms of bloating and abdominal distention experienced by healthy people ingesting a high-calorie, high-fat meal. This finding suggests that pancreatic enzyme supplements might benefit some patients with flatulence.

HERBS AND BOTANICALS

More than 30 herbal and botanical preparations have been listed as carminatives. Grape seed extract containing proanthocyanidins is one botanical preparation that alters GI microflora and decreases fecal release of volatile sulfur compounds in human patients. The dosage, safety and efficacy of grape seed extract and other botanical preparations in pets with flatulence have not been established.

SUMMARY

To date, the best evidence exists for short-term use of bismuth subsalicylate, zinc acetate and nonabsorbable antibiotics as carminatives. Less evidence exists for use of activated charcoal, simethicone, digestive enzyme preparations, *Yucca* extract and grape seed extract. Changing the feeding plan (food and feeding method), rather than using carminatives, offers the best opportunity for successful long-term management of flatulence in pet animals.

Table 65-4. Feeding plan summary for patients with excessive flatulence.

Control aerophagia
Discourage rapid or competitive eating
Feed a mixture of moist and dry foods
Feed several small meals daily
Surgically correct stenotic nares and elongated soft palate in brachycephalic dogs

Decrease production of obnoxious intestinal gas
Select a food with the appropriate key nutritional factors (**Table 65-1**)
Walk the dog outdoors within 30 minutes of meals to encourage defecation and the elimination of intestinal gas. In general, more activity and exercise result in fewer problems with flatus.

Carminatives
If changes in the feeding plan do not result in significant improvement, consider the use of carminatives. To date, the best evidence exists for short-term use of bismuth subsalicylate, zinc acetate and nonabsorbable antibiotics. Less evidence exists for use of activated charcoal, simethicone, digestive enzyme preparations, *Yucca* extract and grape seed extract (**Box 65-1**).

meals daily in an effort to discourage rapid eating and gulping of air. Feeding small frequent meals also improves digestibility and reduces food residues available for bacterial fermentation in the large intestine. A recent study in dogs demonstrated that feeding twice daily resulted in fewer episodes of flatus (9.9/day) than feeding once daily (13.5/day) (Yamka et al, 2006). Feeding in a quiet, isolated location will eliminate competitive eating and reduce aerophagia. Walking dogs outdoors within 30 minutes of eating encourages defecation and elimination of intestinal gas (**Table 65-4**).

REASSESSMENT

Patients should be evaluated for evidence of malassimilation if the methods outlined above are not successful in reducing or controlling flatulence, including objectionable flatus. Relapses in animals that have been controlled often indicate dietary indiscretion. The prognosis for control of flatulence is good in most cases. However, owners should be educated about normal intestinal gas production and should not expect complete cessation of flatulence (Cho, 1994).

If changes in the feeding plan do not result in significant improvement, consider use of carminatives (**Box 65-1**).

CASE 65-1

Flatulence in a Young Puppy

Philip Roudebush, DVM, Dipl. ACVIM (Small Animal Internal Medicine)
Hill's Scientific Affairs
Topeka, Kansas, USA

Patient Assessment

A 16-week-old intact male beagle puppy was examined for routine health maintenance procedures. The owners obtained the puppy from a local animal shelter six weeks ago. The puppy had been active and healthy with no apparent problems. However, the owners complain the puppy passes excessive amounts of intestinal gas with an offensive odor, especially after meals. There has been no evidence of vomiting, diarrhea or other gastrointestinal (GI) problems. Physical examination revealed an active puppy with no abnormalities. A fecal sample was negative for intestinal parasites.

Assess the Food and Feeding Method

The patient was fed a commercial dry puppy food containing the following ingredients: corn, chicken meal, soybean meal, animal fat, beet pulp, rice, fish oil, flaxseed, vitamins and minerals. The daily feeding amount was divided into two equal meals, offered in the morning and evening. The puppy's appetite was very good and the food was usually consumed at each meal within a few minutes. The puppy also enjoyed small amounts of fresh fruit and vegetables as snacks.

Questions

1. What are the common clinical manifestations of flatulence?
2. What are the most common causes of excessive intestinal gas formation?
3. Are there ingredients in the current diet that could be contributing to excessive intestinal gas formation?
4. Outline a feeding plan for this puppy that will help control the problem with flatulence.

Answers and Discussion

1. Flatulence is excessive formation of gases in the stomach or intestine. Excessive flatulence is usually associated with noticeable flatus, belching, borborygmus, abdominal distention or a combination of these signs. Flatus, rather than flatulence, is the term that should be used for gas expelled through the anus. Dog owners often complain of excessive amounts of flatus, with or without an objectionable odor.
2. The quantitatively important gases in the intestinal tract are nitrogen, oxygen, hydrogen, carbon dioxide and methane. These gases comprise more than 99% of the intestinal gas volume and are odorless. The characteristic unpleasant odor of intestinal gas appears to result primarily from the presence of trace gases that contain sulfur. Gas in the GI tract is derived from four sources: 1) air swallowing (oxygen and nitrogen), 2) interaction of bicarbonate and acid (carbon dioxide), 3) diffusion from the blood (carbon dioxide, nitrogen and oxygen) and 4) bacterial metabolism (carbon dioxide, hydrogen, methane and a variety of trace gases). Swallowed air and bacterial fermentation in the colon contribute most of the intestinal gas volume.
3. Foods that contain ingredients with nonabsorbable oligosaccharides (e.g., raffinose, stachyose, verbacose) are likely to produce large amounts of intestinal gas. Dogs and cats lack the digestive enzymes needed to split these sugars into absorbable monosaccharides. Therefore, bacteria in the colon ferment these sugars producing hydrogen and carbon dioxide. Soybeans, beans, peas and other legumes contain large quantities of nonabsorbable oligosaccharides. Fiber-containing foods may contribute to flatus indirectly through reduced dry matter digestibility. Many fibers used in pet foods are fermented by the colonic microflora and may contribute to flatus directly. Rapidly fermentable fibers in pet foods include pectins and most gums. Intestinal gas production is also increased by fresh or dried foods containing fructose and fermentable fiber (e.g., apples, prunes, bananas). The food fed to this puppy contains soybean meal, a source of nonabsorbable oligosaccharides, which is likely contributing to excessive gas formation. The fresh fruits and vegetables used as snacks may also be contributing to the problem. Rice is the most highly digestible carbohydrate source used routinely in pet foods. Pets with flatulence will often improve when fed foods with rice as the sole or predominant carbohydrate source.
4. Feeding plans for animals with flatulence should focus on the food, feeding method, efforts to control aerophagia and management after meals. For this puppy, another commercial dry food that is complete and balanced for growth should be found that does not contain legumes (especially soybean meal), vegetables or fruits. A snack or treat should also be recommended that is not a vegetable or fruit. Aerophagia is most likely associated with rapid eating. Food can be offered more frequently to decrease the amount of air ingested at each meal or other methods can be tried to slow food ingestion and prevent gulping. Finally, the puppy should be walked or allowed to exercise within 30 minutes of each meal to encourage defecation or passage of intestinal gas outdoors.

Progress Notes

A different commercial dry puppy food was recommended (Science Diet Puppy Lamb Meal & Rice Formula[a]). This food contains the following major ingredients: lamb meal, rice, corn gluten meal, wheat, animal fat, egg, beet pulp, fish oil, vitamins and minerals. It does not contain soybean meal and uses rice as the major carbohydrate source; this change in ingredients should help minimize intestinal gas formation from bacterial fermentation. The food was still offered twice daily, but large rubber balls were put in the food bowl in an attempt to slow the rate of food ingestion. Fruits and vegetables were replaced as snacks with an appropriate commercial puppy treat (Science Diet Puppy Treats with Real Chicken[a]). The puppy was allowed to exercise in the fenced yard for 30 to 60 minutes after each meal. During the next health maintenance examination four weeks later, the owners reported a noticeable reduction in objectionable flatus.

Chapter 66

Exocrine Pancreatic Insufficiency

Deborah J. Davenport
Rebecca L. Remillard
Kenny W. Simpson

"To eat is human, to digest divine."
Charles Copeland

CLINICAL IMPORTANCE

Malassimilation is failure of nutrients to pass across the intestinal wall in quantities sufficient to maintain body weight and condition (Jacobs et al, 1989). Malassimilation can be caused by either maldigestive or malabsorptive diseases. Malabsorption occurs with diseases that alter the structure and function of the small intestinal mucosa including the lymphatics. Maldigestion occurs with defects in intraluminal digestion and may result from gastric, pancreatic or biliary dysfunction. Exocrine pancreatic insufficiency (EPI) refers to a partial or complete deficiency of pancreatic enzymes and is the most common cause of maldigestion in dogs (Williams, 1994). Occurring most commonly in young dogs as a congenital disorder, pancreatic acinar atrophy, EPI may also develop as a sequela to acute and chronic pancreatitis (Williams, 1994) or pancreatic neoplasia (Westermarck and Wiberg, 2003). EPI is rare in cats but has been reported to occur in juvenile and acquired forms (Williams, 1994a; Steiner and Williams, 2000).

PATIENT ASSESSMENT

History and Physical Examination

Dogs and cats with EPI have a history of chronic small bowel diarrhea, weight loss and failure to thrive (Raiha and Westermarck, 1989). Pets with EPI defecate frequently (six to 10 bowel movements per day) and stools are typically voluminous, greasy, foul smelling and pale in color. When stained with Sudan III and examined microscopically, fat droplets are readily identified in such feces (**Figure 66-1**). Polyphagia, borborygmus, flatulence, pica and coprophagia are often reported. Vomiting and polydipsia occur less commonly (Raiha and Westermarck, 1989; Westermarck and Wiberg, 2003).

Affected dogs and cats generally have a normal appearance except for poor body condition (body condition score [BCS] 1/5 to 2/5) and poor coat quality. Cats with EPI may soil the coat in the perineal region (Steiner and Williams, 2000). Animals with pancreatic atrophy will be stunted in comparison to unaffected littermates or breed standards. Severely affected

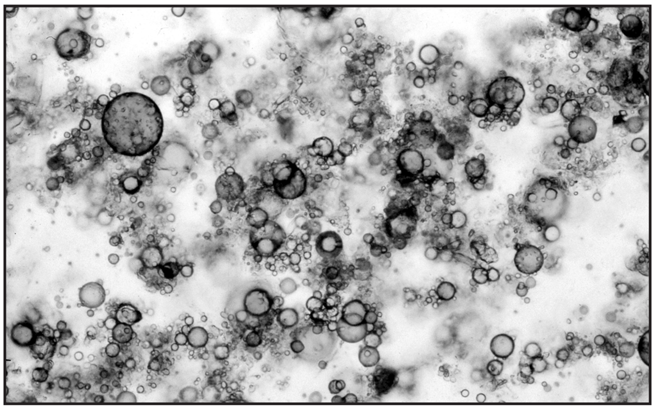

Figure 66-1. Feces stained with Sudan stain demonstrating increased amounts of fat (note globules) typical of exocrine pancreatic insufficiency. (Courtesy Dr. Robert Sherding, College of Veterinary Medicine, The Ohio State University, Columbus.)

patients may have hemorrhages due to a vitamin K-deficient coagulopathy (Perry et al, 1991).

Laboratory and Other Clinical Information

A presumptive diagnosis of EPI is often based on the signalment and patient history. Definitive diagnosis is achieved by radioimmunoassay of serum trypsin-like immunoreactivity (TLI). Low fasting TLI values (<2.5 μg/l) indicate EPI in dogs and cats (Williams and Batt, 1983, 1988; Steiner and Williams, 1996, 2000; Williams, 2006). This sensitive, specific, easy to perform serologic assay has replaced older tests including the bentiromide-PABA challenge, assay of fecal proteolytic activity, x-ray film digestion test and oral fat challenges. TLI measures serum levels of pancreatic trypsin and trypsinogen. Trypsinogen leaks out of pancreatic acini in trace amounts in healthy animals (normal canine serum TLI values = 5.0 to 35.0 μg/l, normal feline serum TLI values = 17.0 to 50.0 μg/l). In EPI, pancreatic acinar atrophy and fibrosis result in reduced serum TLI values. Serum amylase, isoamylase and lipase concentrations are of little value in diagnosing EPI due to pancreatic atrophy (Steiner et al, 2006). These tests may be of benefit when EPI occurs in conjunction with pancreatitis (Meyer and Williams, 1992).

Risk Factors

EPI due to pancreatic acinar atrophy is most common in young, large-breed dogs. German shepherd dogs, Eurasians and rough-coated collies appear to have a genetic predisposition to pancreatic acinar atrophy; however, any breed can be affected (Williams, 1994; Westermarck and Wiberg, 2003; Proschowsky and Fredholm, 2007). In the German shepherd dog and rough-coated collie, the pancreatic acinar atrophy appears to be an autosomal recessive disorder (Moeller et al, 2002) with an estimated disease prevalence of 1% (Westermarck and Wiberg, 2003). In the Eurasian dog breed, the inheritance pattern also appears to be autosomal recessive, but no candidate genes could be identified (Proschowsky and Fredholm, 2007). It is likely that the condition is multifactorial.

Acquired EPI may occur as a consequence of severe or recurrent pancreatic inflammation and resultant fibrosis. Thus, risk factors for acquired EPI are the same as for pancreatitis (Chapter 67).

Etiopathogenesis

Juvenile EPI results from atrophy of pancreatic acinar tissue rather than from congenital hypoplasia (Westermarck and Wiberg, 2003; Steiner, 2008). The disease has been subdivided into subclinical and clinical phases (Wiberg et al, 1999). Reports suggest that histopathologic evidence of atrophy is present before the onset of clinical signs (Westermarck et al, 1993; Wiberg et al, 1999). In the subclinical phase, atrophied and normal acinar cells are present in the pancreatic parenchyma along with a lymphocytic inflammatory infiltrate. The lymphocytic infiltrate suggests an autoimmune reaction. A prospective, placebo-controlled trial of an immunosuppressive drug (azathioprine) in dogs with subclinical EPI demonstrated the natural course of the pancreatic acinar atrophy to be extremely variable with some dogs remaining in the subclinical phase for many years without immunosuppressive therapy (Wiberg and Westermarck, 2002). Unfortunately, the authors were unable to identify markers predictive of disease progression.

Clinical signs do not develop until 85 to 90% of functional exocrine tissue is lost (Jacobs et al, 1989), usually when patients are six to 18 months old (Westermarck et al, 1993). Subnormal serum TLI levels may be present in the subclinical phase even when clinical signs are not present (Wiberg et al, 1999a).

In the juvenile form of EPI, endocrine function is usually normal and diabetes mellitus does not develop. In rare cases, EPI and diabetes mellitus may occur concurrently in young dogs and cats (Sherding, 1979; Boari et al, 1994).

The acquired form of EPI arises as a consequence of the inflammation and fibrosis of endstage chronic pancreatitis (Watson, 1995). Diabetes mellitus may develop concurrently because pancreatic islet cells are similarly affected. EPI may occur as a consequence of pancreatic adenocarcinoma or cholecystoduodenostomy (Williams, 1994).

Several mechanisms are responsible for the severe nutrient malassimilation that occurs in EPI. Most important, the deficiency of pancreatic enzymes results in a failure of intraluminal digestion and inability of the patient to effectively use nutrients. In addition, the lack of other pancreatic secretory products, including bicarbonate, gastrointestinal (GI) trophic factors, antimicrobial factors and intrinsic factor contribute to impaired GI function and nutrient malassimilation. Intestinal mucosal enzyme activity is impaired in experimental and naturally occurring EPI (Williams, 1996). Impaired mucosal enzyme function results in abnormal sugar, amino acid and fatty acid transport. The cause for the intestinal mucosal abnormality is unknown but is suspected to result from the absence of trophic pancreatic secretions and concurrent small intestinal bacterial overgrowth (SIBO).

Dogs with EPI commonly have SIBO because they lack the antibacterial factors present in pancreatic secretions and have

changes in immunity secondary to malnutrition (Williams et al, 1987; Westermarck et al, 1993a; Simpson et al, 1990). In addition, many German shepherd dogs with EPI also have IgA deficiency (Batt et al, 1991; Whitbread et al, 1984). Bacterial overgrowth contributes to malnutrition in EPI by destroying exposed brush border enzymes and consuming unabsorbed intraluminal nutrients. In addition, bacterial hydroxylation of fatty acids may exacerbate fat malabsorption and contribute to osmotic and secretory diarrhea.

Diarrhea in EPI is usually characterized as osmotic. Distal ileal and colonic microflora ferment undigested sugars and fats, releasing osmotically active particles. These particles drive fluid into the gut lumen, which overwhelms the colonic capacity for water reabsorption. Additionally, hydroxy fatty acids formed from bacterial metabolism of undigested fats can trigger secretory diarrhea.

Key Nutritional Factors

Key nutritional factors for patients with EPI are listed in **Table 66-1** and are discussed in more detail below.

Table 66-1. Key nutritional factors for foods for patients with exocrine pancreatic insufficiency.*

Factors	Recommended levels
Digestibility	≥87% for protein and ≥90% for fat and digestible carbohydrate
Fat	10 to 15% for dogs 15 to 25% for cats
Fiber	≤5%**

*Nutrients expressed on a dry matter basis.
**Lower is better.

Digestibility

The primary nutritional factor in the management of EPI is food digestibility. The use of highly digestible foods (fat and digestible [soluble] carbohydrate ≥90% and protein ≥87%) should be coupled with the addition of pancreatic enzyme preparations to the food. In one study, the combination of a highly digestible commercial veterinary therapeutic food plus pancreatic enzymes provided more metabolizable energy to dogs with EPI than a grocery brand food with pancreatic enzyme supplementation (Pidgeon, 1982). Further studies using naturally occurring EPI cases also demonstrated the benefits of feeding highly digestible foods (Westermarck et al, 1990, 1995).

Highly digestible veterinary therapeutic foods contain meat and carbohydrate sources that have been highly refined to increase digestibility. Typical ingredients in such commercial foods include egg, cottage cheese and muscle and organ meats. Carbohydrates in highly digestible foods are primarily starches of corn, rice, barley and wheat, which are readily digested if properly cooked.

Fat

Steatorrhea is the most prominent clinical sign in patients with EPI. As discussed above, feeding a highly digestible food in conjunction with pancreatic enzyme supplementation is more effective than simply decreasing the fat content of the current food (Pidgeon, 1982; Westermarck et al, 1995). Dry matter (DM) dietary fat levels for patients with EPI should be in the range of 10 to 15% for dogs and 15 to 25% for cats. Overall fat digestion of a highly digestible food with added pancreatic enzymes can exceed 70% in dogs with EPI (Pidgeon, 1982). The addition of medium-chain triglycerides (MCT) to the food can result in increased total fat assimilation because they are more water soluble and are digested and absorbed by mechanisms independent of those used for long-chain triglycerides. However, supplementation of foods with MCT generally decreases the food's palatability, which may decrease total food intake and thus be counterproductive. This is not necessarily true for commercial foods that contain MCT. Addition of MCT is unnecessary in most cases (Rutz et al, 2004) (Box 58-1).

Feeding high-fat growth-type foods (>27% DM fat) in conjunction with pancreatic enzymes has been associated with increased frequency of defecation, poor fecal consistency and higher fecal fat content in canine EPI as compared to results obtained from feeding lower fat diets (Westermarck et al, 2006).

Fiber

Foods for patients with EPI should contain very little fiber (≤5% DM, lower is better) to maximize food digestibility. Dietary fiber impairs pancreatic enzyme activity in vitro. Decreasing the fiber content from 4% to less than 1% in a study of people with EPI decreased fecal weight and fat excretion by one-third and reduced bloating and flatus (Dutta and Hlasko, 1985). In a three-week dietary trial in dogs with EPI, feeding a low-fat (7% DM), high-fiber (25% DM) food in conjunction with pancreatic enzymes resulted in mild weight loss, increased consumption of food and increased fecal mass and defecation frequency (Westermarck and Wiberg, 2006). These findings are likely attributable to the low fat and caloric content of the food and the effect of high fiber levels on food digestibility. Interestingly, stool quality in these patients was considered good (firmer) as compared to feces produced when the dogs were fed higher fat foods.

Other Nutritional Factors

Vitamins

Micronutrients should be considered in the dietary management of patients with malassimilation. In EPI, the lack of pancreatic lipase results in failed solubilization and absorption of the fat-soluble vitamins A, D, E and K. Vitamins A and D may be initially administered intramuscularly (0.5 to 1 ml divided into two intramuscular sites every three months), if fat absorption remains impaired. Supplementation of vitamins A and D should be reserved for patients with demonstrably low levels of these vitamins or ongoing fat malabsorption because oversupplementation may be harmful.

Vitamin E supplementation (400 to 500 IU, per os, q24h) may be beneficial when serum concentrations are very low. Clinically, vitamin K deficiency has been described (Perry et al,

1991). Severe hemorrhage may occur when vitamin K stores are depleted because of the vitamin's pivotal role in the post-translational carboxylation of coagulation factors. Parenteral supplementation of vitamin K_1 is recommended (5 to 20 mg, q12h) if coagulopathies are detected in dogs and cats with EPI.

Folate and cobalamin are also of concern. Dogs and cats with EPI often have low serum cobalamin concentrations (Williams, 1996). Reports have identified cobalamin deficiency in 82% of dogs (Batchelor et al, 2007) and 60% of cats (Steiner and Williams, 2000) with EPI. Cobalamin deficiency has been associated with poor outcomes in canine EPI (Batchelor et al, 2007). Several mechanisms may play a role in the development of cobalamin deficiency in EPI. The absence of pancreatic bicarbonate secretion may reduce the intestinal luminal pH and the affinity of cobalamin for intrinsic factor (Simpson et al, 1989). Additionally, the pancreas appears to be the primary source of intrinsic factor in dogs and cats rather than the gastric mucosa (Simpson et al, 1989; Fyfe, 1993). Finally, when SIBO is present, the proximal gut microflora may consume dietary cobalamin before it can be absorbed (Batt and Morgan, 1982; Williams, 1991). If serum levels of cobalamin are low, weekly supplementation by subcutaneous or intramuscular routes is recommended (100 to 250 µg for cats; 250 to 1,200 µg for dogs) for six weeks or until serum cobalamin concentration normalizes (Williams, 1996; Steiner, 2008). Long-term monitoring of serum cobalamin levels is recommended in dogs and cats with EPI to avoid a recurrence (Williams, 2006).

Serum folate levels are elevated in most dogs with EPI probably due to SIBO and bacterial elaboration of folate (Williams, 1996). Serum folate concentration may be decreased, however, in dogs with EPI and concurrent enteropathies involving the ileum (Williams, 1996). In such cases, parenteral supplementation of folate (0.5 to 1 mg, per os q24h) is recommended until the ileal pathology is resolved. Folate deficiency inhibits pancreatic exocrine function in rats (Balaghi and Wagner, 1995).

Minerals

Dogs with experimentally induced EPI had reduced serum and tissue levels of zinc and copper (Adamama-Moraitour et al, 2001). Similar findings have been recognized in some human patients with EPI (Watson et al, 1988) and are speculated to be due to a deficiency in a pancreatic zinc-binding factor, which facilitates zinc transport and absorption within the intestinal epithelium. However, zinc and copper levels have been investigated in spontaneous cases of EPI and were not found to be low (Williams, 1992). Thus, routine supplementation of these minerals does not seem to be warranted in EPI.

FEEDING PLAN

Dietary management is an essential component in the medical management of patients with maldigestive diseases. Dietary intake should meet the patient's nutrient needs in a form that promotes nutrient absorption. The organs of the GI tract have very large reserve capacities and the small intestine has a very large and efficient absorptive area. About 90% of the pancreas must be dysfunctional before clinical signs of maldigestion are seen (Jacobs et al, 1989). Consequently, patients with clinical signs of maldigestion have very little digestive capacity remaining.

Assess and Select the Food

Levels of key nutritional factors should be evaluated in foods currently fed to patients with EPI and compared with recom-

Table 66-3. Key nutritional factors in selected commercial veterinary therapeutic foods for cats with exocrine pancreatic insufficiency compared to recommended levels.*

**Lower is better.

mended levels. Information from this aspect of assessment is essential for making any changes to foods currently provided. Changing to a more appropriate food is indicated if key nutritional factors in the food currently provided do not match recommended levels.

Selected commercial veterinary therapeutic foods that are highly digestible and designed for canine and feline patients with GI disease are listed in **Tables 66-2** and **66-3**, respectively. These foods are marketed for patients with EPI. For comparative purposes, these tables include recommended levels of key nutritional factors. Feeding these foods to patients with EPI often allows smaller amounts of pancreatic enzyme preparations to be used, which results in significant cost savings for pet owners, especially those with large-breed dogs. Foods for young, growing dogs and cats with EPI should also meet the optimal levels of key nutritional factors for growth (Chapters 17 [puppies] and 24 [kittens]).

Assess and Determine the Feeding Method

Because the feeding method is often altered in patients with EPI, a thorough assessment should include verification of the feeding method currently being used. Items to consider include feeding frequency, amount fed, how the food is offered, access to other food and who feeds the pet. All of this information should have been gathered when the dietary history was obtained.

Patients presenting with signs of malnutrition due to chronic maldigestion should be given parenteral nutritional support during the diagnostic workup. Parenteral nutrition in the management of these patients is primarily supportive, may be essential in the initial stages of case management and improves the patient's disposition. Parenteral nutrition also improves caloric, protein and micronutrient balances in veterinary patients, thereby decreasing risks associated with diagnostic procedures including exploratory surgery. Continued administration of parenteral nutrition (more than three days) is necessary in debilitated patients as a supportive procedure until nutrients can be adequately absorbed. Parenteral nutrition can be performed at most practices in a manner similar to other fluid therapies (Chapter 26).

Patients with EPI usually should be fed multiple small meals per day with pancreatic enzyme supplementation to improve digestibility. At home, feeding at least two to three times daily helps prevent dietary overload and osmotic diarrhea. The daily energy requirement of underweight patients should be increased above that for healthy patients (2 x resting energy requirement for their estimated ideal weight) until ideal body weight and condition (BCS 2.5/5 to 3.5/5) are reached. Even after patients reach ideal body weight, it may be necessary to offer an above average amount of food to offset the persistent degree of malabsorption. Pancreatic enzymes should be added immediately before feeding. (See below.)

ADJUNCTIVE MEDICAL MANAGEMENT

Supplemental Pancreatic Enzymes

In addition to dietary management, effective treatment of EPI requires oral administration of pancreatic enzymes. Most often, pancreatic enzymes are supplied as dried, powdered extracts of bovine or porcine pancreas (**Table 66-4**). Such powder extracts are typically more effective than tablets or capsules (Westermarck, 1987; Steiner, 2008). Tablets, capsules and enteric-coated preparations are not recommended. Lipase activity of pancreatic enzyme preparations varies markedly. Generally, the more expensive preparations have better lipase activity.

If available, raw bovine, porcine or ovine pancreas can be effective (Westermarck et al, 1990). Raw pancreas can be frozen in individual doses for several months without losing enzyme activity. Dogs should receive 30 to 90 g (1 to 3 oz.) of freshly thawed, chopped pancreas, whereas cats should

*Enzymatic contents (IU) per capsule, tablet or tsp of powder (2.8 g).

receive 30 g (1 oz.) of chopped pancreas per meal (Steiner, 2008).

Pancreatic enzyme supplementation for dogs should be initiated at a dose of 1 tsp of powdered pancreatic extract per 10 kg body weight at each meal. For cats, a starting dose of 1 tsp should be administered with each meal (Suzuki et al, 1997). Enzymes should be mixed with food immediately before the meal is fed. Owners may be able to decrease the dose of pancreatic enzymes based on their pet's response. Most dogs require at least 1 tsp of enzymes per meal (Williams, 1996).

Despite the administration of pancreatic enzyme preparations, fat digestion does not return to normal in dogs with EPI. Inactivation of pancreatic lipase by the acidic pH of the stomach is likely responsible for failure to normalize fat digestion (Williams, 1994).

Antacids and H_2-Receptor Blockers

Antacids and H_2-receptor blockers have been recommended in the therapeutic regimen to reduce gastric acid-induced destruction of orally administered enzymes. This practice, however, is costly and does not increase efficacy of pancreatic enzyme supplementation (Williams, 1994). Concurrent oral administration of sodium bicarbonate or bile salts and pre-incubation of the meal with pancreatic enzymes are also unnecessary (Williams, 1994, 1996). In one study, adding digestive enzymes to food 20 to 30 minutes before feeding did not improve the response to dietary management (Pidgeon, 1980).

Antibiotics

Oral antibiotics may be necessary to resolve clinical signs in dogs and cats with concurrent SIBO. Tetracycline (20 mg/kg body weight, per os, t.i.d. for 21 days) or tylosin (25 mg/kg body weight, per os, b.i.d. for six weeks) is most often recommended for this purpose; however, metronidazole (10 to 20 mg/kg body weight, per os, every 24 hours for seven to 14 days) may be more effective if SIBO with anaerobic organisms is suspected.

Insulin

Concurrent diabetes mellitus in EPI cases must be managed with insulin. Unfortunately, the fiber-enhanced foods often recommended for diabetic pets are contraindicated for those with EPI (Remillard and Thatcher, 1989). Dietary management of patients with concurrent diabetes mellitus and EPI often requires a modified profile of key nutritional factors. In many cases, foods containing 10 to 15% DM fat, 50 to 55% DM complex, digestible (soluble) carbohydrate and 5 to 10% total dietary fiber can be used.

REASSESSMENT

The prognosis for long-term response to treatment is good in dogs with EPI. In one study, 19% of affected dogs were euthanized within one year of diagnosis due to cost of treatment and/or persistence of clinical signs; however, the median survival time was more than 60 months (Batchelor et al, 2007).

Clinical signs usually resolve within three to five days with proper dietary and enzyme therapy, and weight gain is evident by five to 10 days. Successfully managed canine cases of EPI are recognized by weight gain (0.5 to 1 kg per week) and improved body condition and stool consistency. The food and enzyme dose should be reevaluated if less satisfactory results are obtained. In a retrospective study of dogs with EPI, approximately 10% of patients still had soft to diarrheic stools and 20% were considered underweight (owners' assessment) after 12 months of treatment (Batchelor et al, 2007). Often, the initial dose of pancreatic enzymes is inadequate and must be increased. Every effort should be made to rule out concurrent small bowel disease (e.g., eosinophilic gastroenteritis, lymphoplasmacytic enteritis, SIBO) or diabetes mellitus when clinical response is unsatisfactory. In addition, serum cobalamin levels should be assessed to ensure that cobalamin nutriture is adequate. If not, parenteral cobalamin supplementation should be initiated as described above.

Pancreatic enzyme extract may cause oral mucosal irritation resulting in hemorrhage and reluctance to eat (Rutz et al, 2002; Snead, 2006). If this occurs, decreasing the dose and mixing the pancreatic enzyme powder well in the food may resolve the issue. If not, feeding raw pancreas should be considered.

Well-compensated patients should be evaluated immediately if a change or decline in condition is noted. Feeding more food than expected may be necessary to compensate for

decreased digestibility and to maintain optimal body weight and condition. Regaining or maintaining optimal body weight and condition, normal activity level, improved disposition and absence of clinical signs are measures of successful dietary management.

CASE 66-1

Chronic Diarrhea in a German Shepherd Crossbred Dog

Jörg M. Steiner, med vet, Dr med vet, Dipl. ACVIM (Internal Medicine) and ECVIM (Companion Animal)
College of Veterinary Medicine
Texas A&M University
College Station, Texas, USA

Patient Assessment

A two-and-one-half-year-old neutered male German shepherd crossbred dog was examined for chronic diarrhea, polyphagia and weight loss of six months' duration. The feces were characteristic of small bowel disorders: watery to semi-formed consistency, clay-colored, large volumes passed two to three times per day, no melena or hematochezia and only small amounts of mucus. Body weight had decreased over the past six months from 34 kg to 22 kg and body condition was now poor (body condition score [BCS] 1/5). The dog's coat was dull and brittle.

Diagnostic evaluation included a complete blood count (normal), serum biochemistry profile (normal except for mild elevations in liver enzyme activity), urinalysis (normal), direct fecal smear and fecal flotation for parasites (negative), fecal stain for fat (positive) and testing for serum concentrations of canine trypsin-like immunoreactivity (TLI), cobalamin and folate. Serum canine TLI concentration was decreased (0.6 mg/l, normal 5 to 35), serum cobalamin concentration was decreased (150 ng/l, normal 225 to 1,680) and serum folate concentration was increased (23.4 mg/l, normal 6.7 to 17.4).

Assess and the Food and Feeding Method

The dog had been fed several commercial dry foods free choice during the past six months. A veterinary therapeutic food (Limited Ingredient Diet: Canine Whitefish and Potato[a]) had been fed for the last two months as an elimination trial for suspected food allergy. The dog was fed five cups per day (1,645 kcal [6.88 MJ]).

Questions

1. What is the tentative diagnosis?
2. What are the key nutritional factors for this dog?
3. Outline a feeding plan (foods and feeding method) for this patient.
4. What ancillary therapy is indicated to complement the feeding plan?

Answers and Discussion

1. A history of chronic diarrhea, steatorrhea and weight loss in a young German shepherd dog suggests exocrine pancreatic insufficiency (EPI) or some other cause of malassimilation (i.e., maldigestion or malabsorption). The decreased serum TLI concentration confirms that EPI is present. Mild increases in hepatic enzyme activity are often seen in patients with EPI. Liver disease does not need to be evaluated further unless hepatic enzyme activity continues to increase or if response to therapy is suboptimal. The decreased serum cobalamin concentration and increased serum folate concentration are consistent with small intestinal bacterial overgrowth (SIBO). Increased numbers of many species of bacteria generate large quantities of folate, which is available for absorption via specific carriers in the proximal small intestine. In contrast, most bacteria compete for available intraluminal cobalamin and thereby reduce its uptake in the distal small intestine. SIBO commonly occurs as a secondary problem associated with EPI. The poor coat probably reflects protein-calorie malnutrition and essential fatty acid deficiency.
2. Key nutritional factors to consider in patients with EPI include food digestibility and fat and fiber content. Selected vitamins are sometimes important. The use of highly digestible foods (fat and digestible carbohydrate ≥90% and protein ≥87%) in conjunction with pancreatic enzyme supplements provides more metabolizable nutrients to dogs with EPI than use of foods with average digestibility and comparable supplementation. Although steatorrhea due to fat malassimilation is a prominent sign in patients with EPI, fat restriction is unnecessary. Moderate dietary fat levels in conjunction with pancreatic enzyme supplementation are more effective than simply decreasing the fat content of the food. Some forms of dietary fiber impair pancreatic enzyme activi-

ty in vitro and may have similar effects in animals. Therefore, excess dietary fiber should be avoided (≤5% fiber, dry matter basis) in these patients. Fat-soluble vitamins, cobalamin and folate are sometimes nutrients of concern in patients with EPI complicated by SIBO. Such patients may develop deficiencies in one or more fat-soluble vitamins. Clinical signs of vitamin K deficiency (vitamin K-responsive coagulopathy) have been described in patients with EPI. Several mechanisms may play a role in cobalamin deficiency including alterations in intestinal luminal pH, decreased levels of intrinsic factor and SIBO. Serum folate concentrations are often elevated in EPI patients with SIBO but may be decreased in patients with concurrent enteropathies.

3. Dogs with EPI should be fed commercial or homemade foods that are highly digestible, moderate in fat and low in fiber (**Table 66-2**). The initial daily energy requirement (DER) should be estimated as 2 x resting energy requirement using an ideal body weight of 34 kg (DER = 2,180 kcal [9.12 MJ]). The DER should be adjusted based on weekly assessments of fecal quantity/quality and body weight and condition. Parenteral administration of fat-soluble and B-complex vitamins is also appropriate.
4. Pancreatic enzyme supplementation is necessary using either dried pancreatic extracts (1 tsp/10 kg body weight with meal) or raw bovine, porcine or ovine pancreas (30 g/10 kg body weight with meal). Powdered extracts are usually preferred to tablets and capsules. The amount can be gradually decreased to find the minimum effective dose after clinical improvement occurs. Broad-spectrum antimicrobial therapy is appropriate for most cases of SIBO; oral oxytetracycline or tylosin is often recommended. However, SIBO is often self-limiting in patients with EPI if dietary alterations and pancreatic enzyme supplementation are successful in controlling clinical signs. SIBO is clinically significant in some patients with EPI, so recovery will not be complete unless antimicrobial therapy is given.

Progress Notes

The food was changed to a commercial dry veterinary therapeutic food that was highly digestible, moderate in fat and low in fiber (Prescription Diet i/d Canine[b]). Two tsp of dried pancreatic extract (Pancrezyme[c]) were mixed thoroughly with two cups of slightly moistened food just before feeding. This mixture was fed three times daily.

The dog ate this mixture well and the diarrhea gradually decreased over the next six to eight weeks. As the dog's stool improved, body weight increased, body condition improved and the dog's coat became shinier and less brittle. A body weight of 31 kg and BCS of 3/5 were reached approximately 12 weeks after initiating therapy. At that time the dosage of dried pancreatic extract was reduced to 1.5 tsp with each meal and plans were made to further reduce the dosage if clinical signs did not return.

Chapter 67

Acute and Chronic Pancreatitis

Deborah J. Davenport
Rebecca L. Remillard
Kenny W. Simpson

"What do you want–an adorable pancreas?"
Jean Kerr, The Snake Has All the Lines

CLINICAL IMPORTANCE

Pancreatitis has been recognized as a clinical entity in dogs for more than a century (Simpson, 1993). In dogs, acute pancreatitis is an important differential diagnosis for vomiting and abdominal pain. Because of difficulties in diagnosis, pancreatitis is a less common diagnosis in cats. Based on clinical and pathologic reports, diagnosis of feline pancreatitis is apparently increasing (Akol et al, 1993; Hill and Van Winkle, 1993; Steiner and Williams, 1997; Hines et al, 1996; De Cock et al, 2007; Maddison, 2008). One study reported an incidence of 0.57 to 3.5% in cats (Mansfield and Jones, 2001). Another pathology study reported that exocrine pancreatic lesions are present in approximately 1.5% of patients presented for necropsy and that 59% of dogs and 46% of cats with exocrine pancreatic lesions had evidence of pancreatitis (Hanichen and Minkus, 1990).

PATIENT ASSESSMENT

History and Physical Examination

As many as 90% of dogs with pancreatitis present with acute vomiting (Hess et al, 1998). Vomiting may be sporadic and mild or very severe. Other clinical signs include abdominal pain, depression, anorexia, fever and diarrhea. Icterus and pale-colored stools may be reported if pancreatic inflammation and edema are severe enough to result in common bile duct obstruction. If present, diarrhea is usually of large bowel origin because the transverse colon passes dorsal to the pancreas and is susceptible to local inflammation at that site.

An episode of dietary indiscretion often occurs during the 24 hours before the onset of vomiting. The owner commonly relates consumption of high-fat human food. Occasionally, the onset of clinical signs is preceded by administration of drugs associated with pancreatitis. Corticosteroids, in particular, have been linked to pancreatitis in dogs (Simpson, 1993).

Cats with pancreatitis have highly variable clinical signs. In some cats, the disease may mimic the typical canine presentation (i.e., acute vomiting, lethargy, anorexia, diarrhea and abdominal pain). In others, a more indolent, smoldering course occurs, resulting in a mild chronic illness (Steiner and Williams, 1997). The most common clinical signs in cats are anorexia, lethargy, dehydration and weight loss. Abdominal pain may be difficult to recognize and vomiting occurs in fewer than 50% of cases (Washabau, 2001). Other cats may present with a palpable abdominal mass. In some cats, pancreatitis may be linked to diabetes mellitus and clinical signs may include

polydipsia/polyuria and weight loss (Steiner and Williams, 1997). In others, hepatic lipidosis or cholangiohepatitis may occur concurrently resulting in icterus (Akol et al, 1993; Weiss et al, 1996). In some cats, pancreatitis, cholangiohepatitis and inflammatory bowel disease (IBD) may be present simultaneously (triaditis).

Depression, fever and dehydration may be the most prominent physical examination findings. Abdominal palpation may elicit splinting and discomfort that can be localized to the right cranial quadrant. Icterus, shock and coagulopathies may be detected in severe cases.

Clinical manifestations are variable in chronic pancreatitis. Weight loss and poor body condition may be the only signs noted in cats. An abnormal thickening or hardness of the falciform fat pad may be palpated in some cats, suggesting saponification and fat necrosis.

Laboratory and Other Clinical Information

The laboratory diagnosis of acute and chronic pancreatitis can be very frustrating. Diagnosis is hampered by the poor specificity of available laboratory tests and the inaccessibility of tissue for cytologic or histopathologic examination. Serum amylase and lipase activities are the most commonly used laboratory tests for the diagnosis of pancreatitis in dogs and cats. Unfortunately, these tests are not very specific because they are influenced by a number of other disease conditions (e.g., renal failure, dehydration, hyperlipidemia). In addition, the short half-life of amylase and lipase often precludes their use as diagnostic aids unless the patient is presented promptly after the onset of clinical signs. If present, hyperamylasemia and hyperlipasemia support a diagnosis of pancreatitis if azotemia and hyperlipidemia are not present. In cats, pancreatic amylase secretion is only 10% of that in dogs and serum amylase is usually low in cats with pancreatitis (Zoran, 2007).

Serum trypsin-like immunoreactivity (TLI) concentration has been suggested as a diagnostic aid for evaluating dogs and cats with suspected pancreatitis. Because TLI is specifically pancreatic in origin, high serum TLI concentrations were hoped to be a more reliable indicator of clinical pancreatitis than high amylase or lipase activities (Simpson et al, 1989). However, the sensitivity of TLI assays in dogs and cats with acute pancreatitis appears to be very low (30 to 60%) (Williams, 2006).

More recently, assays for canine and feline specific pancreatic lipase have come into clinical use. In healthy dogs and cats, very little pancreatic lipase is present in blood. In pancreatitis, the inflamed organ leaks larger amounts of lipase into the blood, which is measurable by immunoassay. These species-specific assays appear to be more sensitive (>80%) than TLI concentrations for the diagnosis of pancreatitis in dogs and cats (Steiner, 2006; Forman et al, 2002). Additionally, these assays are not falsely elevated in renal disease (Steiner et al, 2001) or by corticosteroid administration (Steiner et al, 2003).

A complete blood cell count, serum biochemistry profile and urinalysis should be done for any dog or cat suspected to have pancreatitis to rule out other potential causes for the clinical signs. Additionally, these tests may aid in the diagnosis of concurrent medical conditions such as diabetes mellitus, hepatic lipidosis, interstitial nephritis and cholangiohepatitis.

Anorectic or vomiting canine and feline patients with pancreatitis may become hypokalemic. In one retrospective study, hypocalcemia was recognized in 40% of cats with acute pancreatitis and was considered indicative of a poor prognosis (Kimmel et al, 2001). Hypocalcemia may be attributable to conditions such as hypoalbuminemia, parathormone resistance or to the saponification of calcium by fatty acids (Kimmel et al, 2001; Washabau, 2001).

An inflammatory leukogram is typically identified in patients with pancreatitis. A degenerative left shift may indicate severe necrotic pancreatitis. In cats, leukopenia appears to occur more commonly than in dogs and is associated with a poor prognosis (Washabau, 2001). If thrombocytopenia is noted on the hemogram, a complete coagulation screen should be performed to rule out disseminated intravascular coagulation.

Imaging can be useful for diagnosing pancreatitis in dogs and cats. Findings consistent with pancreatic inflammation on survey abdominal radiographs may include haziness and widening of the gastroduodenal angle in the right cranial quadrant. Often, segmental gas distention of the proximal duodenum is noted. In the hands of an experienced operator, abdominal ultrasonography appears to be a sensitive test for the diagnosis of acute pancreatitis in dogs (Mansfield et al, 2008). Typical findings include enlargement of the pancreas, hypoechogenicity, dilatation of the pancreatic duct and hyperechogenicity of the mesentery. Peripancreatic fluid accumulation is a common finding in dogs and cats (Williams, 2006). Ultrasonography may reveal fluid-filled cysts, pseudocysts or abscesses within the pancreatic parenchyma and can be used to guide needle aspiration of pancreatic masses (Salisbury et al, 1988; VanEnkevort et al, 1999). In cats, the reported sensitivity of abdominal ultrasonography ranges from 20 to 67% (Rademacher et al, 2008). Typical ultrasonographic findings in cats are similar to those described in dogs. More sophisticated contrast-enhanced power and color Doppler ultrasonographic procedures also distinguish between normal cats and cats with pancreatitis (Rademacher et al, 2008). When coupled with measurement of serum pancreatic lipase immunoreactivity, abdominal ultrasonography was more sensitive than computed tomography in the diagnosis of acute pancreatitis in cats (Forman et al, 2004).

The gold standard for diagnosing acute and chronic pancreatitis is histopathology. Unfortunately, pancreatic biopsies are rarely performed because of the invasive nature of the procedure and because many patients with pancreatitis are poor anesthetic risks. However, laparoscopic techniques for the diagnosis of pancreatic disease in dogs and cats have been described; these provide a minimally invasive method for collection of pancreatic biopsy specimens (Marmoinen et al, 2002; Webb and Trott, 2008). Unfortunately, laparoscopy does not provide good visualization of the entire pancreas, which can result in failure to biopsy affected areas of the organ (Steiner, 2008).

Risk Factors

Several risk factors have been associated with pancreatitis in dogs and cats (**Table 67-1**). Most patients with these risk factors, however, do not develop pancreatitis.

A number of endocrinopathies such as diabetes mellitus, hypothyroidism and hyperadrenocorticism have been linked to pancreatitis in dogs (Hess et al, 1999). These endocrine conditions are often associated with hyperlipidemia and obesity, two other risk factors for acute pancreatitis.

An association has been made between hyperlipidemia and acute pancreatitis in dogs and people that has led to speculation that disturbances in lipid metabolism may be involved (Simpson, 1993). The exact relationship is unknown in dogs and cats and information is often extracted from human cases. Hyperlipidemia is thought to precede and cause the development of pancreatitis; however, it can also be evident during and after such episodes (Simpson, 1993). The rate of hyperlipidemia in people with pancreatitis has been estimated between 3 and 12% when alcoholics are not included in the case study. The incidence of hyperlipidemia in dogs or cats with pancreatitis is generally thought to be high. In a retrospective study of fatal acute pancreatitis in dogs, 26% of patients were hyperlipidemic (Hess et al, 1998). However, experimentally induced pancreatitis in dogs has not resulted in lipemia or hypertriglyceridemia (Bass et al, 1976; Whitney et al, 1987). Hypertriglyceridemia is present in some but not all naturally occurring cases of canine pancreatitis as determined by serum lipid and electrophoretic patterns (Whitney et al, 1987; Rogers et al, 1975). Most people with pancreatitis do not have hyperlipidemia; however, those that do and who are not alcoholics more often have preexisting hyperlipoproteinemia types I and V; more specifically hypertriglyceridemia. Serum triglyceride levels (>900 mg/dl) increase the risk of pancreatitis in dogs (Xenoulis et al, 2006).

Several pet breeds are predisposed to pancreatitis (e.g., miniature schnauzers, briards, Shetland sheepdogs, Siamese cats). This predisposition may be attributed to the fact that these breeds are also frequently hypertriglyceridemic. Recently, mutations in the pancreatic secretory trypsin-inhibitor gene (SPINK gene) have been described in miniature schnauzers, which may explain this breed's increased risk for pancreatitis (Bishop et al, 2007; Steiner, 2008). A number of other breeds also appear to be at risk for pancreatitis including boxers, cavalier King Charles spaniels, cocker spaniels, collies and Yorkshire terriers (Watson et al, 2007; Hess et al, 1999; Lem et al, 2008). Feeding a high-fat (>20% dry matter [DM]) food, treat or human food has often been associated with the onset of acute pancreatitis and a history of dietary indiscretion of high-fat human foods increases the risk of acute pancreatitis (Steiner, 2008). Ingestion of table scraps, garbage and new/unusual foods has been linked to pancreatitis in a case control study (Lem et al, 2008). Experimentally, feeding high-fat, low-protein foods was associated with the development of pancreatitis and hepatic lipidic changes in dogs (Lindsay et al, 1948; Goodhead, 1971). The most widely repeated explanation for the association between hypertriglyceridemia and acute pancreatitis is that hydrolysis of serum triglycerides by lipase within the pancreatic microvasculature releases free fatty acids locally. Free fatty acids cause microthrombi and/or bind with calcium to cause further capillary damage, which, in turn, releases more pancreatic lipase (Havel, 1969). Consumption of calorically dense, high-fat foods also contributes to obesity in pets, which is also considered a risk factor for pancreatitis (Lem et al, 2008). In one report, 43% of dogs with acute pancreatitis were considered overweight or obese (Hess et al, 1998). Obese patients develop more severe experimental pancreatitis than dogs with lower body condition scores (Relford et al, 2006).

Pancreatitis has been associated with hypercalcemia in several dogs with hyperparathyroidism or cancer and in a dog receiving a calcium infusion (Simpson, 1993; Relford et al, 2006). Experimentally, elevated ionized calcium concentrations can induce pancreatitis in cats (Frick et al, 1990). The pathophysiologic mechanism for pancreatitis in association with hypercalcemia has not been determined.

Drug-induced pancreatitis in people is very common; alcohol consumption is recognized as the most common cause of the disease. Reports of drug-induced pancreatitis in companion animals are uncommon but the following compounds have been implicated: calcium, azathioprine, vinca alkaloids, l-asparaginase, phenobarbital and potassium bromide in dogs and tetracyclines, sulfonamides and organophosphates in cats.

Anecdotal reports suggest that corticosteroids are the most common drug associated with pancreatitis in dogs. Pancreatitis

Intervertebral disk disease
Ischemia or reperfusion
Postgastric dilatation-volvulus
Obesity

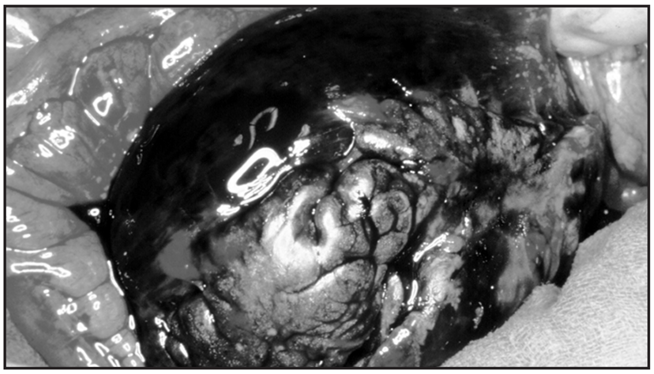

Figure 67-1. Intraoperative photograph of a dog with acute necrotizing pancreatitis. (Courtesy Dr. Dan Smeak, College of Veterinary Medicine, The Ohio State University, Columbus.)

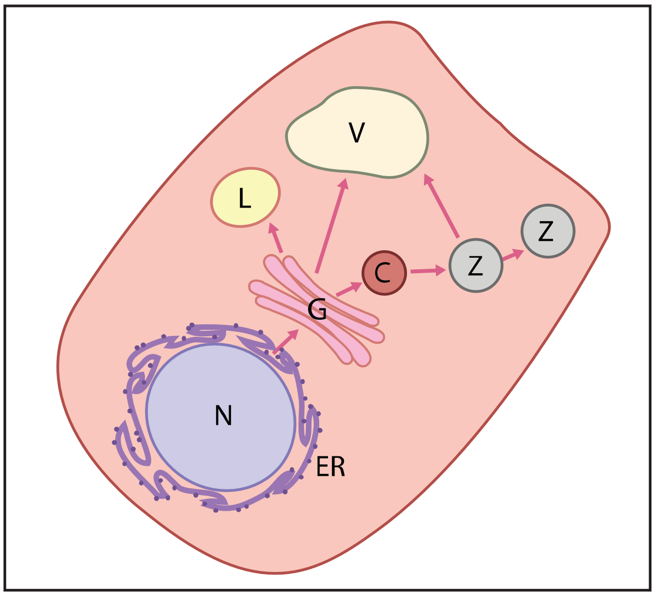

Figure 67-2. Schematic representation of zymogen and lysosomal fusion in acute pancreatitis. Digestive and lysosomal enzymes are synthesized in the rough endoplasmic reticulum (ER) and transferred to the Golgi apparatus (G) next to the nucleus (N). Normally, digestive and lysosomal enzymes are separated. Digestive enzymes are concentrated in zymogen granules within acinar cells and lysosomal enzymes are stored separately in lysosomes (L). Digestive enzymes are concentrated in condensing vacuoles (C) and in zymogen granules (Z) that fuse with luminal-plasma membranes. Hyperstimulation of the pancreas results in mixing of lysosomal and digestive enzymes in large vacuoles (V). (Adapted from Simpson KW. Current concepts of the pathogenesis and pathophysiology of acute pancreatitis in the dog and cat. Compendium on Continuing Education for the Practicing Veterinarian 1993; 15: 247-254.)

is common in dogs with hyperadrenocorticism and in dogs receiving corticosteroids for management of intervertebral disk disease (Moore and Withrow, 1982). Experimentally, corticosteroids increase the sensitivity of dispersed acinar cells to cholecystokinin and stimulate proliferation of the pancreatic ductular epithelium (Simpson, 1993). However direct evidence is lacking for a role of corticosteroids in the development of pancreatitis in dogs and cats (Steiner, 2008).

In dogs, potassium bromide and phenobarbital administration has been associated with elevations in serum pancreatic lipase immunoreactivity and acute pancreatitis (Podell and Fenner, 1993; Gaskill and Cribb, 2000; Steiner et al, 2008). Pancreatitis occurs in as many as 6 to 7% of dogs treated for seizures with potassium bromide.

Ischemia and reperfusion injury have been linked to acute pancreatitis (Williams, 1996; Simpson, 1993). Hypovolemic shock, gastric dilatation-volvulus and abdominal trauma have been reported to precede acute pancreatitis (Williams, 1996; Simpson, 1993). In addition, abdominal surgery marked by inept manipulation of the pancreas can result in pancreatitis (Williams, 1996; Simpson, 1993).

In cats, pancreatitis does not seem linked to obesity, hyperlipidemia, hypertriglyceridemia or to dietary triggers (Mansfield and Jones, 2001; Zoran, 2007). Instead, a number of infectious diseases have been implicated including calicivirus, toxoplasmosis, feline infectious peritonitis, feline immunodeficiency virus, panleukopenia, the fluke, *Amphimerus pseudofelieus*, (Relford et al, 2006) and enterococci (Lapointe et al, 2000).

Etiopathogenesis

Acute pancreatitis is the sudden onset of inflammation of the pancreatic acinar tissue. Typically, the primary histopathologic lesion is edema. After resolution, there is usually no residual pancreatic lesion. However, in more severe cases, the pancreatic lesion may become hemorrhagic or may progress to necrosis (**Figure 67-1**). Mortality is high in acute necrotizing pancreatitis. Acute edematous or hemorrhagic pancreatitis may occur as a singular or recurrent event in dogs and cats.

Pancreatitis occurs as a consequence of intracellular pancreatic acinar enzymatic activation and resultant autodigestion of the pancreas. In the normal pancreas, safeguards ensure that harmful pancreatic enzymes are not activated until they reach the intestinal lumen (**Table 67-2**) (Stewart, 1994). Pancreatic enzymes are synthesized in endoplasmic reticuli, modified in Golgi apparatuses and stored in zymogen granules within acinar cells. Evidence suggests that intracellular pancreatic enzyme activation occurs as a result of abnormal zymogen activation. Normally, zymogens and lysosomes are segregated intracellularly. In pancreatitis, lysosomes containing proteases fuse with zymogen granules (**Figure 67-2**) (Simpson, 1993). The lysosomal contents (e.g., proteases such as cathepsin B) activate trypsinogen. In addition, the acidic environment of lysosomes interferes with self-regulating trypsin inhibitors stored with pancreatic enzymes in zymogen granules.

Cholecystokinin and acetylcholine are widely recognized as the principal physiologic mediators of pancreatic enzyme secretion (Simpson, 1993). Normally, these substances initiate fusion of zymogen granules with the acinar cell membrane. Hyperstimulation of the pancreas with supraphysiologic doses of cholecystokinin appears to cause pancreatitis in experimental animals by interfering with the intracellular movement of zymogens resulting in fusion of zymogens and lysosomes (Simpson, 1993). The lysosomal enzyme cathepsin B is then thought to activate trypsinogen and precipitate pancreatitis

(Simpson, 1993). Pancreatic duct obstruction also appears to facilitate fusion of zymogens and lysosomal enzymes. Foods high in fat and protein (particularly the amino acid arginine) stimulate production and release of cholecystokinin, gastrin and secretin (Simpson, 1993). Organophosphate insecticides and intravenous calcium infusions are hypothesized to cause hyperstimulation via cholecystokinin (Simpson, 1993).

Bile acid and enteric reflux into the pancreatic duct can also activate pancreatic enzymes interstitially (i.e., within the pancreatic duct system and interstitium) (Simpson, 1993). This mechanism is thought to be involved in the development of pancreatitis in cats in conjunction with suppurative cholangiohepatitis and enteritis (Simpson, 1993). The anatomic configuration of the common bile duct and pancreatic duct in cats facilitates this mechanism. Experimentally, free fatty acids generated by the action of lipase on triglycerides damage acinar cell membranes, releasing lecithin, which causes marked necrosis of acinar cells when converted to lysolecithin by phospholipase A_2 (Simpson, 1993).

Regardless of the initiating cause, active pancreatic enzymes (trypsin, phospholipase, collagenase and elastase) and inflammatory mediators are released into the pancreatic tissues and blood vessels. These factors apparently activate coagulation, fibrinolytic, kinin and complement cascades (Simpson, 1993). Circulating defense mechanisms include α_1-antitrypsin and α_2-macroglobulin, which bind to active enzymes to contain local damage and prevent systemic damage (Simpson, 1993). After these defenses are overwhelmed, increased pancreatic permeability leads to fluid loss into the pancreas and the abdomen, a decline in pancreatic blood flow and an increase in the local concentrations of pancreatic enzymes and inflammatory mediators (Simpson, 1993). Large numbers of leukocytes migrate to the inflamed pancreas and serve as a source of free radicals, inflammatory mediators and enzymes (Simpson, 1993). This vicious, self-perpetuating cycle may ultimately lead to thrombosis of pancreatic blood vessels and pancreatic necrosis. Systemic complications may develop, including hypovolemic shock and disseminated intravascular coagulation.

Chronic pancreatitis is less commonly recognized in companion animals vs. people in whom alcohol can serve as a constant stimulus for smoldering acinar inflammation. Some authors suggest that chronic mild interstitial pancreatitis is the most common form of pancreatitis recognized in cats (Williams, 1996; Maddison, 2008). Histopathologic examination of tissues from dogs and cats with chronic pancreatitis reveals irreversible fibrotic changes resulting from the persistent inflammatory condition. Chronic and recurrent pancreatitis may result in acquired exocrine pancreatic insufficiency.

Key Nutritional Factors

Key nutritional factors for patients with pancreatitis are listed in **Table 67-3** and discussed in more detail below.

Water

Water is the most important nutrient in patients with acute vomiting because of the potential for life-threatening dehydration due to excessive fluid loss and inability of patients to replace those losses. Moderate to severe dehydration should be corrected with appropriate parenteral fluid therapy rather than using the oral route. Further nutritional support should be postponed until electrolyte, fluid and acid-base abnormalities have been corrected.

Table 67-2. Protection against pancreatic autodigestion.

- Enterokinase, produced by the duodenal brush border, is required for activation of proenzymes
- Pancreatic enzymes are synthesized as proenzymes (zymogens)
- Serum protease inhibitors bind free trypsin
- The pancreas secretes a trypsin inhibitor in pancreatic juice that binds free trypsin
- Zymogens and lysosomal enzymes are stored in different intracytoplasmic membranes

Table 67-3. Key nutritional factors for foods for canine and feline patients with pancreatitis.*

Factors	Recommended levels
Fat	≤15% for non-obese and non-hypertriglyceridemic dogs ≤ 25% for non-obese and non-hypertriglyceridemic cats ≤10% for obese and/or hypertriglyceridemic dogs ≤15% for obese and/or hypertriglyceridemic cats
Protein	15 to 30% for dogs 30 to 40% for cats

*Nutrients expressed on a dry matter basis.

Protein

Free amino acids (i.e., phenylalanine, tryptophan and valine) in the duodenum are a strong stimulus for pancreatic secretion, in fact, more so than fat (Go et al, 1970). Therefore, excess dietary protein should be avoided, while providing adequate protein for recovery and tissue repair. DM protein levels of 15 to 30% for dogs and 30 to 40% for cats are appropriate.

Fat

Obese and hypertriglyceridemic patients recovering from pancreatitis should receive low-fat foods (≤10 and ≤15% DM for dog and cat foods, respectively). Other patients can be fed moderate-fat foods (≤15 and ≤25% DM for dog and cat foods, respectively). The most clinically relevant form of hypertriglyceridemia in veterinary patients is hyperchylomicronemia because triglycerides make up 84 to 89% of the lipids in chylomicrons (Chapter 28). Plasma chylomicrons are derived from two sources. Large (12-carbon) triglycerides are present for a few hours after ingestion of dietary fat, whereas smaller triglycerides, secreted from the liver, are always present and independent of dietary fat intake.

Other Nutritional Factors

Antioxidants

Recently, results of a randomized controlled clinical trial in people with chronic pancreatitis demonstrated a 50% reduction

in painful days per month with oral antioxidant administration as compared to placebo (Bhardwaj et al, 2009). One third of patients receiving an antioxidant preparation containing selenium, vitamin C, vitamin E, β-carotene and methionine became pain free as compared to 12% of those receiving placebo. Markers of oxidative stress including lipid peroxidation products were higher in chronic pancreatitis than in healthy patients and improved after antioxidant administration. Similar trials have not been performed in chronic or acute pancreatitis in veterinary patients.

Cobalamin

Assessment of serum cobalamin is recommended in cats with pancreatitis complicated by IBD or triaditis. If levels are depleted, parenteral supplementation is recommended. Cats should receive weekly subcutaneous parenteral cobalamin therapy (250 µg/cat) for four to six weeks or until serum levels return to the normal range (Ruaux et al, 2005). Once or twice monthly therapy may be required for longer-term maintenance.

FEEDING PLAN

Dietary management goals for patients with pancreatitis are to decrease stimuli to pancreatic secretion (thus preventing pancreatic autodigestion) and still provide adequate nutrient levels to support tissue repair and recovery. Acute hemorrhagic or necrotizing pancreatitis should be considered a medical emergency. Initially, appropriate parenteral fluid therapy should be provided to correct dehydration and electrolyte and acid-base disturbances.

Oral food intake stimulates pancreatic secretions by several mechanisms. Likewise, the physical presence of food in the stomach stimulates gastrin, which in turn stimulates pancreatic secretion. In addition, many patients with pancreatitis will exhibit abdominal pain and/or vomit when fed, which increases the risk of aspiration. Therefore, nothing per os (NPO) therapy is the initial treatment of choice for a limited time period (≤ three days including days of anorexia pre-presentation). The advent of potent antiemetics (e.g., dolansetron, ondansetron) has led some clinicians to initiate immediate enteral nutritional support (Relford et al, 2006).

Therapy used in conjunction with the feeding plan includes intravenous fluids, antiemetics, plasma transfusions, nasogastric suctioning of gastric secretions and air, control of gastric acidity with H_2-receptor blockers or proton pump inhibitors, anticholinergic agents, somatostatin analogues (octreotide), antibiotics and surgical exploration of the abdomen for extirpation or drainage of pancreatic abscesses or pseudocysts (Johnson and Mann, 2006). Aggressive pain control with single agents or combination therapy with opioids, lidocaine, ketamine or epidurals is also recommended for canine and feline patients with pancreatitis (Whittemore and Campbell, 2005).

Assess and Select the Food

Levels of protein and fat should be evaluated in foods currently fed to patients with pancreatitis and compared with recommended levels. Information from this aspect of assessment is essential for making any changes to foods currently provided. Changing to a more appropriate food is indicated if protein and fat levels in the food currently fed do not match recommended levels. Owners of dogs at risk for acute pancreatitis fed struvite litholytic foods should be counseled about potential adverse events that require medical attention (Chapter 43).

Small amounts of water, ice cubes, oral rehydration solutions or monomeric foods can be offered after vomiting and abdominal discomfort subside. Monomeric foods are liquid foods containing nutrients in their simplest absorbable form. Thus, nutrients in these foods minimally stimulate pancreatic secretion (Green and Guan, 1993). Some monomeric products also contain glutamine to stimulate enterocyte hyperplasia after several days of NPO therapy, which may have induced intestinal mucosal atrophy. In general, 1 to 2 ml/kg body weight q.i.d. are well tolerated and rarely induce vomiting.

If liquids are well tolerated for one to two days, solid food may be slowly reintroduced. Highly digestible, commercial veterinary therapeutic foods designed for patients with gastrointestinal (GI) disease are often used initially (**Tables 67-4** and **67-5**, for dogs and cats, respectively). These foods also contain moderate levels of protein and fat. If vomiting recurs, NPO therapy should be reinstituted and feeding attempted again after 12 to 24 hours. A veterinary therapeutic food formulated for patients with GI diseases should be fed for another seven to 10 days before reintroducing the patient's regular food, if it is to be used at all.

Low-fat (<10% DM fat) foods are often used if obesity or hyperlipidemia was a contributing factor (**Tables 67-6** and **67-7**, for dogs and cats, respectively). High-fat commercial foods (>20% DM fat), table foods and snacks should be avoided. It may be necessary to remind clients of this around the holiday season, when many owners succumb to the desire to share family meals with pets.

Assess and Determine the Feeding Method

Because the feeding method is often altered in patients with pancreatitis, a thorough assessment should include verification of the feeding method currently being used. Items to consider include feeding frequency, amount fed, how the food is offered, access to other food sources including human food and garbage and who feeds the pet. All of this information should have been gathered when the dietary history was obtained. In cases in which acute pancreatitis is associated with eating garbage or other inappropriate foods (most often during a holiday), strict avoidance of foods other than the pet's regular food is recommended.

Discontinuing oral intake of food and water (NPO) has been the cornerstone of initial therapy for acute pancreatitis. Factors (GI distention and hormone release [gastrin, secretin, cholecystokinin]) that would normally stimulate pancreatic secretions, nausea, vomiting and abdominal discomfort are reduced when food and water are withheld. Most patients respond within two to three days. After vomiting and abdominal discomfort resolve or lessen in severity, liquids and food can be reintroduced grad-

ually over several days. Normal feeding methods can be reintroduced after several days without clinical signs, unless dietary indiscretion or inappropriate foods or feeding methods initially contributed to the problem.

After three days (including periods of inappetence before admission) of the NPO protocol, patients with severe pancreatitis should receive enteral or parenteral nutritional support. The method deemed most desirable is the least invasive, supports the patient nutritionally and minimally stimulates pancreatic secretions. Some clinicians suggest feeding anorectic cats even earlier because of the risk of hepatic lipidosis (Zoran, 2007).

Protracted cases of pancreatitis with intractable vomiting often require parenteral nutrition to meet the patient's energy, protein, electrolyte and B-vitamin requirements while minimizing pancreatic secretions (Chapter 26). This is particularly true for patients for which the general anesthesia required for tube placement is considered too risky. Parenteral administration of nutritional solutions (including lipid solutions) has been associated with pancreatic atrophy; thus, pancreatic stimulation is minimal or nonexistent (Relly and Nahrwold, 1976; Betzhold and Howard, 1986). Both total parenteral and partial parenteral nutritional feeding have been used in patients with pancreatitis (Zsombor-Murray and Freeman, 1999; Zoran, 2007). In one review, pancreatitis was the most common diagnosis in hospitalized patients receiving partial parenteral nutrition (Chan et al, 2002). Intravenous administration of nutrients to support patients with pancreatitis through a five- to 14-day course of vomiting is possible, safe and economical in most practices (Chapter 26). Parenteral solutions are of particular benefit for managing pancreatitis in cats, especially when complicated by hepatic disorders, IBD or interstitial nephritis (Akol et al, 1993; Weiss et al, 1996).

Selection of parenteral solutions for feeding patients with pancreatitis is controversial because of the association between hyperlipidemia and pancreatitis. Some authors suggest that selection of parenteral solutions be based on amino acid and dextrose content only, whereas others advocate the use of lipid solutions in the admixture if the patient is not hyperlipidemic.

People with pancreatitis have a decreased capacity to oxidize glucose, peripheral resistance to insulin and hyperglycemia. Administering glucose as the sole nonprotein energy source perpetuates hyperglycemia and increases the risk of hepatic steatosis (Helton, 1993). Lipids in total nutrient admixtures (Chapter 26) have been used successfully in dogs and cats with pancreatitis.[a] Lipid emulsions administered intravenously are synthetic 0.5-µm chylomicrons that appear to be well used by rats, people and dogs with pancreatitis (Raasch et al, 1983; Silberman et al, 1982; Kawaura et al, 1976; Zieve, 1968). People with pancreatitis and concurrent hypertriglyceridemia or hyperlipoproteinemia types I and V are not given lipids intravenously until levels of these parameters have decreased (Helton, 1993). Plasma lipid data from dogs with naturally occurring pancreatitis are sparse; however, not all canine patients with pancreatitis are hypertriglyceridemic (Whitney et al, 1987; Rogers et al, 1975). Therefore, serum triglyceride levels should be assessed before lipids are administered intravenously. Although isolated cases of pancreatitis in people have been linked to lipid infusion, these cases are considered rare and were complicated by concurrent diseases such as alcoholism and IBD (Wolfe and Ney, 1986). Second, respiratory quotients in people with pancreatitis are between 0.76 and 0.91, indicating mixed fuel (glucose and lipid) use. Finally, adding fat to dextrose infusions improves nitrogen balance (Sitzmann et al, 1989). Although respiratory quotients have not been measured in dogs and cats with pancreatitis, lipid administration is well tolerated, most likely because the liver would be using endogenous fat stores if lipid were not supplied exogenously as in people.

Enteral nutritional support by nasoesophageal, esophagostomy, gastrostomy or jejunostomy tubes should also be considered in prolonged cases of pancreatitis. Human reports suggest that enteral feeding after a short period of NPO (two days) may be superior to parenteral feeding in acute pancreatitis. Intra-jejunal feeding reduced complications and shortened hospital stays as compared to total parenteral nutrition (Windsor et al, 1998; Meier and Beglinger, 2006). Similar findings have been reported in experimental canine pancreatitis; enteral feeding was found to improve gut barrier function without increasing enteric hormone release (Qin et al, 2002, 2007). Studies have not been performed in spontaneous pancreatitis in dogs or when enteral routes proximal to the jejunum were used (Watson, 2007; Mansfield, 2007).

Jejunostomy tubes bypass the stomach and duodenum but are best placed when patients must undergo general anesthesia and abdominal surgery for other reasons (Swann et al, 1997). Studies have demonstrated the efficacy of nasojejunal feeding in people with mild and complicated acute pancreatitis (McClave et al, 1997; Kudsk et al, 1990). Jejunal feedings in people and dogs stimulate pancreatic secretion no more than parenteral feedings (Ragins et al, 1973; Cassim and Allardyce, 1974). In veterinary patients, however, a practical technique for nasojejunal feeding has not been developed; thus, jejunal feeding requires abdominal surgery. For that reason, some clinicians prefer parenteral feeding or the use of minimally invasive techniques such as nasoesophageal or percutaneous gastrostomy tube placement in patients with prolonged, refractory pancreatitis (Zoran, 2007).

Monomeric liquid foods infused directly into the duodenum of dogs stimulate some pancreatic output, whereas oral administration of the same monomeric foods stimulated a greater volume of pancreatic secretion (Relly and Nahrwold, 1976). If jejunal tube feeding is selected, a liquid food supplemented with glutamine to maintain intestinal integrity that minimally stimulates the pancreas and meets the patient's resting energy requirement (RER) is most suitable. Directly infusing a readily absorbable monomeric liquid food (vs. a polymeric product) into the jejunum should also reduce pancreatic secretions because whole nutrients elicit a greater response from the pancreas than monomeric nutrient forms. Monomeric liquid foods may be infused into the jejunum by slow continuous gravity drip (1 to 2 ml/kg body weight/hour) or, preferably, by an enteral pump. This rate of enteral feeding meets the RER of most patients and precludes other forms of nutritional support until oral intake is possible. If patients tolerate this rate of administration, solid food in small frequent meals may be given

Table 67-7. Key nutritional factors in selected commercial veterinary therapeutic foods for obese or hypertriglyceridemic cats with pancreatitis compared to recommended levels.*

Moist foods	Fat (%)	Protein (%)

for several days in addition to the liquid feedings. Liquid feedings may cease and the number of oral meals per day increased when solid food is well tolerated. Hydrolyzed or novel protein foods may be of value in cats with concurrent pancreatitis and inflammatory bowel disease (Zoran, 2009). These foods are typically highly digestible and may be beneficial for managing intestinal and pancreatic disorders (Chapter 31).

REASSESSMENT

Hospitalized patients with pancreatitis should be assessed frequently. Assessment of body weight and condition are recommended to ensure adequate hydration and caloric intake, if feeding is instituted. Electrolyte and acid-base status should be monitored to assess adequacy of therapy. If parenteral nutrition is used, daily monitoring of electrolytes, glucose and triglycerides is necessary to allow adjustment of parenteral solution composition (Whittemore and Campbell, 2005). Certain laboratory parameters (leukogram and serum concentrations of amylase, lipase, pancreatic lipase immunoreactivity and bilirubin) are helpful markers of progress. However, the patient's attitude, appetite and presence or absence of vomiting and abdominal pain are often the most important predictors of progress. In addition, it is imperative that sera be evaluated for triglyceride concentration initially and then monitored daily for lipemia. It is important to distinguish between lipemia from endogenous sources vs. exogenous fat emulsions when parenteral nutrition is administered.

Discharged patients should be reevaluated in a number of weeks. If a low-fat, high-fiber food was recommended to control obesity or hyperlipidemia, body weights should be recorded and serum triglyceride concentrations determined (or the sample should be inspected visually for lipemia) to assess compliance with the dietary management program. Regaining or maintaining optimal body weight and condition, normal activity level and absence of clinical signs are measures of successful dietary management.

Patients that relapse should be reevaluated and assessed for evidence of pancreatic pseudocysts, pancreatic necrosis or abscesses because these are potential sequelae to acute pancreatitis (Coleman and Robson, 2005).

CASE 67-1

Anorexia in a German Shepherd Crossbred Dog

Philip Roudebush, DVM, Dipl. ACVIM (Small Animal Internal Medicine)
Hill's Scientific Affairs
Topeka, Kansas, USA

Patient Assessment

A five-year-old neutered male German shepherd crossbred dog was examined on an emergency basis for acute onset of anorexia and depression. The owners found the dog outside hiding under a large shrub. The dog seemed lethargic and refused food and water. Past clinical problems included multiple seizures, hyperlipidemia and recurrent superficial staphylococcal pyoderma. The dog was receiving phenobarbital for seizures and had just completed six weeks of therapy with cephalexin for superficial pyoderma.

Physical examination revealed a very depressed, febrile (rectal temperature 40.0°C [104.0°F]) dog. Pain was elicited when the cranial abdomen was palpated and the dog vomited a small amount of clear liquid. Oral mucous membranes were brick red. The dog was overweight (body condition score [BCS] 4/5, body weight 45 kg).

Blood was drawn for a complete blood count and serum biochemistry profile. Therapy for shock was initiated with intravenous fluids, antibiotics and corticosteroids. Results of diagnostic studies included leukocytosis with a marked left shift (**Table 1**, Day 1) and very lipemic serum. Fluid therapy and antibiotics were continued through the night.

Intermittent vomiting continued. The next morning, abdominal radiographs were taken. Loss of serosal detail in the cranial abdomen consistent with focal fluid accumulation or peritonitis was noted. Results of a complete blood count were still consistent with severe inflammation (**Table 1**, Day 2) and the serum was still lipemic. Results of a serum biochemistry profile included increased serum amylase and lipase activities and increased liver enzyme activity (**Table 1**, Day 2). Fluid recovered by abdominal lavage was evaluated cytologically. The abdominal lavage fluid contained many nondegenerative neutrophils with no evidence of bacteria. Pancreatitis with non-septic peritonitis was diagnosed.

Assess the Food and Feeding Method

The dog was fed a commercial dry premium brand dog food free choice plus a variety of leftover foods from the owner's meals.

Questions

1. What are potential complications of pancreatitis?
2. What are the key nutritional factors for this patient?
3. Outline a short-term (i.e., next few days) and long-term (i.e., next several months) treatment and feeding plan for this dog.

Answers and Discussion

1. Life-threatening complications of pancreatitis include shock, pulmonary edema, cardiac dysrhythmias, peritonitis, sepsis, disseminated intravascular coagulopathy, hepatic lipidosis (cats) and extrahepatic bile duct obstruction. Other complications include diabetes mellitus and exocrine pancreatic insufficiency.
2. Key nutritional factors for patients with pancreatitis include water, protein and fat. Aggressive intravenous fluid therapy to correct water, electrolyte and acid-base deficits is a cornerstone of successful treatment for acute pancreatitis. Potassium supplementation in fluids is often indicated because of potassium losses in vomitus. Dietary protein and fat are the major stimuli for pancreatic secretions; therefore, excessive levels should be avoided. Excess dietary fat should also be avoided in patients with hyperlipidemia.
3. Initially, oral food and water are withheld for three to five days to minimize pancreatic secretions and help control vomiting. Parenteral fluid therapy is used to correct fluid deficits and electrolyte and acid-base disturbances and to meet maintenance water requirements. Colloids (e.g., dextrans, hetastarch) may be needed initially to maintain blood volume and pancreatic microcirculation. After replacement of deficits, additional fluids are given to match the patient's maintenance requirements and ongoing losses. Drug therapy usually includes corticosteroids (only in shock), antiemetics, antibiotics and analgesics. Food and water are gradually introduced in multiple small feedings while clinical signs, especially vomiting, are monitored. Foods for patients with pancreatitis should avoid excessive levels of protein and fat, and contain balanced levels of other nutrients. Some clinicians suggest using a "bland," low-protein, low-fat, high-carbohydrate food such as cooked rice for the initial few days of feeding. Parenteral nutritional support should be considered if clinical signs persist beyond five days (Chapter 26). Long-term use of foods that avoid excess dietary fat (i.e., <10% dry matter fat) may be especially important in this overweight dog with a history of hyperlipidemia (Chapter 28).

Table 1. Selected laboratory parameters from a dog with pancreatitis.

Parameters	Day 1	Day 2	Day 6	Day 107	Day 121	Day 154	Reference values
Packed cell volume (%)	68	57	53	45	45	56	37-55
Total white blood cells (/µl)	20,900	22,500	12,900	12,500	10,800	26,200	8,000-17,000
Total segmented neutrophils (/µl)	9,614	9,450	11,868	8,750	7,236	19,388	3,600-13,100
Total band neutrophils (/µl)	5,852	8,775	258	0	1,944	1,834	0-400
Total juvenile neutrophils (/µl)	1,254	112	0	0	0	0	0
Amylase (IU/l)	ND	1,608	563	897	2,340	2,640	350-1,200
Lipase (U/l)	ND	107	133	64	ND	260	0-100
ALT (IU/l)	ND	99	77	42	ND	120	0-75
Alkaline phosphatase (IU/l)	ND	333	309	30	ND	757	0-80

Key: ND = not done, ALT = alanine aminotransferase.

Progress Notes

Intravenous fluids, antibiotics and phenobarbital were continued for several days. The dog apparently felt much better by the sixth day of hospitalization and the hemogram indicated that the peripheral inflammatory response had improved (**Table 1**, Day 6). No vomiting had occurred for 24 hours and the dog readily ate cooked rice. The dog continued to improve and was released to the owner's care four days later.

A commercial low-fat, moderate-fiber veterinary therapeutic food (Prescription Diet w/d Canine[a]) was dispensed for use at home. The dog began eating this food during its last two days in the hospital. The daily energy requirement (DER) was calculated to achieve mild weight loss (1.2 x resting energy requirement [RER] [RER = $30Wt_{kg}+70$] for an ideal body weight of 39 kg) while supporting recovery from pancreatitis and peritonitis. DER equals approximately 1,500 kcal (6.28 MJ), which was met by feeding three and one-half cups of food twice daily. The owners were asked to eliminate table food and other snacks from the diet.

Three months later, the dog was examined for recurrent pyoderma. Blood parameters were normal and the serum was not lipemic (**Table 1**, Day 107). The dog's weight remained stable. Antibiotics were dispensed, oral phenobarbital was continued and the amount of food offered was reduced to two and two-thirds cups of food twice daily. Two weeks later, the dog developed anorexia, vomiting and mild abdominal pain after eating fried chicken. Serum was lipemic and blood parameters were consistent with recurrent pancreatitis (**Table 1**, Day 121). Five days of therapy with intravenous fluids, antibiotics and nothing per os resulted in clinical improvement. The dog was released to the owner's care with instructions to strictly follow the previously developed feeding plan.

A month later, the dog was again examined for anorexia, vomiting, icterus and severe cranial abdominal pain. Laboratory parameters were consistent with pancreatitis and bile duct obstruction (**Table 1**, Day 154). Exploratory celiotomy revealed severe, chronic, fibrosing pancreatitis with entrapment and compression of the extrahepatic bile duct. The fibrotic portion of the pancreas was excised and the gallbladder was attached to the duodenum (cholecystoduodenostomy). The dog recovered uneventfully from anesthesia and surgery and was released from the hospital seven days later. The low-fat, moderate-fiber food was fed for the next three years until the dog died from other causes. Significant weight loss did not occur but body weight was stabilized at 43 kg and there was no evidence of hyperlipidemia or further pancreatitis.

Hepatobiliary Disease

David C. Twedt
Philip Roudebush
Elizabeth Dill-Macky

"Life loves the liver of it."
Maya Angelou

CLINICAL IMPORTANCE

Among the most challenging problems in medicine are those that involve failure of a metabolically active organ such as the liver. The liver is the second largest organ of the body and performs an estimated 1,500 essential biochemical functions (Zakim, 1985). In addition to its role in drug metabolism, the removal of environmental and endogenous noxious substances and synthesis of important substances (e.g., albumin and blood clotting factors), the liver plays a key role in food digestion and nutrient metabolism. The liver influences nutritional status through its elaboration of bile salts and central role in intermediary metabolism of protein (amino acids), carbohydrate, fat and vitamins. **Table 68-1** lists the most important hepatic functions.

Patients with hepatobiliary disease are often seen in companion animal practice. An estimated 2 to 3% of all animals presented at a veterinary teaching hospital have some form of hepatobiliary disease (Meyer, 2000). Hereditary portosystemic shunts (PSS), tumors (metastasis, malignant lymphoma and primary liver tumors) and chronic hepatitis account for more than 60% of these patients (Rothuizen and Meyer, 2000). Hereditary PSS occur in 2 to 5% of investigated breeds (Meyer et al, 1995). The liver may also be damaged secondarily by other disease processes. Resultant changes are often classified as a reactive hepatopathy. Because the liver plays an essential role in the metabolism of protein, carbohydrate and fat, nutritional support plays an essential role for many patients with hepatobiliary disease.

The liver has tremendous storage capacity, functional reserve and regenerative capabilities. All of these functions protect the body from profound metabolic alterations. However, these same characteristics complicate the clinical recognition of serious liver disease. Consequently, hepatobiliary disease must be severe before clinical signs occur. As a result, the patient may be suffering longstanding and profound metabolic alterations by the time a diagnosis is made and an appropriate management plan is implemented.

The liver is also unique in that it derives its nutrient blood supply from venous and arterial sources (Anderson and

Table 68-1. Major hepatobiliary functions related to nutrient digestion and metabolism.

Metabolic functions
Converts glucose to glycogen and triglycerides during absorptive state
Converts glycogen to glucose in postabsorptive period
Synthesizes glucose from glucogenic precursors such as glycerol and amino acids in postabsorptive period (gluconeogenesis)
Transforms amino acids (transamination and deamination), synthesizes nonessential amino acids as needed for metabolism
Synthesizes triacylglycerols and secretes them as lipoproteins
Synthesizes and releases cholesterol into blood
Forms ketones from degraded fatty acids during fasting
Synthesizes urea from ammonia (sole site in body)
Synthesizes plasma albumin, fibrinogen and various other coagulation factors
Biliary functions
Synthesizes bile salts from cholesterol, which are secreted into bile for lipid emulsification and absorption in the small intestine
Secretes a bicarbonate-rich solution to help neutralize acid in the duodenum
Secretes plasma cholesterol into bile
Conjugates and excretes bilirubin in bile
Detoxifies substances by biotransformation before biliary excretion
Excretes endogenous and foreign organic molecules in bile
Storage functions
Stores glucose as glycogen and triglycerides
Stores vitamins, particularly A but also D, E, K, B_{12} and to a lesser extent other B vitamins
Stores minerals such as iron, copper, manganese and zinc
Stores blood, especially with pressure increases in the hepatic vein or posterior vena cava
Endocrine functions
Activates (partial) vitamin D by dehydroxylation
Converts thyroxine to triiodothyronine
Secretes IGF-1 in response to growth hormone
Metabolizes (deactivates) and excretes hormones
Miscellaneous functions
Removes bacteria and food antigens that regularly cross the intestinal epithelial barrier (Kupffer cells of mononuclear-macrophage system in the sinusoids)

Anderson, 1994). The portal vein provides 70 to 75% of total hepatic blood flow (Center and Strombeck, 1996). Portal venous blood is nutrient rich in the absorptive state but oxygen poor. The hepatic artery provides about 25 to 30% of blood flow with oxygen-rich blood (Center and Strombeck, 1996). Hepatotropic factors especially from portal venous blood modulate the functional and structural integrity of the liver (Diehl, 1991). Concentrations of several hormones, including hepatocyte growth factor, insulin, glucagon, glucocorticoids, thyroid hormones, parathyroid hormone, calcitonin, α- and, β-adrenergic agents and insulin-like growth factors I and II, increase after hepatic injury or resection and affect the ensuing hepatic regenerative growth (Bucher and Malt, 1971; Stolz et al, 1999; Nishino et al, 2008).

Unlike most terminally differentiated cells, hepatocytes in adult liver retain the capacity to proliferate. After partial (70%) hepatectomy, compensatory hyperplasia begins within minutes of resection and is typically completed within two weeks in rats and in less than one month in people (Higgins and Anderson, 1931; Francavilla et al, 1990). The unique regenerative ability of the liver should be a consideration in the management of many hepatic diseases (Bauer and Schenck, 1989).

Hepatobiliary diseases can be categorized depending on their cause (**Table 68-2**). (See Common Hepatobiliary Diseases below.) Irrespective of the primary liver disease, the hepatic reaction pattern is similar; thus, most of these disorders, if severe and/or longstanding, often lead to a few syndromes with potentially serious metabolic consequences (e.g., cholestasis, icterus, portal hypertension, ascites and hepatic encephalopathy [HE]). **Table 68-3** lists the frequency distribution of liver diseases in dogs and cats.

Cholestasis is decreased bile flow and can happen at any level of the complex interplay of bile formation, excretion, hepatic re-uptake or intracellular transport. Cholestasis is present to some degree in most patients with hepatobiliary disease. Severe cholestasis becomes apparent as icterus. Moreover, deposition of increased amounts of extracellular collagen and reorganization of the hepatic architecture (i.e., cirrhosis) may lead to an increase in hepatic vascular resistance, which results in portal hypertension. Portal hypertension in turn may lead to formation of multiple portosystemic collaterals and ascites. Portosystemic shunting in combination with a decrease in functional liver mass may lead to the development of HE, the complex of neurologic and behavioral signs due to gastrointestinal (GI) toxins bypassing the liver.

Malnutrition is a common finding in patients with advanced hepatic disease and is an independent risk factor for predicting clinical outcome in human patients with chronic hepatic disease (Qiao et al, 1988). In human patients with nonalcoholic cirrhosis, 14% had significant weight loss (O'Keefe et al, 1980), 50% had mild to moderate steatorrhea and 40% had deficiencies of fat-soluble vitamins (Morgan et al, 1976). Food intake was normal and was unrelated to the degree of malnutrition, suggesting that factors other than decreased food intake are involved in the malnutrition of human patients with hepatic disease. Potential causes of malnutrition in animals with hepat-

**Hepatic encephalopathy may be present.

ic disease include: 1) anorexia, nausea and vomiting, 2) impaired nutrient digestion, absorption and metabolism, 3) increased energy requirements and 4) accelerated protein catabolism with impaired protein synthesis (Marks et al, 1994).

Nutritional management of hepatobiliary disease is usually directed at clinical manifestations of the disease rather than the specific cause. The goals of nutritional management for hepatobiliary disease include: 1) maintaining normal metabolic processes and homeostasis, 2) avoiding and managing HE, 3) providing substrates to support hepatocellular repair and regeneration, 4) decreasing further oxidative damage to damaged liver tissue and 5) correcting electrolyte disturbances (Center, 1998; Blackburn and O'Keefe, 1989).

PATIENT ASSESSMENT

History and Physical Examination

Recognition of liver disease based on history and clinical signs is usually difficult. Signs are often nonspecific and few indications of liver disease are found on physical examination. Consequently without appropriate laboratory evaluation, liver disorders are often overlooked and either the patient recovers without treatment or becomes worse despite symptomatic treatment. This section considers the expected clinical signs of liver disease and the difficulties in interpreting them.

Table 68-4 lists the most important clinical signs and the frequencies with which they occur in primary liver diseases. These signs occur in a variety of combinations in many liver diseases. Physical findings are often similar and include lethargy, neurologic signs, low body condition score (BCS), icterus and ascites.

GI abnormalities include anorexia, vomiting and diarrhea (Center, 1995). Ptyalism (hypersalivation) is especially common in cats (**Figure 68-1**) with HE. Hematemesis suggests GI ulceration, which can also be a complication of hepatobiliary disease. The anorexia, GI disturbances and metabolic alterations associated with liver disease often contribute to chronic

Figure 68-1. A 14-year-old Persian cat with ptyalism due to liver disease.

Figure 68-2. An eight-month-old Himalayan cat with clinical signs of aggression associated with hepatic encephalopathy due to a congenital portosystemic shunt.

weight loss. Bleeding tendencies (which are rarely noted clinically) may develop due to a decrease in hepatic production of clotting factors, to consumption coagulopathy (disseminated intravascular coagulation) (Rothuizen and Meyer, 2000) or malabsorption of vitamin K, which is essential for production of vitamin K-dependent factors in patients with prolonged extrahepatic bile duct obstruction (Center, 1995). Subclinical blood clotting abnormalities may become clinically evident during liver biopsy procedures or surgery. Icterus may be observed with severe cholestasis. Acholic feces due to total bile duct obstruction occur rarely in dogs and cats. Consequently, serious disturbances in fat digestion and absorption, which rely on functional biliary excretion, are rare in hepatobiliary disease (Rothuizen and Meyer, 2000).

Neurobehavioral signs of HE develop in animals with portosystemic vascular anomalies and a decreased functional liver mass. Typical signs include aggression (cats) (**Figure 68-2**), aimless wandering, manic barking (dogs), ataxia, lethargy, episodic weakness, ptyalism (cats especially), altered consciousness (disorientation, stupor or rarely coma), head pressing (**Figure 68-3**), sudden blindness, circling, pacing and seizures (Center, 1995). These signs may be episodic and may be linked to meals, dietary changes, GI hemorrhage or some other event.

A normal liver can be difficult to palpate in dogs and cats; the edges are normally sharp and the liver resides cranial to the ribcage. Hepatomegaly, however, is readily palpated in most cases. Hepatomegaly may be caused by passive venous congestion, inflammation, neoplasia, nodular hyperplasia and infiltration by fat, amyloid or glycogen. On the other hand, reduced liver size is difficult to palpate in dogs and cats. Abdominal enlargement associated with ascites usually develops slowly and insidiously. Small amounts of effusion may go undetected, whereas moderate to severe abdominal effusion becomes obvious. Hyperadrenocorticism may also cause distention from abdominal wall muscle weakness and hepatomegaly from steroid hepatopathy.

When liver disease is included in the differential diagnosis based on one or more of the historical or physical findings, additional diagnostics are required. **Figure 68-4** presents a diagnostic algorithm for liver diseases.

Laboratory Evaluation

It is beyond the scope of a nutrition textbook to discuss in detail, specific laboratory tests and imaging techniques (i.e., ultrasound, nuclear imaging techniques, laparoscopy) used to detect and confirm hepatobiliary disease. Readers are referred to small animal internal medicine, GI and surgical texts for these details. However, routine tests that help establish parameters for developing feeding and reassessment plans are summarized below.

Liver disease is most often discovered during hematologic, serum biochemistry and urine tests performed either as part of a routine wellness screen or diagnostic evaluation of sick dogs and cats. Hematologic changes may include anemia, abnormal erythrocyte morphology, reduced platelet numbers or function and detection of icteric or lipemic plasma (Center, 1995, 1996e; Dial, 1995). A regenerative anemia caused by blood loss due to GI hemorrhage and/or a bleeding diathesis may by present. More commonly, a nonregenerative anemia is found and is associated with chronic disease, chronic blood loss, malnutrition and reduced erythrocyte survival (Center, 1995, 1996e). Target cells, poikilocytes and spur cells, Heinz

bodies (cats) and microcytosis are erythrocytic abnormalities seen in animals with liver disease (Center, 1995, 1996e; Dial, 1995). Erythrocyte microcytosis is associated with acquired and congenital portosystemic vascular shunts in dogs.

Measurement of plasma enzyme activities (usually but not entirely correctly called "liver enzymes") is based on the concept that certain enzymes are released and enter the bloodstream when changes occur in the liver or bile ducts. The most important enzymes for dogs and cats are discussed below.

Alkaline Phosphatase

Alkaline phosphatase (AP) is found in almost all organs but primarily in bone, liver, kidney, small bowel mucosa, placenta and bile duct epithelium. The plasma half-life of intestinal, renal and placental AP is only a few minutes; their contribution to total serum AP is negligible. In dogs, measurable serum AP arises from bone, liver or corticosteroid induction.

The half-life of AP from liver and bone in dogs is about 70 hours. Bone AP increases from osteoblastic activity in young growing dogs or occasionally from osteoblastic bone tumors. AP increases from cholestatic disorders resulting in induction of a liver AP and subsequent enzyme solublization and elution from damaged membranes into the blood (Gary and Twedt, 2009). Abnormal bile acid concentrations may play a role in AP production and release. Thus, significant extrahepatic cholestasis usually causes very high plasma AP activity. Finally, in dogs but not cats, corticosteroids, either endogenous or exogenous, can induce specific corticosteroid AP isoenzyme produced in the liver, leading to higher AP activity. The corticosteroid fraction of AP can be determined by heating plasma to 65°C (149°F) for two minutes, which inactivates AP of liver and bone origin, but not that induced by corticosteroids. Clinically determining the percent fraction arising from corticosteroids is generally not helpful in determining hyperadrenocorticism from other diseases.

In cats, AP is of less diagnostic importance because the half-life is very short (i.e., 5.8 hours); thus, it is only elevated in severe hepatobiliary diseases. In addition, feline hepatic AP concentrations are low; therefore, the sensitivity of AP in detecting feline liver disease is low. The highest concentrations of plasma AP in cats often occurs with hepatic lipidosis.

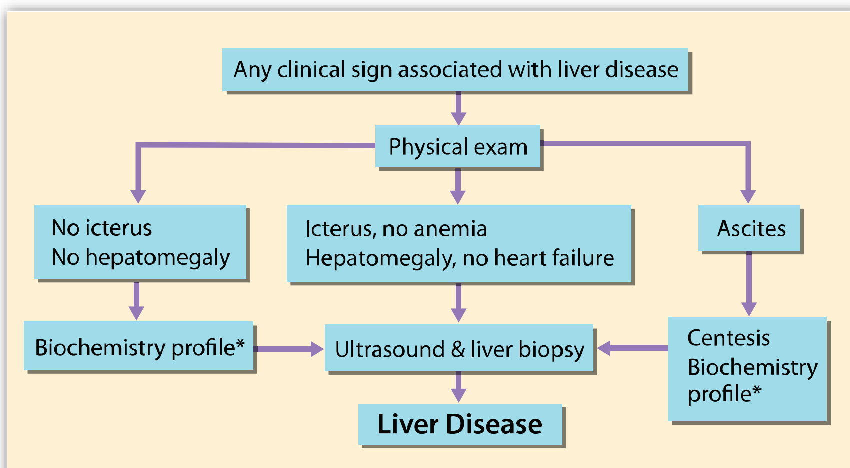

Figure 68-4. Algorithm for the diagnosis of hepatobiliary disease. (Adapted from Rothuizen J, Meyer HP. History, physical examination, and signs of liver disease. In: Ettinger SJ, Feldman EC, eds. Textbook of Veterinary Internal Medicine: Diseases of the Dog and Cat, 5th ed. Philadelphia, PA: WB Saunders Co, 2000; 1272-1277.)
*Alkaline phosphatase, alanine aminotransferase, bile acids, ammonia.

Gamma Glutamyl Transferase

Hepatic γ-glutamyl transferase (GGT) is associated with hepatocyte canalicular membranes and bile ducts. Highest concentrations generally are associated with disease of biliary epithelium such as bile duct obstructions or cholangitis. Cats with cholangitis, biliary tract disease or hepatobiliary disease generally have higher GGT concentrations than AP. GGT concentrations are usually only mildly elevated in feline idiopathic hepatic lipidosis (Center et al, 1986).

Alanine Aminotransferase and Aspartate Aminotransferase

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were known in the older nomenclature as GPT and GOT, respectively. They are often collectively referred to as "hepatic leakage" enzymes. ALT is very liver-specific in dogs

and cats. It is localized in the cytoplasm of hepatocytes and released with even mild damage to cell membranes. Hepatocytes, however, do not need to be irreversibly damaged and a number of metabolic or systemic conditions can alter membrane function without being a primary liver disorder. The biologic half-life of ALT is about two and one-half days in dogs and approximately six hours in cats (Webster and Cooper, 2009). ALT is fairly sensitive and specific in dogs and cats and thus a good parameter for use in screening for liver disease.

AST is not liver specific. In dogs, it is mainly present in cardiac and skeletal muscle and other tissues and to a lesser degree in the liver. In cats, AST is more limited to the liver. Although not liver specific, AST is useful because it is chiefly located in the mitochondria and thus only released by cell death. The half-life of serum AST in dogs is five to 12 hours and 77 minutes in cats (Webster, 2005). Increased activities of AST and ALT generally indicate more severe hepatocellular damage than does an increase in ALT alone. However, this reasoning has proved to have no real diagnostic meaning, hence AST is not used.

Other Blood Examinations

Laboratory tests found in most biochemistry profiles that can reflect, in part, hepatic function include bilirubin, albumin, cholesterol, glucose and urea nitrogen. Other specialized tests of hepatic function include serum bile acid concentrations. Because the liver is involved in a multitude of functions, no single test can reflect its functional state and interpretation of function must be made in light of the clinical and laboratory testing results. Chronic hepatic dysfunction can cause hypoalbuminemia and clotting disorders. The liver exclusively produces albumin and coagulation factors except factor VIII. A number of non-hepatic conditions cause hypoalbuminemia; however, albumin synthesis declines with the loss of approximately 70% of hepatic function. Serum albumin concentrations may fall even lower with concurrent ascites and third-spacing in the ascitic fluid. The biologic half-life of albumin is approximately two weeks. Glucose and clotting factor concentrations decline when more than 75% of hepatic function is lost.

Abnormal blood coagulation generally reflects significant hepatic dysfunction due to reduced protein synthesis. Rarely, chronic bile duct obstruction can deplete intestinal bile acid concentrations required for adequate vitamin K absorption and can result in depletion of hepatic production of vitamin K-dependent clotting factors (factors II, VII, IX and X). When this situation occurs, clotting times are quickly corrected following parenteral vitamin K administration.

Ammonia is an important parameter to consider when HE is suspected. Elevated ammonia concentrations generally reflect the presence of portosystemic circulation abnormalities (e.g., congenital PSS or acquired shunts from portal hypertension). Plasma ammonia concentration is less sensitive and specific in reflecting hepatocellular function but is the method of choice when HE is suspected. Most in-house dry chemical methods provide reliable results (Sterczer et al, 1999). Care should be taken when handling samples because a number of factors may interfere with accurate results. When results are equivocal, an ammonia tolerance test can be performed. Bile salts (primarily taurocholate in dogs and cats), also erroneously called bile acids, are produced by the liver and excreted in the bile. After uptake in the portal blood, the liver re-extracts bile salts (i.e., enterohepatic circulation). Concentration of bile salts increases in the systemic circulation in cholestasis (either intrahepatic or extrahepatic), hepatocyte dysfunction (failure to extract bile acids from the sinusoidal circulation) and when vascular portosystemic shunting is present. Thus, determination of the venous concentration of total bile salts is a specific and an early, sensitive indicator of liver function. Bile salts are stable and easy to measure (Webster and Cooper, 2009). An eight-hour fasted sample should be obtained followed by a postprandial sample two hours later in dogs and cats. After hemolysis has been ruled out, bilirubin elevations reflect hepatic or extrahepatic cholestasis. The ratio between conjugated and unconjugated bilirubin fractions is not useful for differentiating among various hepatic disorders; other diagnostic testing is required. Also, urinary urobilinogen concentrations have a very low diagnostic accuracy for supporting a diagnosis of extrahepatic cholestasis.

Imaging the Liver

Radiographs are useful to determine the size and shape of the liver and to identify other concurrent abdominal disorders. Advanced studies of the hepatobiliary system include ultrasonographic imaging (Szatmari and Rothuizen, 2006). Hepatic ultrasonography is useful for initially identifying disease and monitoring its progression (Partington and Biller, 1995, 1996; Barr, 1990; Nyland et al, 1995; Lamb, 1998). Ultrasonography can detect and differentiate focal and diffuse hepatic parenchymal disorders and changes in the hepatobiliary (gallbladder and bile ducts) system. The evaluation should also include the hepatic vascular system because portosystemic anomalies are extremely common. Ultrasonography is highly operator dependent and imaging expertise takes time to develop. Readers are referred to diagnostic imaging textbooks and manuals for detailed descriptions and classifications of hepatic lesions identified by ultrasonography (Barr, 1990; Nyland et al, 1995; Partington and Biller, 1996; Lamb, 1998).

Nuclear imaging procedures (e.g., hepatic scintigraphy) and magnetic resonance imaging are used to further assess hepatic structure and vasculature or measure the degree of portosystemic vascular shunting. These techniques are usually only available at specialty referral centers.

Liver Biopsy

Histopathologic tissue examination is essential for definitive diagnosis of hepatobiliary disease (Center, 1995; Meyer, 1996; Kerwin, 1995). Liver biopsy is an invasive procedure that must be carefully considered before implementation. Common options for securing liver tissue include ultrasonographic-guided needle biopsy, "blind" biopsy techniques, laparoscopic needle or pinch biopsy and celiotomy for wedge biopsy (Center, 1995). A minimum of three full 16-gauge needle samples should be collected if a needle procedure is used. Small sample size decreas-

es the diagnostic accuracy of the histologic diagnosis (Rothuizen et al, 2006). One study showed a poor histologic correlation when only two 18-gauge needle biopsy specimens were compared to a wedge biopsy (Cole et al, 2002).

The advantage of fine-needle aspiration cytology (**Figure 68-5**) is decreased risk of complications or bleeding. However, a representative sample might not be obtained with this technique because of the very small amount of tissue that is obtained and the fact that liver architecture is not left intact during fine-needle aspiration procedures. Interpretation of hepatic cytology should be used in light of all clinical findings because hepatic cytology does not always correlate with histopathology. Ideally, liver tissue should be submitted for histopathologic and cytologic evaluation, aerobic and anaerobic bacterial cultures and copper quantification when copper toxicosis or chronic hepatitis is suspected. Specific stains for collagen, lipid, copper, iron and infectious agents may be required in some cases (**Figure 68-6**).

Abnormal concentrations of copper can occur from either a primary metabolic defect in copper metabolism reported to occur in certain dog breeds or secondarily as a result of chronic cholestatic liver disease. Abnormal copper levels damage hepatocytes. Hepatic copper content can be determined using either fresh or formalin-fixed liver tissue (Meyer, 1996; Thornburg et al, 1985). Most laboratories require one gram or less of tissue for analysis (Center, 1996a; Thornburg et al, 1990, 1996, 1985a). Normal canine hepatic copper concentrations should be 400 μg/g dry weight (DW) or less. Concentrations ranging from 750 to 2,000 μg/g DW may result from primary or secondary causes. The disease most likely results from a breed-associated copper accumulation disorder when hepatic copper concentrations exceed 2,000 μg/g DW. Hepatic copper concentrations can also be subjectively estimated using a histochemical copper stain grading system. Copper grading ranges tends to correlate with quantitative copper analysis (Teske et al, 1992).

Fine-needle aspiration of the liver using special copper staining correlates with histochemical grading but the extent of liver pathology cannot be adequately determined (Stockhaus et al, 2004). Genetic markers have been made available for testing Bedlington terriers (Yuzbasiyan-Gurkan et al, 1997).

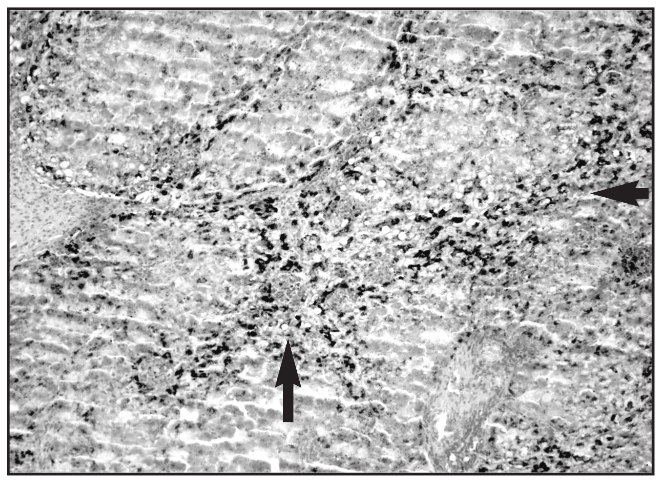

Figure 68-6. Photomicrograph of a liver biopsy specimen from a Doberman pinscher with chronic hepatitis. Note the accumulation of copper (arrows) as detected with rubeanic acid stain. In such cases, the hepatic copper content should be determined by quantitative methods.

Common Hepatobiliary Diseases

Feline Hepatic Lipidosis

Hepatic lipidosis in cats is a well-recognized syndrome characterized by accumulation of excess triglycerides in hepatocytes with resulting cholestasis and hepatic dysfunction (**Figures 68-7** and **68-8**) (Biourge et al, 1990, 1993; Center et al, 1993; Cornelius and Jacobs, 1989; Dimski and Taboada, 1995). Lipidosis can occur secondary to diabetes mellitus, diseases resulting in anorexia and weight loss (such as pancreatitis or inflammatory bowel disease) or as an idiopathic disorder of unknown etiology. Cats with idiopathic hepatic lipidosis often present with a history of prolonged anorexia after a stressful event. The biochemical mechanisms responsible for inducing hepatic lipidosis during fasting are not completely understood (Biourge et al, 1990, 1994; Center, 1996c). Potential causes include protein deficiency, excessive peripheral lipolysis, excessive lipogenesis, inhibition of lipid oxidation and inhibition of the synthesis and secretion of very low-density lipoproteins. The prognosis for this life-threatening disorder has improved dramatically during the past several years as a result of long-term enteral feeding (i.e., three to eight weeks or longer) (Biourge et al, 1990, 1994a; Dimski and Taboada, 1995). Hepatic lipidosis is a reversible process but resolution of hepatic lipidosis secondary to pancreatitis, infection or other causes depends on the success of treating the underlying disorder (Cornelius and Jacobs, 1989) and providing appropriate nutritional support.

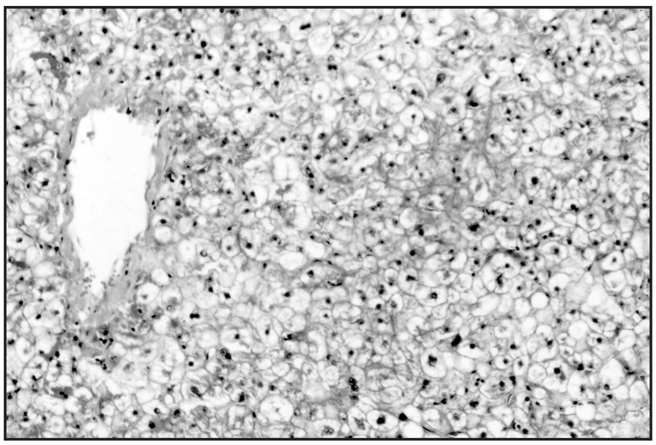

Figure 68-8. Photomicrograph of a liver specimen from a cat with hepatic lipidosis. Hepatocytes containing lipid appear empty with an inconspicuous nucleus when processed routinely with formalin fixation and hematoxylin and eosin stain.

Canine Chronic Hepatitis and Cirrhosis

Chronic hepatitis in dogs is a poorly defined group of clinicopathologic entities characterized by parenchymal necrosis, particularly piecemeal and/or bridging necrosis, with associated lymphoplasmacytic inflammation (Meyer, 1996; Thornburg, 1998; Speeti et al, 1998). Chronic hepatitis can result from many different causes including copper accumulation (See below.), infectious diseases, drugs, breed-associated hepatitis and possibly autoimmune disease. An etiology is never determined in most cases (Watson, 2004).

Lymphoplasmacytic inflammation suggests an immune-mediated mechanism. Autoantibodies have been recognized in dogs with chronic hepatitis but it is unknown if such an immune reaction is the cause or result of the disease (Weiss et al, 1995; Andersson and Sevelius, 1992; Thornburg, 1998). The insidious onset contributes to the poor understanding of the pathogenesis because most patients have an advanced stage of the disease when it is recognized.

Hepatic fibrosis is an accumulation of extracellular collagen and connective tissue within the liver (Center, 1996c) and is a sequela to hepatic inflammation. Fibrosis not only results in distortion of normal hepatic architecture, but also becomes a barrier to movement of substances back and forth between blood and hepatocytes. Cirrhosis is defined as fibrosis with loss of normal acinar liver architecture and with regenerative nodules (**Figure 68-9**) (Meyer, 1996). The architectural changes in cirrhosis impair blood and bile flow and nutrient exchange, thus perpetuating hepatocellular injury.

Canine Copper-Associated Hepatotoxicosis

Hepatic copper storage disease was first described in the Bedlington terrier breed. The disease has some similarities to Wilson's disease in people (Hultgren et al, 1986). It is an inherited autosomal recessive trait that impairs biliary excretion of copper (Su et al, 1982, 1982a). Affected dogs progressively accumulate copper. Evidence of hepatic necrosis is observed when copper concentrations exceed approximately 2,000 ppm (µg/g) DW liver (normal copper concentrations are <400 µg/g DW (Twedt et al, 1979; Twedt, 1990). As copper concentrations increase, damage progresses to chronic hepatitis and ultimately cirrhosis (Hultgren et al, 1986; Twedt et al, 1979; Twedt, 1990). Rarely, massive widespread hepatic necrosis can result in some dogs presenting with acute liver failure. Without appropriate treatment with dietary management and copper chelation, affected dogs usually succumb to their liver disease by approximately seven to 10 years of age (Hultgren et al, 1986; Twedt et al, 1979; Twedt, 1990). The gene responsible for this defect has been identified (Van De Sluis et al, 2002) and it has become possible to distinguish affected, homozygous normal and carrier Bedlington terrier dogs using DNA markers (Yuzbasiyian-Gurkan et al, 1997). It was once estimated that about 25% of Bedlington terriers were affected with copper toxicosis and another 50% were carriers. Now, through genetic testing and responsible breeding programs, the incidence of this disease is significantly lower.

Hepatic mitochondria are important intracellular targets of copper toxicosis. Functional abnormalities of mitochondria associated with oxidative injury (i.e., lipid peroxidation) have been documented to occur in people, rats and Bedlington terriers with copper-induced hepatic injury (Sokol et al, 1993, 1994). Oxidative injury and abnormal hepatic mitochondrial respiration may be involved in the pathogenesis of copper toxicosis. This theory forms the basis for using vitamin E and other antioxidants as potential therapeutic agents in addition to chelation therapy.

The role of copper in hepatic diseases observed in other dog breeds is less clear. Abnormal concentrations of copper in the liver can result secondary to cholestatic liver disease (Center, 1996c; Haywood et al, 1988; Johnson et al, 1982) or as a primary defect in hepatic copper excretion resulting in hepatic

injury (Thornburg et al, 1984, 1985, 1986, 1996). Breeds that are currently thought to have primary copper-associated hepatopathies include Skye terriers (Haywood et al, 1988; McGrotty et al, 2003), West Highland white terriers (Thornburg et al, 1996), Doberman pinschers (Specti et al, 1998), Dalmatian dogs (Webb et al, 2002) and Labrador retrievers (Hoffman et al, 2006).

The liver diseases in these dogs are distinct from copper toxicosis in Bedlington terriers in that hepatic copper concentrations are generally lower and do not always increase with age. Other factors may be responsible for hepatic damage in some breeds. The exceptions might be Doberman pinschers and Dalmatian dogs because they tend to accumulate hepatic copper in concentrations similar to Bedlington terriers, suggesting defects in hepatic copper excretion (Mandigers, 2005).

Cholangitis in Cats

Cholangitis (i.e., inflammation of the biliary ducts, especially the intrahepatic ducts and the surrounding liver tissue) is the most common feline inflammatory liver disease (Gagne et al, 1999; Armstrong et al, 1997; Day, 1995). The World Small Animal Veterinary Association Liver Pathology Standardization Working Group categorized the two most common forms of cholangitis into neutrophilic and lymphocytic forms (2006). Bacterial infection from enteric bacteria (especially *Escherichia coli*) ascending through the bile ducts is thought to be the cause of most neutrophilic forms, whereas immunologic mechanisms may be involved in the lymphocytic type. Chronic cholangitis may progress to biliary cirrhosis.

Many cats with cholangitis develop significant cholestasis and may have sludged or inspissated bile, causing partial or complete biliary obstruction (Armstrong et al, 1997; Day, 1995). Concurrent cholecystitis, pancreatitis and inflammatory bowel disease are common in feline cholangitis patients (Armstrong et al, 1997; Day, 1995).

Portosystemic Shunts in Dogs and Cats

PSS are vascular communications between the portal and systemic venous circulation. PSS can be either congenital or acquired. Congenital shunts can be further subdivided into intrahepatic shunts, occurring mostly in large-breed dogs or extrahepatic shunts, occurring mostly in smaller dog breeds and cats. Intrahepatic shunts are the remnant of a ductus venosus that did not completely close after birth. Extrahepatic shunts are seen as anomalous embryonic vessels between the portal vein and the systemic circulation (mostly to caudal vena cava or azygos vein) (Moon, 1990; Lamb, 1998; Center, 1996b). A hereditary basis for congenital shunts has been established in Irish wolfhounds (Meyer et al, 1995) and a number of other breeds have a significant risk for development of congenital shunts, supporting a hereditary etiology. Acquired PSS may develop as multiple shunts in response to portal hypertension caused by cirrhosis or other causes (e.g., tumors or portal vein thrombosis). Both congenital and acquired PSS are more common in dogs than in cats.

Primary portal vein hypoplasia (also referred to as microvascular dysplasia) is a second congenital vascular anomaly occurring in dogs, but rarely in cats. This anomaly is a consequence of portal vein hypoperfusion that results in hepatic arterialization in the portal triad and the development of microscopic intrahepatic shunts. Commonly affected breeds include cairn terriers, Yorkshire terriers and Maltese (Schermerhorn et al, 1996). Affected dogs have abnormal bile acid concentrations and variable liver enzymes but rarely have clinical signs. A less common variant of portal vein hypoplasia associated with fibrosis in the portal triads results in portal hypertension, ascites and PSS (Christiansen et al, 2000; Bunch et al, 2001).

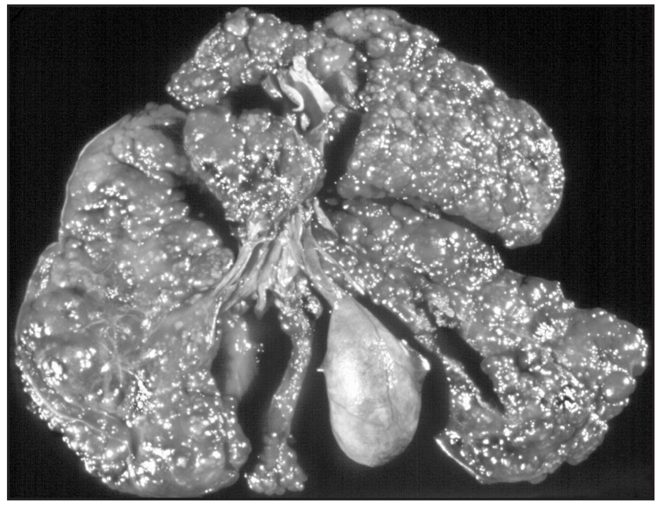

Figure 68-9. Cirrhotic liver from an eight-year-old female Doberman pinscher with chronic hepatitis. (Photograph courtesy Dr. Susan Johnson, The Ohio State University, Columbus.)

Clinical signs of HE usually predominate in patients with PSS (**Box 68-1**). Polydipsia and polyuria are also commonly seen. Ammonium urate and other purine uroliths occur in some animals because of high urinary excretion of ammonia and uric acid (Chapter 39). Stunted growth or failure to gain weight may occur in young animals with congenital shunts. Surgical closure is the treatment of choice for congenital PSS but not for acquired PSS. Dietary management is the cornerstone of successful case management and prevention of HE in the pre- and immediate postoperative phase and in partially closed shunts (Meyer and Rothuizen, 1996).

Neoplasia

The most commonly encountered hepatic malignancies in dogs and cats are metastases, lymphoma, hemangiosarcoma, hepatocellular carcinoma and cholangiocarcinoma (Cullen and Popp, 2002). The appearance may be localized or diffuse. Because the liver has such a tremendous reserve capacity, tumors, especially localized malignancies may be undetected for long periods. In advanced stages, tumors may be visible or palpable during physical examination. Severe liver dysfunction with icterus, coagulopathies and portal hypertension may occur especially in diffusely distributed malignancies (e.g., malignant lymphoma and hemangiosarcoma).

Box 68-1. Hepatic Encephalopathy.

Hepatic encephalopathy (HE) is a neurologic syndrome that may arise due to liver dysfunction and portosystemic shunting (**Figure 1**). HE is categorized as acute or chronic, based on duration of signs and relative importance of the two main etiologic factors. Striking differences exist in the pathogenesis of acute and chronic HE. Because acute HE occurs rarely in dogs and cats, this summary will focus on chronic HE. Chronic HE results from disturbances in various neurotransmitter systems caused by a variety of gut-derived toxins and compounds. These toxins and compounds reach the systemic circulation when liver function is compromised and collateral circulation develops (**Figure 2**).

The pathogenesis of HE remains partly unknown due to the complex interplay between various pathogenetic factors and neurotransmitter systems. However, there seems to be consensus that the main neurotransmitter systems involved in HE are the GABA-ergic (the most abundant inhibitory neurotransmitter system in the brain) and the glutamatergic (the most important excitatory neurotransmitter system in the brain). Other neurotransmitters that may play a role include catecholamines, serotonin and opioids. Without doubt, ammonia is the main causative agent behind neurologic changes. Other contributing factors may include accumulation of manganese (Mn), increased concentrations of neurosteroids and peripheral benzodiazepine receptor ligands and changes in the molar ratio between branched-chain amino acids (BCAA) and aromatic amino acids (AAA) in plasma and cerebrospinal (CSF) fluid.

An abundance of evidence suggests that GABA-ergic tone is increased in HE. Although the nature of this increase is partly unknown, ammonia plays a key role. The role of increased concentrations of endogenous benzodiazepine receptor ligands in HE, an attractive hypothesis postulated in the late 1990s, has been abandoned. However, neurosteroids, which increase in people with HE, may have a direct influence on the GABA-ergic tone.

Although total brain glutamate is decreased in HE, intrasynaptic glutamate is increased, leading to down regulation of various postsynaptic glutamatergic receptor types.

Methionine, degraded by gut bacteria to the mercaptans methanethiol and dimethyldisulfide, has been implicated in the pathogenesis of HE, alone or synergistically with ammonia and free fatty acids. However, previous diagnostic methods overestimated the importance of these compounds; in rats and dogs, there was no correlation between the severity of HE and the concentrations of methanethiol and dimethyldisulfide. Thus these compounds do not play an important role in the pathogenesis of HE. On the other hand, S-adenosylmethionine (SAMe), an important precursor of liver glutathione, may play a role in the treatment of chronic liver disease because liver glutathione, an important antioxidant compound, is depleted in liver disease.

In human HE patients, a relation was found between high Mn concentrations in blood and/or the globus pallidus and hyperintensity of the magnetic resonance imaging signal in the globus pallidus. High Mn concentrations in the globus pallidus were accompanied by a loss of dopamine binding sites. Binding of Mn to dopamine receptors may have resulted in auto-oxidation of dopamine and formation of free radicals that caused tissue damage. No studies have been done to confirm increased Mn concentrations in the brains of dogs and cats with HE.

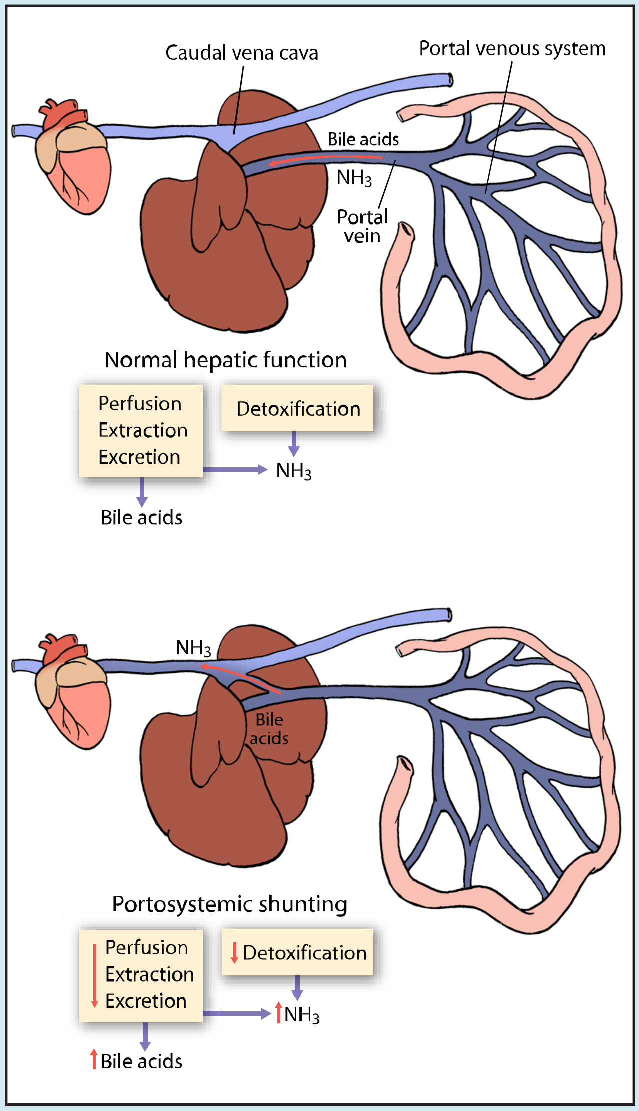

Figure 1. The effect of portosystemic shunting on hepatic extraction of bile acids and ammonia. (Adapted from Center SA. Hepatic vascular diseases. In: Guilford WG, Center SA, Strombeck DR, et al, eds. Strombeck's Small Animal Gastroenterology, 3rd ed. Philadelphia, PA: WB Saunders Co, 1996; 805, 813.)

Although a consistent decrease in the molar ratio between BCAA and AAA in plasma and in CSF has been reported in longstanding HE in many species, the importance of this molar ratio change in the pathogenesis of HE remains unclear. It may play a role in the reported dopaminergic dysfunction in HE, but others have not confirmed this hypothesis. The main beneficial effect of correction of the BCAA:AAA ratio by infusions or diet is reversal of the catabolic state in patients with HE.

Cats develop HE if fed foods deficient in arginine. Cats affected with hepatic lipidosis have low serum arginine concentrations. Because animal-origin protein is generally rich in arginine, most commercial cat foods and foods for stress and recovery are well

fortified with this amino acid. Homemade vegetable-based foods and human enteral foods fed to cats with encephalopathic clinical signs should be supplemented with arginine. Arginine levels in food should always be above the minimum dietary allowance for adult maintenance (>0.5% dry matter [DM] in dogs, >1.0% DM in cats). A dietary arginine level of 1.2 to 2.0% DM in dogs and 1.5 to 2.0% DM in cats seems appropriate for most patients with liver disease.

Bile Duct Obstruction in Dogs and Cats

Extrahepatic bile duct obstruction, which is rarely seen in companion animals, can be caused by a number of conditions and pancreatitis is thought to be the most common cause in dogs (**Table 68-5**) (Neer, 1992). Cholestasis associated with occlusion of the major bile ducts leads to serious hepatobiliary injury within a few weeks (Center, 1996d). Obstructed bile flow and the resulting stagnation of bile acids and other compounds injure cell membranes and organelles. Bacterial cholecystitis may develop due to biliary reflux of intestinal bacteria or lymphohematogenous dissemination. Biliary injury is associated with cytokine-mediated inflammation and free radical injury. Long-term changes include biliary epithelial hyperplasia, cholangitis, multifocal parenchymal necrosis, fibrosis and cirrhosis (Center, 1996d). Coagulopathies associated with vitamin K deficiency may develop within three weeks.

Most patients with bile duct obstruction are candidates for exploratory celiotomy and corrective surgery. Enteral- or parenteral-assisted feeding is often used before and after surgery while the patient recovers (Chapters 25 and 26). Appropriate adult maintenance-type foods are generally indicated after recovery. Patients with inflammatory bowel disease, exocrine pancreatic insufficiency or concurrent pancreatitis may require a food with an altered nutrient profile (Chapters 57, 66 and 67, respectively).

Metabolic Alterations in Hepatocellular Dysfunction

Hepatocellular dysfunction is responsible for a number of metabolic disturbances that alter usage of various nutrients (**Table 68-6**). Changes in protein, carbohydrate and fat metabolism are particularly prominent in the fasting state (Marks et al, 1994; McCullough and Tavill, 1991; Latfi et al, 1991; Bauer, 1986, 1996; Chang et al, 1996). Attempts to correct these alterations by manipulating nutrient supply represent an important strategy in the management of patients with significant hepatic disease.

Impaired hepatic metabolism and storage may result in vitamin and mineral deficiencies. A combination of these metabolic and storage problems usually exists in patients with hepatic

disease; each problem should be considered before appropriate dietary therapy is begun.

Carbohydrate Alterations

The liver plays a key role in the metabolism of the major monosaccharides glucose, fructose and galactose (Owen et al, 1981). Glucose can be used for energy production or to synthesize other substrates (e.g., amino acids, fatty acids), or it can be stored as glycogen. Liver glycogen can be readily mobilized when glucose is in demand. Hepatic glycogen can normally meet glucose needs (primarily for the brain) for 24 to 36 hours (Center, 1996). In human patients with hepatic cirrhosis, glycogen stores are more rapidly depleted (in 10 to 12 hours), which results in premature protein catabolism to supply amino acids for gluconeogenesis (Zakim, 1982). Gluconeogenesis, the production of glucose from amino acids, glycerol or lactate, is carried out only in the liver and the renal cortex. Glycolysis is the pathway by which glucose can be metabolized anaerobically with production of ATP. Regulation of glycolysis in the liver is highly integrated with that of gluconeogenesis, lipogenesis, glycogen synthesis and glycogenolysis.

Fasting hypoglycemia is uncommon in patients with liver disease because euglycemia can be maintained with as little as one-fourth to one-third of normal liver parenchymal mass (Zakim, 1982). However, hepatogenic hypoglycemia can occur in dogs with cirrhosis, congenital portosystemic vascular anomalies, fulminant hepatic failure, septicemia and extensive hepatic neoplasia (Center, 1996).

Glucose intolerance is more common than hypoglycemia in people with severe hepatic dysfunction; as many as 80% of cirrhotic patients have this abnormality (Zakim, 1982). The importance and causes of glucose intolerance in dogs and cats with liver disease are poorly documented. Hyperglycemia has been observed in some dogs with cirrhosis and portosystemic vascular shunts and in some cats with hepatic lipidosis and cholangitis (Center, 1996).

Protein and Amino Acid Alterations

The liver synthesizes the majority of circulating plasma proteins. The most abundant is albumin, which represents 55 to 60% of the total plasma protein pool (Center, 1996). Albumin serves as a binding and carrier protein for hormones, amino acids, steroids, vitamins, calcium and fatty acids, as well as exogenous compounds, drugs, toxins, etc. Albumin also helps maintain normal plasma oncotic pressure. The other proteins synthesized and secreted by the liver are usually glycosylated proteins (i.e., glycoproteins) that function in hemostasis, protease inhibition, transport and ligand binding. Hypoalbuminemia and increased bruising/bleeding tendencies result from decreased plasma protein production due to liver disease and/or increased usage (consumption coagulopathy) (Center, 1996). Ascites results from a combination of hypoalbuminemia and portal hypertension.

Protein regulatory events in the liver include amino acid storage and deamination of amino acids for intermediary metabolism. Generally, the liver degrades essential amino acids (including the aromatic amino acids [AAA], but not the branched-chain amino acids [BCAA]) and some of the nonessential amino acids (Center, 1996; Skeie et al, 1990). When dogs and other omnivores consume a minimal amount of dietary protein, the activities of key degradative enzymes are typically down regulated to ensure amino acid availability for protein synthesis. Alternatively, when omnivores ingest excess dietary protein, the activities of these key metabolic enzymes rapidly increase. This down regulation does not occur in carnivores such as cats (Chapter 19). Amino acids not required for protein synthesis are deaminated and oxidized or will be converted to carbohydrate and lipid. In this way, the liver plays an important role in energy balance and regulation of plasma concentrations of important amino acids (Chapter 5).

The deamination of amino acids is linked to carbohydrate and lipid metabolism by a number of common intermediates. These intermediates (e.g., pyruvate, fumarate, succinyl-CoA, oxaloacetate and acetyl-CoA) are entry points for amino acid carbon skeletons into the tricarboxylic acid (TCA or Krebs) cycle after deamination (Chapter 5). Intermediates are used primarily for energy production, gluconeogenesis and storage of excess dietary energy as triglycerides.

Alterations in nitrogen metabolism are one of the most prominent biochemical changes in chronic liver failure. Hyperammonemia is a common finding and results from a combination of factors including: 1) impaired ureagenesis due to decreased functional mass, 2) inadequate delivery of ammonia to the liver because of portosystemic vascular shunting and 3) increased ammoniagenesis due to amino acid deamination and gluconeogenesis (Meyer, 1998) (**Box 68-2**).

Plasma amino acid concentrations may be altered in patients with liver disease (Center, 1996; Strombeck and Rogers, 1978; Strombeck et al, 1983, 1984; Rutgers et al, 1987; Aguirre et al, 1974). Plasma amino acid concentrations differ depending on

Table 68-6. Metabolic alterations in hepatic failure.*

Alterations	Mechanisms
Hyperglucagonemia	Portosystemic shunting Impaired hepatic degradation Increased plasma aromatic amino acid levels Hyperammonemia
Hyperinsulinemia	Increased peripheral insulin resistance Decreased insulin to glucagon ratio Impaired hepatic degradation
Increased plasma cortisol levels	Deranged feedback mechanism
Decreased liver and muscle carbohydrate stores	Accelerated glycogenolysis Impaired glycogenesis
Increased gluconeogenesis	Hyperglucagonemia
Hyperglycemia (fasting and postprandial)	Portosystemic shunting Increased gluconeogenesis Decreased insulin-dependent glucose uptake Decreased insulin-hepatic glycolysis
Increased plasma aromatic amino acid levels	Decreased hepatic clearance and incorporation into proteins Increased release into the circulation
Decreased plasma branched-chain amino acid levels	Hyperinsulinemia and excessive uptake Increased usage as an energy source
Increased plasma methionine, glutamine, asparagine and histidine levels	Decreased hepatic clearance

the type of hepatic failure present. In health, the AAA (i.e., tyrosine, phenylalanine and tryptophan) are efficiently extracted from the portal circulation and metabolized by the liver. Reduced liver function is associated with an increase in circulating levels of AAA because of continued mobilization of amino acids for gluconeogenesis and impaired hepatic AAA metabolism (Center, 1996; Strombeck and Rogers, 1978). Plasma concentrations of BCAA (i.e., leucine, isoleucine and valine), and most other amino acids metabolized in peripheral tissues are reduced because of an increased rate of usage by muscle and adipose tissue (Center, 1996; Strombeck and Rogers, 1978). The molar ratio between BCAA and the AAA (BCAA:AAA ratio) in healthy dogs usually ranges between 3.0 to 4.0. This ratio is often reduced to 1.0 or less in dogs with portosystemic vascular anomalies and chronic hepatitis (Meyer, 1998; Center, 1996e; Strombeck et al, 1983, 1984; Rutgers et al, 1987). Conversely, massive, acute hepatic necrosis in dogs (which is a rare disorder in dogs and cats) increases the plasma concentrations of all amino acids except arginine (Strombeck and Rogers, 1978). Increased circulating catecholamines, insulin and glucagon concentrations are thought to contribute to the altered amino acid metabolism seen in patients with liver disease (Center, 1996; Strombeck et al, 1983). Because all neutral amino acids (which includes BCAA, AAA and glutamine) use the same carrier to cross the blood-brain barrier, the decreased BCAA:AAA ratio is even more pronounced in cerebrospinal fluid than in plasma. Alterations in plasma amino acid profiles may also play a role in the pathogenesis of HE (Fischer et al, 1975; Maddison, 1992; Meyer, 1998a). Increased cerebral AAA levels have been hypothesized to form "false neurotransmitters," leading to decreased dopaminergic tone. Dopaminergic disinhibition at the pituitary level has been documented to occur in dogs with PSS (Rothuizen and Mol, 1987). Attempts to show that normalization of the BCAA:AAA ratio in cerebrospinal fluid would restore dopaminergic inhibition at the pituitary level have failed in dogs with induced HE (Meyer, 1998a).

Lipid Alterations

Lipid metabolic processes in the liver include: 1) fatty acid and triglyceride synthesis, 2) phospholipid and cholesterol synthesis, 3) lipoprotein metabolism and 4) bile salt synthesis. The liver synthesizes fatty acids from carbohydrate precursors by converting these precursors to acetyl-CoA. Fatty acids are generally stored in the liver as triglycerides. After hepatic glycogen stores are depleted, fatty acids are mobilized from adipose tissue and their rate of hepatic oxidation increases. The ketone bodies produced are an important energy source for peripheral tissues (i.e., brain, skeletal muscle) and decrease the rate of glucose usage.

The liver is a site for β-oxidation of fatty acids, producing energy from fatty acid substrates (Chapter 5 and 6). L-carnitine functions to transport long-chain fatty acids across the inner mitochondrial membrane to the mitochondrial matrix for β-oxidation. The liver is also a major site of cholesterol synthesis from acetyl-CoA. Cholesterol is found throughout the body as a structural component of cell membranes, a substrate for synthesis of steroid hormones and is important in the liver as the precursor for bile acid synthesis. The liver secretes lipoprotein particles and is an essential organ for their uptake and metabolism.

The composition of plasma lipids and lipoproteins is altered in patients with liver disease. These abnormalities are associated with changes in lipoprotein and cholesterol synthesis, lec-

Box 68-2. Ammonia Metabolism and the Urea Cycle.

Ammonia is highly toxic and lethal. Therefore, excretion of excess ammonia is necessary for life. Animals have developed different approaches to this problem. Mammals use the urea cycle and glutamine synthesis as ammonia disposal mechanisms.

UREA SYNTHESIS

Urea is synthesized in the liver via the urea cycle (**Figure 1**). The initial step in urea production is synthesis of carbamoyl phosphate from bicarbonate and ammonia. Carbamoyl phosphate synthetase I catalyzes carbamoyl phosphate formation in mitochondria. This reaction requires free Mg^{++} and magnesium adenine triphosphate, the rate-limiting step of the urea cycle.

Next, citrulline is formed from carbamoyl phosphate and ornithine. Ornithine transcarbamoylase, another mitochondrial enzyme, catalyzes this reaction. This step is followed by the cytosolic portion of the urea cycle, beginning with a reaction catalyzed by argininosuccinate synthetase that combines citrulline with aspartate, a second nitrogen donor, to form argininosuccinate. Argininosuccinate is cleaved to arginine and fumarate via the action of argininosuccinate lyase. Finally arginine is cleaved by arginase to form urea and ornithine. Urea is released into the circulation and ornithine reenters the urea cycle.

THE UREA CYCLE IN NONCARNIVOROUS ANIMALS

In noncarnivorous mammals (i.e., herbivores and omnivores), the urea cycle is controlled by the activities of constituent enzymes, which in turn are controlled by the substrates they act upon. Additionally, during periods of normal protein intake, most enzymes involved in urea synthesis in noncarnivorous animals operate only at 20 to 50% capacity, allowing for adaptation to high or low protein foods. These mechanisms conserve nitrogen during periods of food deprivation, but slow the response time for ammonia detoxification after ingestion of a high protein meal.

The amino acid intermediates used in the urea cycle (i.e., ornithine, citrulline and arginine) are formed within the cycle itself and are provided by dietary sources of amino acids. In noncarnivorous mammals, amino acids for the urea cycle can be synthesized via alternative pathways; for example, rats can synthesize ornithine via proline or glutamate, a process that doesn't occur in obligate carnivores. Therefore, noncarnivorous animals can better adapt to foods containing protein of lower quality that may not contain all of the amino acids required for urea cycle function or foods that vary in protein content over time.

THE UREA CYCLE IN CARNIVOROUS ANIMALS

In contrast to noncarnivorous animals, carnivores (e.g., cats and ferrets) have not developed adaptive mechanisms to conserve nitrogen during periods of low protein intake. Only minimal changes in enzymatic activity are seen in cats fed either high or low protein foods. Thus, urea cycle enzymes act continuously, independent of dietary protein intake. Because enzymatic activity is constant, carnivores control the urea cycle via concentrations of urea cycle intermediates, which allows for rapid detoxification of ammonia.

Carnivores are also unable to synthesize ornithine from proline and glutamate. Therefore, ornithine for the urea cycle must be synthesized exclusively from arginine. Although the kidneys synthesize a small amount of arginine from citrulline, the high activity of

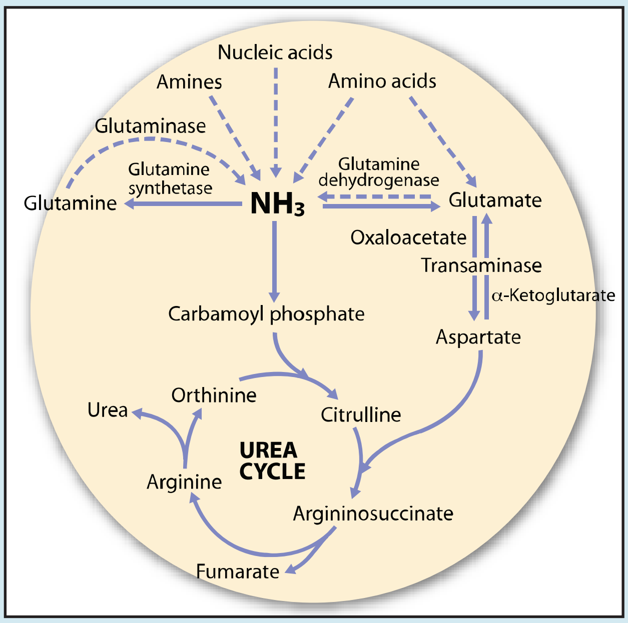

Figure 1. General scheme of hepatic ammonia metabolism, illustrating the pathways of ammonia usage (solid arrows) and ammonia formation (broken arrows). (Adapted from Ampola MG. The urea cycle: Enzymes and defects. In: Arias IM, Boyer JL, Fausto N, et al, eds. The Liver: Biology and Pathobiology, 3rd ed. New York, NY: Raven Press, 1994; 366.)

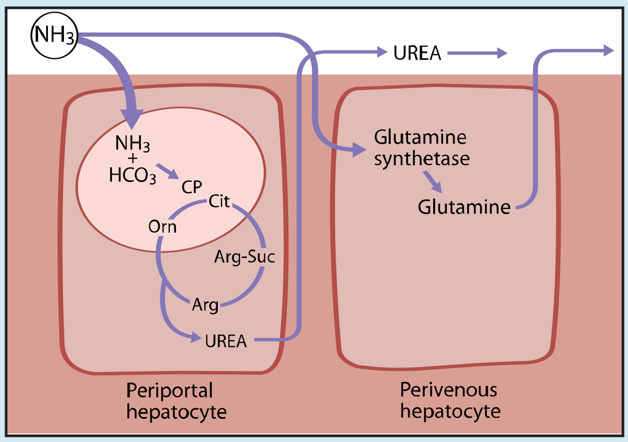

Figure 2. The scavenger role of perivenous hepatocytes. Most ammonia is metabolized to urea in the periportal hepatocytes. Ammonia not metabolized to urea is metabolized to glutamine by the perivenous hepatocytes (catalyzed by glutamine synthetase). This prevents ammonia from entering the systemic circulation and allows for uncoupling of urea production, which may be useful in acid-base regulation. Key: CP = carbamoyl phosphate, Cit = citrulline, Arg-Suc = argininosuccinate, Arg = arginine, Orn = ornithine. (Adapted from Dimski DS. Ammonia metabolism and the urea cycle: Function and clinical implications. Journal of Veterinary Internal Medicine 1994; 8: 75.)

Box 68-2 continued

hepatic arginase dictates that food primarily supply arginine for the urea cycle. To illustrate this point, adult cats and ferrets develop hyperammonemia and hepatic encephalopathy when fed foods devoid of arginine.

GLUTAMINE SYNTHESIS

Glutamine synthesis is the second primary mechanism by which mammals can metabolize excess ammonia. Hepatic glutamine synthetase is compartmentalized in a small area surrounding the centrilobular vein; thus, perivenous cells serve as "scavengers" for any ammonia that has not been converted to urea by periportal hepatocytes (**Figure 2**). Approximately one-third of the total ammonia from portal blood is detoxified by glutamine synthesis, although this percentage varies depending on acid-base status.

The glutamine synthetase pathway is a high affinity system, ensuring that ammonia does not reach the systemic circulation in toxic concentrations. In contrast, urea production is a low affinity, high capacity system for detoxifying ammonia. Thus, glutamine synthesis acts as a backup system for ammonia detoxification, allowing urea production to be decreased as required for acid-base regulation, while preventing hyperammonemia.

Glutamine synthetase activity is also high in brain astrocytes, which detoxify ammonia that may reach the brain. However, this system has limited capacity. Thus, increases in brain ammonia cannot be prevented in cases of severe hyperammonemia.

The Bibliography for **Box 68-2** can be found at www.markmorris.org.

ithin-cholesterol acyltransferase deficiency, defective lipolysis, abnormal recognition and uptake of lipoproteins by the liver and regurgitation of biliary lipids into plasma (Center, 1996). Obstructive icterus may lead to hypercholesterolemia and hypertriglyceridemia (Center, 1996). Hypocholesterolemia has been recognized in animals with portosystemic vascular anomalies and acquired hepatic insufficiency (Center, 1996). Hypotriglyceridemia has been recognized in dogs with PSS and hepatic necrosis (Center, 1996). Little is known about changes in lipoprotein fractions in dogs and cats with liver disease. Because the well-known relationship between plasma lipid and lipoprotein disturbances and cardiovascular disease in people is lacking in dogs and cats, the clinical relevance of the aforementioned disturbances in liver disease in these species may be limited.

Vitamin and Mineral Alterations

The liver serves as a storage reservoir for certain vitamins and minerals. Vitamin A can be stored in quantities sufficient for several months. The other fat-soluble vitamins (D, E and K) and vitamin B_{12} are also stored in the liver. The rest of the B vitamins are found in high concentrations in hepatic tissue, but the liver is not generally considered as their storage reservoir. Iron from dietary sources and from erythrocyte degradation is sequestered in hepatic tissue. Copper, manganese, selenium and zinc are trace elements normally present in high concentrations in the liver (Chapter 6).

Changes may occur in the patterns of storage and availability of all of these micronutrients in patients with significant liver disease. Malabsorption and alterations in hepatic blood flow may decrease availability and liver concentrations of certain vitamins and minerals. Vitamin B_{12} appears to be important in cats and subnormal concentrations of vitamin B_{12} have been reported in cats having liver disease. An adequate supply of B-complex vitamins is essential for the liver to perform a myriad of metabolic activities.

Copper is an essential trace metal required for diverse and numerous metabolic functions. The liver is essential for regulating copper concentrations and excreting excess copper via bile. Hepatic copper concentrations increase as a result of a primary metabolic defect in hepatic copper metabolism noted in some breeds of dogs. In dogs, the concentration of accumulated copper caused by cholestatic disease is less than the concentrations occurring from breed-associated copper hepatotoxicity (Spee et al, 2006). Subcellular damage to hepatocytes can result from significant copper accumulation. Copper is referred to as a transitional metal and is a catalyst (through the Fenton reaction). Free copper can directly damage hepatocyte mitochondria resulting in electron leak with free radical formation leading to lipid membrane peroxidation (Sokol et al, 1989).

Iron accumulates in the liver of canine patients with chronic hepatitis/cirrhosis, congenital portosystemic shunting and possibly other types of liver disease (Schultheiss et al, 2002; Simpson et al, 1997). Iron accumulation is thought to result from three mechanisms: 1) dietary iron uptake from the intestine, which is then deposited in the liver, 2) hepatic sequestration of iron released during hepatic inflammation and 3) abnormal hepatic retention secondary to cholestasis. Most hepatic iron is sequestered as hemosiderin and found in Kupffer cells or as lipogranulomas. Iron in hepatocytes occurs as ferritin or hemosiderin. Kupffer cell damage from iron results in cytokine release with subsequent inflammation and fibrosis. Because iron is a transition metal much like copper, abnormal levels of iron can catalyze the generation of free radicals and initiate lipid peroxidation of hepatocyte membranes and damage cellular proteins (Britton, 1996; Sokol and Hoffenberg, 1996).

Key Nutritional Factors

The specific nutrient requirements of patients with various naturally occurring hepatobiliary diseases are not well understood or documented. Most key nutritional factor recommendations for these patients are based on understanding normal hepatic function, studies in animals with experimentally induced disease, results in human patients with comparable diseases and

**For liver disease patients with signs of hepatic encephalopathy, dry matter dietary protein levels should be limited to 10 to 15% for dogs and 25 to 30% for cats until signs resolve.

clinical experience. The key nutritional factors discussed below support a common nutrient profile that will benefit most liver disease patients. However, it should be noted that due to the wide range of hepatobiliary diseases and their differing severity, one nutrient profile might not always be ideal for all patients. The following section will discuss these key nutritional factors in more detail and outline specific recommendations for the most common hepatobiliary disorders. **Tables 68-7** (feline hepatic lipidosis and cholangitis) and **68-8** (canine and feline hepatobiliary diseases) summarize these key nutritional factors.

Energy

Provision of adequate daily energy intake is the cornerstone of successful medical management of cats with hepatic lipidosis (Biourge et al, 1990, 1994a; Center, 1996c; Biourge, 1997; Marks et al, 1994a). An adequate supply of energy is needed to: 1) prevent catabolism of amino acids for energy, 2) inhibit peripheral lipolysis and 3) avoid excess energy consumption, which will promote hepatic triglyceride accumulation. Cats with hepatic lipidosis are often fed commercial veterinary therapeutic products via assisted-feeding techniques (Chapter 25). Foods with energy densities of at least 4.4 kcal metabolizable energy (ME/g) (18.4 kJ ME/g) (dry matter [DM]) are well tolerated by most cats and result in clinical improvement when fed in appropriate amounts. Energy density recommendations for cats with cholangitis are similar to those outlined for cats with hepatic lipidosis. Achieving this level of energy density typically requires at least 25% DM dietary fat.

Providing adequate daily energy intake is also important in managing dogs and cats with chronic hepatitis, portal hypertension and PSS and dogs with copper-associated hepatotoxicosis. An adequate supply of energy is needed to allow protein synthesis and prevent tissue catabolism that generates ammonia. Foods for patients with these diseases should provide at least 4.0 and 4.2 kcal ME/g DM (16.7 and 17.6 kJ ME/g), for dogs and cats, respectively.

The role of dietary fat in patients with hepatic disease has not been specifically determined. Dietary lipids are beneficial because they have a protein-sparing effect, reduce carbohydrate intolerance, augment fat-soluble vitamin absorption, enhance palatability and are an important source of energy and essential fatty acids.

A minor decrease in fat digestibility (i.e., from 92 to 85%) was found in dogs with experimentally created PSS (Laflamme et al, 1993). Other studies showed that dogs with experimental shunts tolerate foods containing 20 to 25% DM fat (Center, 1996b). Clinically significant impaired fat digestion may occur in animals with severe biliary disease with subtotal or total biliary obstruction.

There appears to be no reason for routinely restricting dietary fat in dogs and cats with liver disease. One of two different situations may be occurring if steatorrhea is a problem in patients with hepatobiliary disease. First, the patient may have concurrent disease that is contributing to fat malassimilation, such as exocrine pancreatic insufficiency. Second, the patient may have subtotal or total biliary duct obstruction.

Medium-chain triglycerides (MCT; i.e., carbon chain lengths <12) have theoretical advantages over long-chain triglycerides (LCT) for the treatment of GI and some forms of hepatobiliary disease (Guilford, 1996). MCT may be more easily hydrolyzed and absorbed than LCT; however, these advantages have yet to be proved. Caloric supplementation with MCT is useful for malnourished human cirrhotic patients with steatorrhea and those with advanced cholestatic hepatic disease (Munoz, 1991). Controlled clinical trials using MCT in animals with cirrhotic or cholestatic liver disease have not been reported.

The inflammatory component of hepatic disease may be attenuated by omega-3 (n-3) fatty acid supplementation. However, the specific amounts to include in foods and the optimal ratio of omega-6 (n-6) to omega-3 fatty acids have not been determined. Some veterinary therapeutic foods for liver disease are enhanced with omega-3 fatty acids (Remillard and Saker, 2005).

Protein and Amino Acids

Dietary protein and the amino acids arginine and taurine are important in cats with hepatic lipidosis. Cats are less efficient in sparing protein during fasting than other animals. As such,

protein deficiency may play a major role in the development of feline idiopathic hepatic lipidosis. Cats with hepatic lipidosis have signs of protein malnutrition include hypoalbuminemia, anemia, muscle wasting and negative nitrogen balance (Biourge et al, 1994; Barsanti et al, 1977). Specific amino acids (e.g., methionine and arginine) become limiting during fasting in obese cats (Biourge et al, 1994). Protein or amino acid deficiency may induce lipid accumulation in the liver by limiting lipoprotein synthesis needed for normal lipid metabolism and transport (Biourge et al, 1994). Protein supplementation at only one-fourth of the daily requirement (22 g protein/day) significantly reduced lipid accumulation in the liver and promoted positive nitrogen balance during long-term fasting in obese cats (Biourge et al, 1994a).

Cats with hepatic lipidosis will usually tolerate moderate amounts of dietary protein unless they are suffering from concurrent HE, which is uncommon. Commercial veterinary therapeutic foods containing 30 to 45% DM protein are well tolerated by cats with hepatic lipidosis and have been used successfully in many cases. Protein needs for cats with cholangitis are similar to those for cats with hepatic lipidosis.

Adult cats and ferrets developed hyperammonemia and HE when fed foods devoid of arginine (**Boxes 68-1** and **68-2**). Foods for cats with hepatic lipidosis should provide adequate arginine. Arginine levels in food should always be above the minimum dietary allowance for adult maintenance (≥0.77% DM [NRC, 2006]). More arginine is required in cat foods that contain more than 20% DM protein (NRC, 2006). Arginine levels in foods for cats with liver disease should be between 1.5 to 2.0% DM. Good quality commercial foods are typically adequate in arginine. Homemade vegetable-based foods and human enteral foods fed to cats with encephalopathic clinical signs should be supplemented with arginine.

Ensuring adequate taurine intake is important for anoretic cats with hepatic lipidosis. Cats and dogs primarily synthesize taurine in the liver and bile salts are mainly conjugated with taurine. Compared to cats, dogs have a high capacity to synthesize taurine; therefore, dietary taurine is usually not essential. Food-induced bile salt excretion into the gut can result in significant loss of taurine, particularly when normal enterohepatic recycling is interrupted. Taurine synthesis is limited in cats; therefore, dietary taurine is essential. Adequate taurine nutriture is important in patients with enterohepatic circulation abnormalities and possibly in liver disease. In certain species, taurine also stimulates synthesis and turnover of bile independent of its role as a bile acid conjugate. Taurine appears to aid choleresis in dogs and possibly cats. This role may explain the observation that taurine prevents cholestasis in certain models of liver disease. Most commercial cat foods and foods for stress and recovery for dogs and cats are fortified with taurine. However, homemade and human enteral foods fed to cats should be supplemented with taurine (250 to 500 mg/day) (Chapter 10). The minimum recommended allowance for dry expanded and moist foods for adult cats is 0.10 and 0.17% DM, respectively (NRC, 2006). Foods for cats with hepatic lipidosis and other liver diseases should probably contain at least 0.3% DM taurine. Although no minimum recommended allowances for taurine for healthy dogs have been defined, foods for dogs with liver disease should contain at least 0.1% DM taurine.

Appropriate amounts of high quality dietary protein are also important in patients with chronic hepatitis and/or cirrhosis, portal hypertension and dogs with copper-associated hepatotoxicosis. Hypoalbuminemia, which reflects depleted body stores and reduced protein synthesis, is a frequent and serious problem in patients with chronic liver disease. Protein plays a leading role in hepatic regeneration; therefore, patients with liver disease require adequate protein intake to remain anabolic and support regeneration of hepatocytes. On the other hand, dietary protein restriction may be important in patients with endstage cirrhosis, hyperammonemia and HE. Protein, or more accurately, nitrogen excess, is a major contributor to neurotoxic precursors formed when amino acids are metabolized to ammonia. For patients with liver disease, the goal is to provide adequate dietary protein to support hepatic regeneration while avoiding excess dietary protein that might contribute to HE.

The protein requirements for patients with PSS have been roughly estimated from a nutritional study in adult dogs with surgically created shunts (Laflamme et al, 1993). This study showed that ingestion of 2.11 g crude protein/kg body weight/day with an 80% or greater availability was adequate to maintain body protein reserves without producing HE. In the absence of other data, this recommendation for dietary protein intake seems appropriate. This equates to approximately 14 to 16% protein calories (15 to 20% DM protein) for dogs and 25 to 30% protein calories (30 to 35% DM protein) for cats. These protein levels are also appropriate for dogs and cats with most other forms of liver disease, except hepatic lipidosis (described above) and HE. Patients with evidence of HE will often need restricted dietary protein levels for the short term (10 to 15% DM for dogs and 25 to 30% DM for cats). For a point of reference, the minimum recommended protein allowances for foods for normal adult dogs and cats are 10 and 20% DM, respectively (NRC, 2006).

In addition to the absolute amount of protein fed, the amino acid profile and digestibility are important for optimal protein usage. Amino acids from poor-quality protein sources are deaminated and metabolized to a greater extent than amino acids from higher quality protein sources and exacerbate hyperammonemia. Intestinal bacteria may degrade poorly digested proteins and add to the body's ammonia burden.

The importance of the dietary protein source has been studied in human patients with HE and in several experimental studies in dogs with PSS (Center, 1996b). Vegetable and dairy protein sources have produced the best results in maintaining positive nitrogen balance with minimal encephalopathic signs in human patients with liver disease (Uribe, 1990; Bianchi et al, 1993; Weber et al, 1985). Foods containing soybean meal averted encephalopathic signs in dogs with experimentally created shunts (Center et al, 1997; Thompson et al, 1986; Schaeffer et al, 1986). In addition, dairy products (especially cottage cheese) have been recommended for use in homemade foods for dogs and cats with PSS and chronic hepatic insufficiency (Center,

Box 68-3. Adjunctive Use of Copper Chelating Agents for Patients with Hepatic Copper Toxicosis.

For Bedlington terriers with subclinical or clinical liver disease, in addition to selection of a low-copper (<5 mg/kg, [dry matter]) veterinary therapeutic food (**Table 68-11**), adjunctive treatment with copper chelating agents is clearly indicated. Chelator treatment is used for breeds of dogs with copper-associated chronic hepatitis and cirrhosis and other breeds in which copper accumulation is documented by liver histopathology and/or elevated hepatic copper concentrations (generally >1,000 to 2,000 ppm dry weight).

Adjunctive treatment of hepatic copper toxicosis involves use of zinc or copper chelating agents such as D-penicillamine or trientine (**Figure 1**). Zinc blocks copper absorption. Chelating agents bind to copper and increase its excretion in urine. D-penicillamine, the copper chelating agent most frequently recommended for use in dogs, should be given at a dosage of 10 to 15 mg/kg body weight twice daily, on an empty stomach. Vomiting is the most common side effect in dogs, but can be alleviated by giving the agent more frequently in reduced doses. D-penicillamine therapy also has been associated with pyridoxine deficiency in people. However, this problem has not been recognized in dogs.

Trientine[a] (2,2,2-tetramine) is another chelating agent. In a clinical trial, chelation results with trientine (10 to 15 mg/kg body weight, per os, twice daily) were comparable to those of D-penicillamine and fewer side effects were noted. Modification of 2,2,2-tetramine to 2,3,2-tetramine increases the potency as a copper chelating agent. Use of 2,3,2-tetramine in affected Bedlington terrier dogs significantly reduced liver copper concentrations after 200 days of treatment at a dose of 15 mg/kg body weight. This drug is not commercially available but can be obtained from chemical supply companies in the form of N,N'-bis(2-aminoethyl)-1,3-propanediamine and prepared as a salt for oral administration.

Oral zinc therapy blocks copper absorption from the intestine. In early human studies, therapy with combined zinc and copper chelators found no benefit over single chelator therapy suggesting the chelator most likely binds zinc in the intestinal tract. However, more recently, human patients having Wilson's disease who are intolerant to penicillamine are sometimes treated with a combination trientine and zinc regimen with apparently good results. Affected dogs should be fed copper-restricted foods and be given the faster acting copper chelator. When hepatic copper concentrations approach normal levels, switching to zinc therapy alone may prevent further copper accumulation.

The initial report in dogs used 100 mg of elemental zinc acetate b.i.d. for one to two months during an induction phase followed by a maintenance dose of 50 mg of elemental zinc b.i.d., thereafter. Serum zinc concentrations should be monitored with a goal of approximately a twofold increase in serum concentrations (<200 µg/ml). Hemolysis can occur if serum zinc concentrations increase significantly (>750 µg/ml). Zinc can be given as an acetate, sulfate, gluconate or methionine salt but should be administered on an empty stomach to ensure adequate absorption. Common problems encountered with zinc therapy include anorexia, nausea and vomiting shortly following administration. If concurrent chelator therapy is used, dosing should be staggered to ensure adequate absorption of the chelator.

ENDNOTE

a. Syprine. Merck & Company, Inc., Rahway, NJ, USA.

The Bibliography for **Box 68-3** can be found at www.markmorris.org.

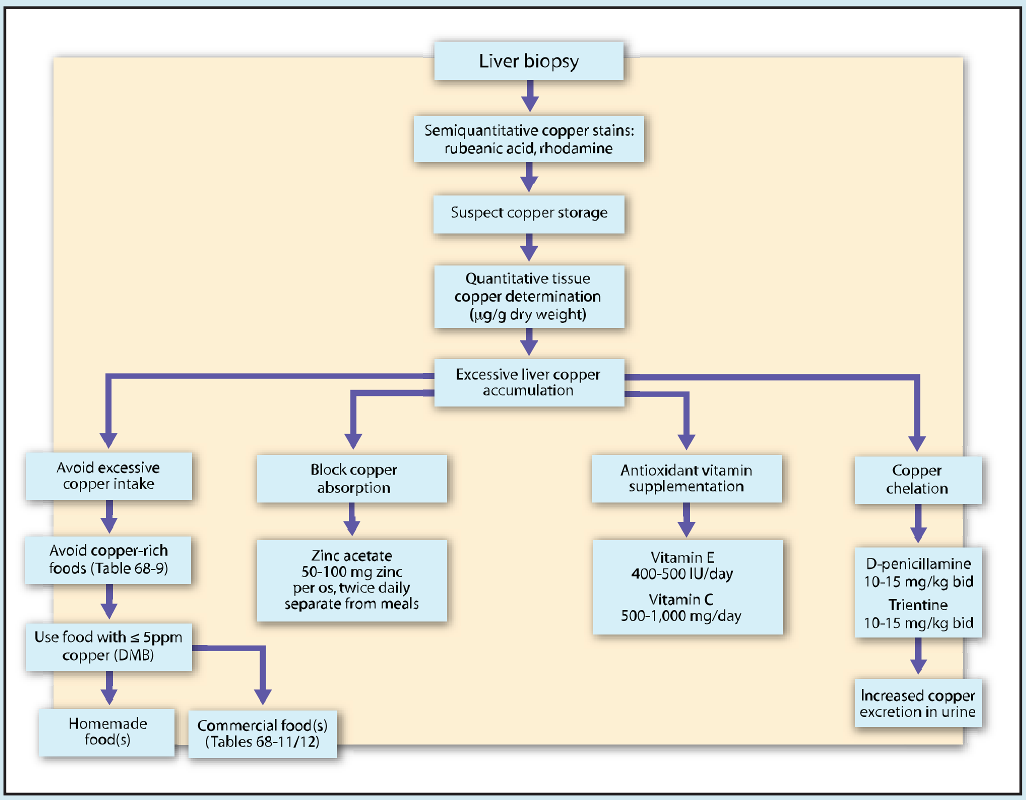

Figure 1. Algorithm for treating copper hepatotoxicosis in dogs. (Adapted from Center SA. Chronic liver diseases. In: Guilford WG, Center SA, Strombeck DR, et al, eds. Strombeck's Small Animal Gastroenterology, 3rd ed. Philadelphia, PA: WB Saunders Co, 1996; 749.)

1996b; Marks et al, 1994a). The amino acid composition of these protein sources is not significantly different from that of meat sources, suggesting that other food factors such as digestibility and levels of digestible (soluble) carbohydrate and fermentable fiber are important. Fermentable carbohydrates increase microbial nitrogen fixation, reduce intraluminal ammonia production in the gut and promote colonic evacuation (Center, 1996b). (See Fiber below.)

Superficial necrolytic dermatitis (hepatocutaneous syndrome) is an uncommon skin disease associated with systemic metabolic disease. Afflicted dogs commonly have concurrent skin erosions and ulcerations with alopecia, exudation and thick adherent crusts on the footpads and around mucocutaneous junctions. The hepatopathy grossly has the appearance of macronodular cirrhosis but is characterized by regenerative hyperplastic nodules separated by fibrous septa containing ductular structures and is void of inflammation. Some authors believe this condition results from exaggerated amino acid catabolism and the resultant hypoaminoacidemia is responsible for the skin and liver lesions (Gross et al, 1990, 1993). Most affected dogs also have low plasma amino acid concentrations and parenteral amino acid replacement with nutritional protein supplementation may resolve the skin lesions (Gross et al, 1993). In these cases, high protein foods, various protein supplements and intravenous amino acid solution administration is recommended. Note that rapid amino acid infusion can result in HE. Repeated amino acid infusions are given weekly as needed if a clinical response is observed using this protocol.

Potassium

Cats with hepatic lipidosis may develop hypokalemia due to inadequate potassium intake, vomiting, polydipsia and polyuria, magnesium depletion and concurrent chronic renal failure. In one study, hypokalemia was present in 19 of 66 cats (29%) with severe hepatic lipidosis (Center et al, 1993). Hypokalemia was significantly related to nonsurvival in this group of cats. Dogs with chronic liver disease and HE also frequently develop hypokalemia due to vomiting and alkalosis (Meyer, 1998). Hypokalemia is exacerbated by ascites due to activation of the renin-angiotensin-aldosterone axis. Hypokalemia, especially in combination with alkalosis (which is also a common feature in the same patients due to decreased use of bicarbonate in the urea cycle and vomiting), is dangerous because it may prolong anorexia and exacerbate expression of HE. This is due to intracellular trapping of ammonia in hypokalemic alkalosis. Foods for cats with hepatic lipidosis should be potassium replete (0.8 to 1.0% DM potassium), or potassium supplementation (2 to 6 mEq potassium gluconate per day) should be considered.

Sodium and Chloride

Excessive dietary sodium chloride should be avoided in liver disease patients with ascites, portal hypertension and/or significant hypoalbuminemia. Dietary sodium chloride restriction to levels recommended for patients with renal and cardiac failure is appropriate. Thus, sodium levels should be restricted to 0.08 to 0.25% DM for dogs and 0.07 to 0.3% DM for cats. Recommended DM chloride levels are typically 1.5 times sodium levels (NRC, 2006).

Copper

Avoiding excessive copper intake is important for dogs with copper-associated hepatotoxicosis, especially when serious hepatic injury has not yet occurred. The minimum recommended allowance for dietary copper in foods for healthy adult dogs is 6 mg/kg DM (NRC, 2006). However, studies have shown that Bedlington terriers achieve copper balance when consuming approximately 0.4 mg copper/day (Brewer et al, 1989). This equates to approximately 2.6 mg/kg of food. Foods for dogs with suspected or confirmed copper-associated hepatotoxicosis should not provide more than 5.0 mg/kg DM copper from an available copper source. Hepatic copper content is also increased (although not to the levels found in patients with inherited copper-related hepatotoxicosis) in patients with cholestasis. Therefore, moderate copper restriction is recommended for most patients with cholestatic liver disease. The role of copper in cats with liver disease has not been adequately investigated but it is generally considered that copper plays a minimal part, if any, in feline liver diseases.

Feeding selected commercial veterinary therapeutic (i.e., those formulated for patients with liver disease) or homemade foods to patients with liver disease can control copper intake, especially those with cholestasis. For patients with copper-associated hepatotoxicosis, copper restriction should be more aggressive and copper chelating agents (**Box 68-3**) or dietary zinc supplementation (See below.) should be used. Dogs should not be fed supplements containing copper or table foods that have a high copper content (**Table 68-9**). Certain fiber sources and minerals in food inhibit copper absorption (Chapters 5 and 6). The appropriate levels of these nutrients in foods for patients with copper toxicosis have not been determined. Zinc supplementation is important for blocking copper absorption and is discussed below.

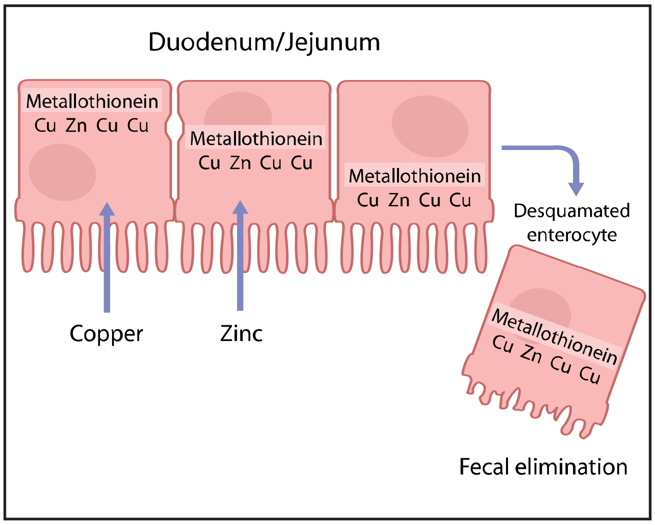

Figure 68-10. Diagrammatic representation of zinc and copper interaction in the intestine. Copper hepatotoxicosis is often treated with zinc supplementation. Zinc appears to induce synthesis of intestinal metallothionein, which has greater affinity for copper than for zinc. Metallothionein binds zinc and copper making them unavailable for systemic absorption. The metals are excreted in the feces with desquamated enterocytes. (Adapted from Center SA. Pathophysiology of liver disease: Normal and abnormal function. In: Guilford WG, Center SA, Strombeck DR, et al, eds. Strombeck's Small Animal Gastroenterology, 3rd ed. Philadelphia, PA: WB Saunders Co, 1996; 596, 599.)

Zinc

Zinc is an important metal involved in intermediary metabolism, enhanced ureagenesis, glutathione concentrations and immune function. The direct hepatoprotective effects of zinc include inhibition of lipid peroxidation and destabilization of lysosomal membranes. Zinc reportedly has antifibrotic activities (Brewer et al, 1992).

Zinc deficiency probably occurs in people with chronic hepatic disease (Riggio et al, 1991). Some dogs with chronic hepatitis or cirrhosis also have subnormal hepatic zinc concentrations (Schultheiss et al, 2002). Urea synthetic capacity may be reduced in zinc-deficient patients because of decreased hepatic ornithine transcarbamoylase activity and increased muscle glutamine synthetase activity (Marks et al, 1994). Zinc deficiency could adversely affect multiple aspects of ammonia metabolism (Mullen and Weber, 1991). Foods for patients with liver disease should contain more than 200 mg/kg DM zinc (Marks et al, 1994). This inclusion level is approximately three times the minimum recommended allowance for foods for healthy dogs and cats (60 and 74 mg/kg DM, respectively) (NRC, 2006), but is probably safe. A study in dogs and cats fed 80 and 200 mg zinc/kg body weight/day, respectively, for several months found no ill effects (Drinker et al, 1927; NRC, 2006). The levels of zinc intake in this study would be at least 60 times higher than would occur with the recommended amount for foods for dogs with liver disease. Similarly, the level is more than 100 times higher than would occur with the recommended amount for foods for feline patients with liver disease.

Dietary zinc blocks intestinal absorption of copper in dogs with copper-associated hepatotoxicosis. Animal and human studies have shown that zinc induces synthesis of intestinal metallothionein, which has greater affinity for copper than for zinc (Brewer, 1993; Friedman, 1993; Yuzbasiyian-Gurkan et al, 1992). In enterocytes, metallothionein acts as an intracellular ligand binding zinc, copper, mercury and cadmium to form mercaptides, thereby rendering them unavailable for systemic absorption. Thus, these metals are excreted in the feces with desquamated epithelial cells (**Figure 68-10**). In people with Wilson's disease, intestinal metallothionein concentrations were significantly elevated during zinc therapy when compared with the concentrations in patients not receiving zinc therapy (Friedman, 1993; Yuzbasiyian-Gurkan et al, 1992). A marked increase in intestinal metallothionein levels was observed in two human patients within a few days after zinc treatment was initiated. This finding was accompanied by suppression of copper uptake (Friedman, 1993; Yuzbasiyian-Gurkan et al, 1992). Discontinuation of zinc therapy was associated with progressive decreases in intestinal metallothionein concentrations and increased copper uptake. Thus, foods for canine patients with copper-associated hepatotoxicosis should also contain more than 200 mg/kg DM zinc, or the food should be supplemented with zinc gluconate (3 mg/kg body weight/day) or zinc sulfate (2 mg/kg body weight/day) divided into three doses (Marks et al, 1994).

Iron

Iron loading by hepatocytes and Kupffer cells has been recognized in some patients with inflammatory liver diseases and hepatic iron content is increased in dogs with cholestasis. Iron is a potent catalyst of oxidative processes (Fenton reaction) and iron-associated hepatic injury may involve lipid peroxidation of membranes and damage to organelles (Center, 1996c). Foods for dogs with chronic hepatitis and those with secondary hemosiderosis documented by evaluation of liver biopsy specimens should avoid excessive iron levels. The minimum recommended iron allowances for foods for normal adult dogs and cats are 30 and 80 mg/kg DM, respectively (NRC, 2006). Iron levels of 80 to 140 mg/kg DM meet the dietary allowance without providing excessive intake. This range is recommended for patients with liver disease. Injectable or oral supplements containing iron should be avoided in these patients.

On the other hand, iron deficiency may also occur in some liver patients with GI ulceration and hemorrhage associated with chronic hepatitis, portal hypertension or bile duct obstruction. Microcytosis, an erythrocyte abnormality associated with iron deficiency, also develops in dogs with portosystemic vascular shunts despite increased hepatic iron stores (Center, 1995, 1996b; Laflamme et al, 1994).

Iron supplementation is only indicated when serum iron concentrations are low, hypochromia is recognized and chronic gastroenteric bleeding or another source of chronic blood loss is recognized (Center, 1996a). Homemade foods, depending on the recipe, may require iron supplementation.

Antioxidant Vitamins E and C

Lipid peroxidation may be involved in the pathogenesis of some forms of acute liver injury and chronic hepatitis (Scalfani et al, 1986). Free radicals are an important component of most forms of liver damage. Abnormal concentrations of bile acids and the accumulation of heavy metals, such as copper and iron, cause free radical generation in the liver (Sokol and Hoffenberg, 1996; Sokol et al, 1994; Twedt et al, 1998). Activated inflammatory cells, damaged hepatocyte mitochondria and release of cytochrome P450 enzymes contribute to the production of reactive oxygen species. As the cascade proceeds, further hepatocyte damage occurs due to subsequent oxidation of cellular lipids, proteins and DNA. Oxidative stress may also activate pro-apoptotic protein kinases, proinflammatory transcription factors and modulators of apoptosis (Medina and Moreno-Otero, 2005).

Vitamin E functions as a cellular membrane-bound antioxidant that protects membrane phospholipids from oxidative damage. Results of vitamin E supplementation studies in human liver disease patients have been inconsistent. Vitamins E and C improved fibrosis scores in patients with nonalcoholic steatohepatitis (Harrison et al, 2003). Results of animal studies have also been mixed, perhaps due study design issues. However, in a study using a rat model of steatocholestasis, subcutaneous vitamin E provided significant protection against bile acid-induced hepatic injury, including a reduction in the release of apoptosis-inducing factor. Bile acid-induced necrotic hepatocyte injury was responsive to vitamin E therapy (Soden et al, 2007). Bedlington terriers with copper-associated hepatopathy have oxidative damage in their mitochondria and reduced mitochondrial vitamin E concentrations (Sokol et al, 1994). Vitamin E has a protective effect in the liver from copper-related oxidant damage and bile acids (Gaetke and Chow, 2003; Sokol et al, 1998). In a study using 20 dogs with naturally occurring chronic hepatitis fed a vitamin E-supplemented food for three months, increases in serum and hepatic vitamin E concentrations were accompanied by an increased hepatic reduced glutathione to oxidized glutathione (GSH:GSSG) ratio, suggesting an improved hepatic redox status. However, no changes in clinical or histologic scores were noted (Twedt et al, 2003).

Vitamin C is an important soluble intracellular antioxidant that helps convert oxidized vitamin E back to its reduced, active form. Vitamin C is also necessary for the synthesis of L-carnitine, which is important for transport of long-chain fatty acids across the mitochondrial membrane. People with liver disease often have low hepatic vitamin C concentrations, in part because human beings are unable to synthesize vitamin C, unlike dogs and cats. Although vitamin C supplementation may be beneficial in treating liver disease, supplementation with excessive amounts of vitamin C may be deleterious in patients with increased hepatic copper or iron concentrations.

No specific dosages of vitamins E and C have been documented to be safe and effective for dogs with liver disease. However, 50 to 400 IU vitamin E/day and 500 to 1,000 mg vitamin C given per os daily have been recommended as supplements for dogs with inflammatory liver disease (Rolfe and Twedt, 1995).

Alkenals (malondialdehyde and 4-hydroxyalkenals) in blood or tissues indicate lipid peroxidation, which may be a result of in vivo oxidative reactions. Alkenals are sometimes measured to determine the effectiveness of antioxidant interventions. Although dietary levels of antioxidant vitamins needed to reduce serum alkenal levels in dogs and cats with liver disease have not been established, a study found that food levels of 445 and 540 IU of vitamin E/kg (as fed basis) were necessary to reduce serum alkenal concentrations in apparently healthy dogs and cats, respectively (Jewell et al, 2000). Until more specific data are available, foods for canine and feline liver patients should provide at least 400 and 500 IU/kg DM, respectively.

Vitamin C is important for regenerating oxidized vitamin E. Foods for canine liver disease patients should contain at least 100 mg vitamin C/kg DM; foods for feline liver disease patients should contain 100 to 200 mg vitamin C/kg DM. This recommendation is based on the vitamin E levels in foods for dogs and cats with liver disease and data that show vitamin C regenerates vitamin E at about a 1:1 molar ratio (Barclay et al, 1985). Also, this range is not a risk for urinary oxalate production (Yu and Gross, 2005).

The earlier antioxidants are used to manage the oxidative damage that accompanies acute and chronic hepatobiliary disease, the more likely they are to be effective.

L-Carnitine

Food and hepatic biosynthesis are the primary sources of L-carnitine for animals. L-carnitine transports long-chain fatty acids across the inner mitochondrial membrane into the mitochondrial matrix for β-oxidation. L-carnitine also removes potentially toxic acyl groups from cells and equilibrates ratios of free CoA/acetyl-CoA between the mitochondria and cytoplasm.

Obesity is a risk factor for feline hepatic lipidosis; several studies have investigated the relationship between L-carnitine, weight loss in obese cats and feline hepatic lipidosis. Mean concentrations of L-carnitine in plasma, liver and skeletal muscle were significantly greater in cats with idiopathic hepatic lipidosis than in control cats (Jacobs et al, 1990). These findings suggest that systemic L-carnitine deficiency does not appear to contribute to the pathogenesis of feline idiopathic hepatic lipidosis. However, other studies have shown that feline foods supplemented with L-carnitine benefit obese cats undergoing rapid weight loss. Dietary L-carnitine supplementation protected obese cats from hepatic lipid accumulation during caloric restriction and rapid weight loss (Armstrong et al, 1992). Foods supplemented with L-carnitine can safely facilitate rapid weight loss in obese cats (Center et al, 1997). Based on these studies, the use of L-carnitine supplements or L-carnitine supplemented foods seems appropriate for obese cats undergoing weight reduction.

Besides being of value in preventing hepatic lipidosis, L-carnitine supplementation may also benefit cats with hepatic lipidosis (Center, 1996c). One author has recommended a dose of 250 to 500 mg L-carnitine/day for cats with hepatic lipidosis (Center, 1996c). Others have found that lower doses

(7 to 14 mg/kg body weight) also benefit weight loss, obesity prevention and hepatic lipidosis (Blanchard, 1998). Foods for cats with hepatic lipidosis should provide at least 0.02% DM L-carnitine.

Other Nutritional Factors

Depending on the type of hepatobiliary disease, some of the following nutritional factors may also be important.

Carbohydrate

Patients with clinical evidence of HE should receive adequate carbohydrate intake. Studies suggest that feeding foods with a high carbohydrate component is advantageous (Zieve and Zieve, 1987). Providing at least 30 to 50% of dietary calories in the form of easily digested, complex digestible carbohydrate (e.g., corn, rice, wheat, barley) may help avert encephalopathic clinical signs (Center, 1996b). Thus, the recommendations for DM digestible carbohydrates in foods for dogs and cats with liver disease are 45 to 55% and 30 to 40%, respectively.

Fiber

Foods with increased dietary fiber levels may benefit patients with hepatobiliary disease. Dietary fiber reduces the availability and production of nitrogenous wastes in the GI tract. Although highly digestible foods were previously advocated to maximize digestion and absorption and reduce colonic residues, considered a major source of encephalopathic toxins, this practice is currently not recommended. Increased amounts of fermentable fiber encourage nitrogen fixation by enteric bacteria, resulting in reduced quantities of nitrogenous substances available for absorption. Increased dietary fiber may bind noxious bile acids, endotoxins and other bacterial products. Dietary fiber is also useful in maintaining euglycemia (Chapter 29) and altering the pH of colonic contents. Total dietary fiber levels should be between 3 and 8% and be primarily soluble fiber. However, pet food labels and available product information list fiber content as crude fiber rather than total dietary fiber. Crude fiber analyses do not represent the soluble or fermentable fiber content of foods. Thus, for all practical purposes, this recommendation cannot be readily evaluated. Crude fiber levels in combination with knowledge of the soluble content of the fiber sources obtained from the foods' ingredient lists could provide imprecise guidelines. Commercial and homemade foods can be supplemented with psyllium husk fiber (1 tsp/5 to 10 kg body weight, added to each meal). If loose stools occur, reduce the supplemental fiber by half.

Branched-Chain Amino Acids

The abnormal plasma amino acid profile in patients with hepatic disease can be improved by feeding a protein with an amino acid composition high in BCAA and low in AAA, or by an intravenous amino acid infusion with a similar profile. However, a causal relationship between a deranged BCAA:AAA ratio in plasma and cerebrospinal fluid and HE has yet to be elucidated. Plasma ammonia levels decrease in dogs with HE after administration of BCAA-enriched intravenous infusions (Meyer, 1998a). The same effect could not be reproduced by feeding a BCAA-enriched food vs. an isonitrogenous control food in dogs with HE. This finding may have been due to reduced consumption of the test diet, leading to a severe catabolic state and increased endogenous ammonia production (Meyer, 1998a). The primary positive effect of dietary and intravenous BCAA enrichment may be the normalization of nitrogen balance, rather than a direct effect on neurotransmitter imbalances per se (Meyer, 1998a).

Vitamins

Vitamin deficiencies are common in patients with chronic hepatic disease. Deficient dietary intake and malabsorption are the principal causes of vitamin deficiency, although decreased storage, metabolic defects and increased requirements also may be involved (Marks et al, 1994).

Deficiency of water-soluble vitamins may occur due to inadequate intake, vomiting and urinary losses. Hepatic concentrations of folate, riboflavin, nicotinamide, pantothenic acid, pyridoxine and vitamin B_{12} are decreased in people with cirrhosis (Leevy et al, 1982). Commercial pet foods usually contain sufficient quantities of water-soluble vitamins to meet the needs of most patients with liver disease. Supplementation with water-soluble vitamins is indicated in patients: 1) receiving aggressive diuretic therapy for ascites, 2) with profound polydipsia and polyuria, 3) with prolonged anorexia and 4) eating homemade foods.

Abnormal blood coagulation tests and excessive bleeding reflect impaired hepatic synthesis, activation of clotting factors and/or a consumptive coagulopathy. Vitamin K stores in the liver are limited and can be rapidly depleted when dietary sources are inadequate or lipid (and therefore fat-soluble vitamin) malabsorption is severe. Among other functions, vitamin K catalyzes the activity of several clotting factors and normally is recycled in the healthy liver back to its active form (this step of vitamin K metabolism is sensitive to inhibition by dicumarol).

Vitamin K deficiency may develop in patients with hepatobiliary disease for several reasons. Oral antibiotic therapy may destroy the intestinal microflora that normally synthesize vitamin K. Chronic bile duct obstruction can interfere with enterohepatic circulation of bile acids causing intestinal bile acid deficiency and fat-soluble vitamin (including vitamin K) malabsorption. Inadequate intake of vitamin K may be a component of overall vitamin K deficiency, particularly if the patient has experienced prolonged anorexia (cats with hepatic lipidosis).

Coagulation abnormalities are common in dogs and cats with hepatobiliary disease. In dogs with naturally occurring liver disease, 50 and 75% had an abnormal prothrombin time (PT) and activated partial thromboplastin time (APTT), respectively. More than 90% of dogs had at least one abnormality (Center, 1996; Webster, 2005). At least one coagulation abnormality was present in 82% of cats with liver disease. Prolonged PT was noted in 73% of cats and factor VII activity was below reference range (<60%) in 68% of cats. When classified according to underlying pathogenesis, vitamin K deficiency was the most common abnormality found (11/22). Other abnormalities were less common and included hepatic

Table 68-10. General therapy for patients with hepatobiliary disease.*

Fluid therapy	
Maintain hydration	Give appropriate parenteral fluid therapy
Prevent hypokalemia	Add KCl to maintenance fluids
Maintain acid-base balance	Use potassium-replete food or potassium supplement
Prevent or control hypoglycemia	Avoid alkalosis in patients with hepatic encephalopathy Add dextrose to parenteral fluids as needed
Nutritional support	
Maintain caloric intake	Ensure that daily energy requirement is being met; if not, begin assisted feeding
Provide adequate vitamins and minerals	Add B vitamins to fluids or give as injection
Modify feeding plan to control complications	Use complete and balanced food See specific complications below
Control hepatic encephalopathy	
Modify food and prevent formation and absorption of enteric toxins	Avoid excess dietary protein Use retention enemas q6h containing lactulose or povidone iodine solution Give lactulose orally
Control GI hemorrhage	Treat GI parasites, treat gastric ulcers, avoid drugs that exacerbate GI hemorrhage (e.g., aspirin, glucocorticoids)
Correct metabolic imbalances	See fluid therapy above
Avoid drugs or therapies that exacerbate hepatic encephalopathy	Do not administer sedatives, analgesics, anesthetics, diuretics, stored blood or methionine-containing products
Control seizures	Use appropriate anticonvulsant drugs (e.g., potassium bromide)
Control infection	Give systemic antimicrobials (see below)
Control ascites and edema	Avoid excess dietary sodium chloride Administer diuretics (e.g., furosemide, spironolactone)
Control coagulation defects and anemia	Give vitamin K_1 parenterally Give fresh plasma or blood transfusion as needed
Control GI ulceration	Give H_2 blockers (e.g., ranitidine) or cytoprotective agents (e.g., sucralfate)
Control infection and endotoxemia	Give systemic antibiotics (e.g., penicillin, ampicillin, cephalosporins, aminoglycosides, metronidazole) Give intestinal antibiotics (e.g., neomycin)
Manage cholestasis	Give bile “altering” or choleretic drugs (e.g., ursodiol) Correct extrahepatic bile duct obstruction

synthetic failure (3/22), indeterminate (3/22) and disseminated intravascular coagulation (1/22). Increased AP activity was the only biochemical abnormality statistically correlated with coagulation abnormalities ($p = 0.23$). Cats with marked increases in AP activity were more likely to have coagulation abnormalities than those with only mild increases in AP activity (Lisciandro et al, 1998). Despite the common presence of coagulation test abnormalities, spontaneous hemorrhage in liver disease patients is rare. However, it should be assumed that liver disease patients have a higher than normal risk of bleeding.

At the very least, foods for patients with liver disease should contain the minimum recommended allowance of vitamin K (menadione) for foods for normal adult dogs and cats: 1.63 and 1.0 mg/kg DM, respectively (NRC, 2006). Supplementing foods with active vitamin K (vitamin K_1) is expensive and the vitamin would likely not survive the heat of processing. The water-soluble form of menadione, menadione sodium bisulfite, is much less expensive, is heat stable and is passively absorbed from the small intestine and colon. However, menadione is biologically inactive, as is vitamin K_1, and requires alkylation by gut microorganisms or animal tissues to biologically active menaquinone-4 (NRC, 2006).

FEEDING PLAN

The universal goals for dietary management of hepatobiliary disease are directed at clinical manifestations of the disease rather than the specific cause itself. The goals of nutritional management for hepatobiliary disease include: 1) maintaining normal metabolic processes and homeostasis, 2) avoiding and managing HE, 3) providing substrates to support hepatocellular repair and regeneration, 4) decreasing further oxidative damage to liver tissue and 5) correcting electrolyte disturbances (Blackburn and O’Keefe, 1989; Center, 1998).

The therapeutic goals for patients with HE also include: 1) recognizing and correcting precipitating causes of encephalopathy (e.g., hypokalemic alkalosis), 2) reducing intestinal production and absorption of neurotoxins, with special emphasis on ammonia and 3) finding the balance between providing too much and too little protein, both of which increase ammonia generation.

Dietary therapy is only beneficial when performed in conjunction with proper medical and surgical management of the specific hepatobiliary disease involved. Medical management often includes use of antiinflammatory agents, immunomodu-

***For liver disease patients with signs of hepatic encephalopathy (HE), dietary protein levels should be limited to 10 to 15% dry matter until signs resolve. In these cases, several commercial veterinary therapeutic foods designed for patients with kidney disease that provide less protein than the foods intended for liver disease may be appropriate (Chapter 37). If these foods are used, the patient should be transitioned to the selected food specifically formulated for liver disease after signs of HE have subsided.

lators, nonabsorbable disaccharides and bile "altering" agents (**Table 68-10**). In acute hepatic failure, correction of fluid and electrolyte imbalances and treatment of other complications such as metabolic acidosis, excessive bleeding, hypotension, hypoglycemia, cardiac dysfunction, renal failure, cerebral edema and infections take precedence over nutritional support. Surgical management can include partial or total ligation of congenital PSS, correction of bile duct obstruction or removal of focal liver masses.

Assess and Select the Food

A wide variety of foods are typically used or recommended for patients with hepatic disease (Marks et al, 1994a; Michel, 1995). **Tables 68-11** and **68-12** list the recommended levels of key nutritional factors for canine and feline hepatobiliary disease patients, respectively, and compare them to the key nutritional factor content of selected veterinary therapeutic foods. This information will help the veterinary health care team select the best food for patients with liver disease. Special consideration should be given to young patients with congenital PSS.

Although the total protein content of some veterinary therapeutic foods formulated for patients with liver disease is lower than that of regular commercial pet foods, protein quality and digestibility are usually high. Also, as discussed above, these foods still exceed minimum requirements. Thus, these foods provide adequate protein to support hepatic function and hepatocyte repair and regeneration while avoiding higher protein levels that exacerbate hyperammonemia. However, further short-term protein reduction may be necessary in patients with HE. In these cases, some commercial veterinary therapeutic foods designed for patients with renal disease that provide less protein than the foods intended for liver disease may be appropriate (Chapter 37). If these foods are used, the patient should be transitioned to the selected food specifically formulated for liver disease after signs of HE have subsided (**Tables 68-11** and **68-12**). Lactulose may be considered for patients with HE. **Box 68-4** provides information about lactulose products, their use and their mode of action.

Supplemental treatment should also be considered for dogs with hepatic copper toxicosis. Copper is considered a key nutritional factor for liver disease in dogs and the recommended DM level in foods is less than 5 mg/kg. This level may still provide too much copper for some patients with hepatic copper toxicosis. In these instances, adjunctive use of copper chelating agents should be considered. Copper chelating agents are discussed in **Box 68-3**. **Box 68-5** reviews other cytoprotective

**Energy density values are listed on an as fed basis and are useful for determining the amount to feed; cup = 8-oz. measuring cup. To convert to kJ, multiply kcal by 4.184.

***For liver disease patients with signs of hepatic encephalopathy (HE), dietary protein levels should be limited to 25 to 30% dry matter until signs resolve. In these cases, several commercial veterinary therapeutic foods designed for patients with kidney disease that provide less protein than the foods intended for liver disease may be appropriate (Chapter 37). If these foods are used, the patient should be transitioned to the selected food specifically formulated for liver disease after signs of HE have subsided.

agents that are sometimes considered for liver disease patients.

Anorectic cats with cholangitis or hepatic lipidosis will need to be fed via assisted-feeding techniques until they resume eating on their own. This dictates the use of nutrient-dense foods with textures intended for assisted feeding (Chapter 25). These patients should be fed a food intended for dietary management of other hepatic diseases after they start eating (**Table 68-12**).

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Assess and Determine the Feeding Method

Sick, anorectic and severely malnourished patients with hepatobiliary disease should be hospitalized to initiate supportive care and assisted-feeding techniques. Early tube feeding via nasogastric or gastrostomy tube remains the cornerstone of therapy for feline patients with hepatic lipidosis and all other anorectic patients with liver disease. Chapter 25 details foods and enteral feeding techniques commonly used in dogs and cats. Patients that are eating enough food to meet their daily energy requirement (DER) can usually be managed at home.

The DER for cats with hepatic lipidosis should be at least the resting energy requirement (RER) for ideal body weight when cats are managed in the hospital and 1.1 to 1.2 x RER when managed at home. The DER of canine liver disease patients managed at home should be approximately 1.2 to 1.4 x RER. Young patients with congenital shunts may be stunted or underweight. DER calculations for these patients should be based on ideal rather than current body weight. These calorie values can be converted to an amount of food to eat by dividing the energy density of the food (as fed basis) by the DER. The as fed energy density (in cups or cans) of foods for liver disease can be found in **Tables 68-11** and **68-12**.

Multiple daily feedings rather than one or two large meals may benefit patients with hepatobiliary disease. Multiple daily meals minimize the release of free fatty acids from adipose tissue, improve digestibility and reduce the quantity of ingesta at any one time that enters the colon where bacterial fermentation

Box 68-4. Adjunctive Lactulose for Patients with Hepatic Encephalopathy.

Administration of lactulose is considered one of the treatments of choice for hepatic encephalopathy (HE). Lactulose is a synthetic disaccharide that is hydrolyzed by colonic bacteria principally to lactic and acetic acids. Lactulose probably exerts its beneficial effects by: 1) increasing intraluminal nitrogen retention by increasing the colonic flora, 2) increasing intestinal transit rate due to its cathartic properties and 3) decreasing ammonia generation from glutamine in the intestinal wall by providing acetic acid as an alternative energy source. The dosage required to achieve these goals varies greatly, with a range of 2.5 to 25 ml, three times daily for dogs and 1.0 to 3.0 ml, three times daily for cats. The dosage should be titrated to produce a "porridge-like" stool and should be reduced if watery diarrhea develops.

Lactulose also is highly effective when added to water (30% lactulose and 70% water) and given as a retention enema. Approximately 20 to 30 ml/kg body weight are infused and retained in the colon for 20 to 30 minutes before evacuation. Lactulose requires intestinal bacteria for activation. Although neomycin and other nonabsorbable antibiotics are used in the treatment of HE in people, their use is limited to cases that do not respond to lactulose alone. Furthermore, patients should be monitored carefully. Moreover, evidence of their effectiveness in the treatment of dogs and cats with HE is lacking.

The Bibliography for **Box 68-4** can be found at www.markmorris.org.

occurs. Studies involving people with hepatic failure have shown that nitrogen balance can be improved if the food is divided into small, frequent meals, including a snack at bedtime (Swart et al, 1989). Nauseated patients may also better tolerate multiple small meals.

Appetite stimulants and force feeding moist food can be used to encourage caloric intake, but these strategies often fail to ensure enough food is consumed to meet the patient's nutrient requirements and typically frustrate the owner. Appetite stimulants such as anabolic steroids and benzodiazepine derivatives are not recommended and should be used cautiously in patients with hepatic disease, because of the potential for hepatotoxicity and, benzodiazepines may possibly be involved in the pathogenesis of HE (Wilson, 1990; Meyer, 1998).

Many patients may develop learned aversion to the foods they are offered if GI disturbances accompany liver disease. This is the classic scenario in cats with hepatic lipidosis. Cats that refuse to eat a food they associate with nausea may continue to avoid that food even after a complete recovery. Therefore, tube feeding should be started in cats immediately after a diagnosis of hepatic lipidosis is made. Such an approach is preferred to offering several commercial foods and possibly having the cat develop an aversion to them. The prognosis for hepatic lipidosis is influenced largely by the ability of the veterinarian and owner to aggressively meet the nutrient requirements of the cat via enteral feeding.

Managing cats with hepatic lipidosis that are starved or severely malnourished can be complicated by a refeeding syndrome, a condition that results in metabolic electrolyte disturbances that can lead to neurologic, pulmonary, cardiac, neuromuscular and hematologic complications. Cats with hepatic lipidosis often have hypophosphatemia and hypokalemia from low food intake, decreased intestinal absorption or increased renal loss. With the introduction of food and a sudden shift to carbohydrate metabolism, stimulation of insulin secretion promotes intracellular uptake of phosphorus, potassium, magnesium, water and glucose and further lowers serum electrolyte levels within 12 to 72 hours after feeding. Hypophosphatemia can result in muscle weakness, hemolytic anemia, leukocyte dysfunction, platelet dysfunction and decreased tissue oxygenation as a result of decreased levels of 2,3,-diphosphoglycerate. Electrolyte abnormalities should be corrected before feeding hepatic lipidosis patients. Approximately one-fourth of the patient's caloric needs should be provided by tube feeding on Day 1, then the amount should be gradually increased to provide the caloric need within the first week of feeding (Justin and Hohenhaus, 1995; Center et al, 1993).

REASSESSMENT

The owner and veterinarian should monitor the appetite, body weight and condition of the patient, while observing the frequency and severity of GI disturbances (i.e., vomiting, diarrhea), icterus and neurobehavioral signs. One of the most important clinical findings is improvement in the patient's attitude and activity level. This finding is highly correlated with nutritional success. Serial laboratory evaluations (every few days to weeks) of serum liver enzyme activity, bile acids and potassium and blood ammonia concentrations are useful. Serial hepatic biopsy specimens (i.e., every four to six months) can be evaluated for hepatic copper concentrations and assessed for inflammatory hepatopathies. Body weight, abdominal configuration and ultrasonography can be used to monitor patients with ascites.

Assisted-feeding tubes for cats with hepatic lipidosis and/or cholangitis can often be removed after several weeks to months. Enteral tubes are usually removed after the cat has shown clinical improvement and has begun eating two-thirds to three-fourths of its normal DER on its own. Many of these patients can be fed typical adult maintenance-type foods after hepatobiliary disease is resolved. These include patients that have recovered from an acute hepatic insult or hepatic lipidosis and patients that have undergone successful (partial or total) closure of PSS.

Chapter 69

Effects of Food on Pharmacokinetics

Martin J. Fettman

Robert W. Phillips

"Give me a lever long enough and a fulcrum on which to place it, and I shall move the world."
Archimedes

INTRODUCTION

When the effects of veterinary pharmaceuticals are evaluated and standardized doses are determined, researchers typically use relatively healthy, fasted animals that have been maintained on foods with acceptable nutrient balance. However, in clinical settings, animals receiving a drug often have variable food intake or specific nutrient imbalances, or they must be given a drug in conjunction with a meal, or some combination of these factors may occur. The patient's health status and the nutrient ingredient profile of the diet being consumed may greatly affect drug absorption, distribution, metabolism, elimination, efficacy and toxicity (**Table 69-1**). Concurrent food intake also may markedly affect drug availability and pharmacokinetics (**Tables 69-2** and **69-3**).

Veterinarians should be acquainted with the effects diet can have on drug disposition to anticipate adjustments in the food or drug dose, properly time administration of drugs and allow for changes in the margin for error between efficacy and toxicity of pharmaceutical agents.

GENERAL TYPES OF FOOD AND DRUG INTERACTIONS

Food-drug interactions that occur as a result of the physical form or chemical properties of food may lead to drug binding, precipitation, inactivation or ionization, which alter gastrointestinal (GI) absorption. These interactions may occur in vitro after mixing the drug with food to make administration more convenient, to enhance palatability or to reduce GI irritation. Another concern is adsorption of drugs to synthetic surfaces of the equipment used for nutrient and drug administration (e.g., food containers, feeding syringes and tubing for assisted feeding). Physiochemical interactions may occur in vivo, whereby drug absorption from the GI tract is decreased because of chelation by dietary fiber or minerals, or increased because of favorable changes in ionization or solvent partitioning.

Metabolic Interactions

Both nutrient and non-nutrient substances in foods can alter the metabolism of absorbed drugs. Nutrients are nourishing ingredients of food. Non-nutrient substances are chemicals without metabolic value, including naturally occurring phytochemicals and synthetic chemicals added inadvertently or purposely to food. Protein and energy malnutrition can alter the synthesis of plasma proteins, affecting drug distribution and pharmacokinetics. Individual dietary lipid, carbohydrate, protein, vitamin and mineral levels can effect changes in xenobiotic-metabolizing enzymes, resulting in altered clearance, circulating concentrations and resultant therapeutic efficacy and toxicity. Naturally occurring non-nutrient food ingredients and added synthetic preservatives may similarly

Table 69-2. Selected factors that can determine the effects of nutrients on drug absorption.

Factors	Examples
Physiochemical properties of drugs	Lipophilic or hydrophilic
Drug formulation	Tablet, capsule or liquid
Meal type	Volume, temperature, moisture
Drug dose	Amount and concentration
Route of administration	By mouth, gastric tube, etc.
Order of administration	Pre- vs. postprandial
Time interval between food and drug administration	Phase of digestion
Owner/patient compliance	Mixing drugs and food for ease of administration

alter pharmacokinetics and apparent drug effectiveness.

Indirect Physiologic Effects
The rate of drug elimination is also affected by changes in blood flow and drug delivery to the principal organs of metabolism for that particular agent. Thus, postprandial alterations in blood flow to the liver may affect drug clearance from the portal and systemic circulation, and altered blood flow to the kidneys may change the rate of urinary elimination. Likewise, changes in functional morphology or pathology due to specific nutrient deficiencies or excesses can affect drug clearance.

GENERAL EFFECTS OF FOOD AND DRUG INTERACTIONS

Ameliorating Potential Adverse Effects
The composition and volume of food consumed can modify the degree of GI irritation caused by concurrently administered oral drugs. Enteral and parenteral fluid intake can augment drug absorption and distribution and protect against renal damage induced by nephrotoxic agents. Supplementation with specific nutrients may prevent deficiencies secondary to adverse drug effects on nutrient absorption and metabolism.

Potentiating Drug Action
Specific nutrients can increase drug effects by facilitating GI absorption, improving drug distribution or decreasing drug metabolism and excretion. Furthermore, some nutrients may be necessary for optimal drug effects (e.g., arginine for nitric oxide production, cysteine for nitroglycerin action and carnitine for optimal activity of cardiac glycosides).

Impaired Drug Action
Impaired drug action is the adverse effect most often considered when evaluating nutrient-drug interactions that impair therapeutic efficacy. These adverse effects may result from decreased drug absorption, inadequate amounts of the drug reaching the site of action, or nutrient interference with the drug's action. Drug action may be impaired for variable periods of time after food composition and feeding behavior are altered, if target cell receptor numbers or affinity are suppressed or long-lived biotransforming enzyme systems have been induced.

Adverse Side Effects
Pathologic reactions to nutrient-induced changes in drug distribution and metabolism can be of greater immediate consequence than loss of disease control following impaired drug action. Drug metabolism and excretion routes may be altered, resulting in accumulation of toxic quantities of the agent itself or the products of its biotransformation. This phenomenon is similar in principle to adverse interactions between concurrently administered drugs, but may be more difficult to identify because mental recollection and written records of nutrient intake are not usually as complete as for administration of pharmaceutical agents.

EFFECTS OF NUTRIENTS ON DRUG ABSORPTION

General Observations
The absorption of orally administered drugs may be: 1) decreased, 2) delayed, 3) unaffected or 4) enhanced by the con-

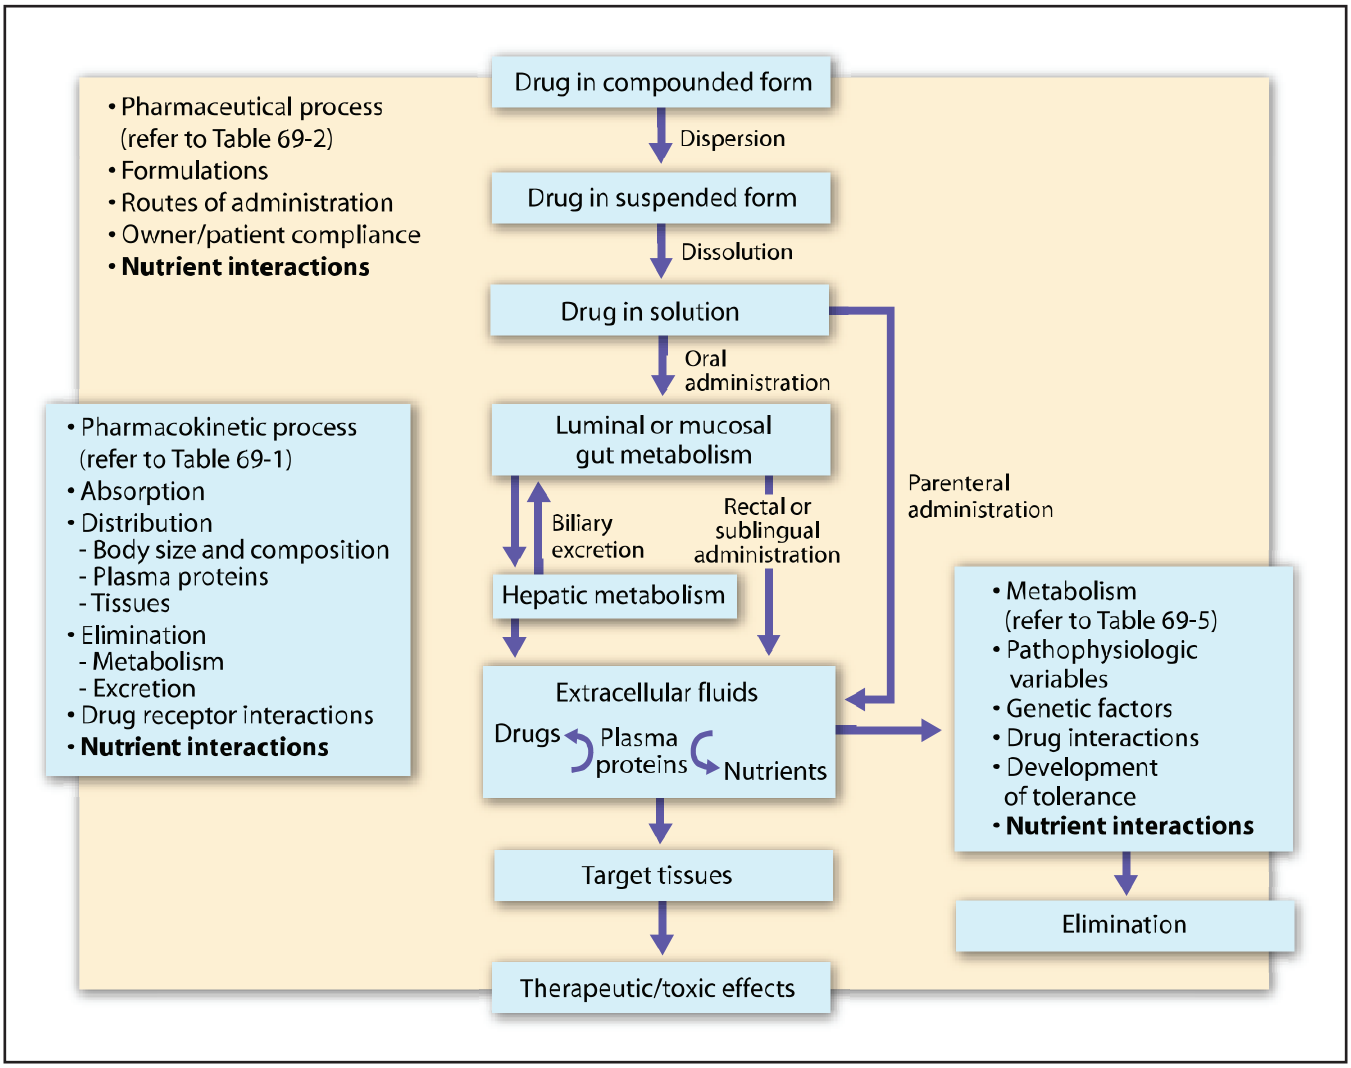

Figure 69-1. Determinants of drug absorption, distribution, metabolism and excretion that may be modified by nutrient interactions. (Adapted from Grahame-Smith DG, Aronson JK. In: The Oxford Textbook of Clinical Pharmacology and Drug Therapy. Oxford, UK: Oxford University Press, 1985.) Rectal absorption in dogs and cats is subject to first-pass hepatic metabolism due to the small relative size of the rectum and the lack of a hemorrhoidal plexus in these species. Transdermal could be substituted for rectal delivery (e.g., fentanyl patches in dogs and cats). A good example of a drug absorbed across oral mucous membranes is buprenorphine in cats.

comitant consumption of food (**Figure 69-1** and **Tables 69-2** and **69-3**). This interaction depends on the physical and chemical nature of the food and the drug, including such things as meal size and type, the formulation in which the drug is administered, the order in which the food and drug are ingested and the interval between their consumption (Roe, 1989).

Any food can reduce drug absorption by creating a barrier that prevents dispersion of the drug and dissolution of the active agent in GI luminal contents. Drugs are better absorbed in dilute vs. concentrated solution because of greater dissolution and more rapid gastric emptying. In people, absorption of erythromycin stearate is reduced by approximately one-half when taken with food or a small fluid volume, as compared with a large fluid volume (Toothaker and Welling, 1980). Absorption of acetylsalicylic acid (aspirin), cephalexin, metronidazole, digoxin, hydralazine and cimetidine are similarly affected (Toothaker and Welling, 1980).

Alternatively, food does not affect absorption of other drugs in people, including erythromycin estolate, oxazepam, propylthiouracil and enteric-coated aspirin granules in caplet form (Toothaker and Welling, 1980). In fact, food enhances the absorption of certain drugs (e.g., erythromycin ethylsuccinate, nitrofurantoin, hydrochlorothiazide and diazepam) (Toothaker and Welling, 1980). The rate and quantity of drug and nutrient delivery are important, as evidenced by studies of hydralazine absorption. A bolus of nutrients impairs hydralazine uptake whereas a constant infusion over several hours does not (Semple et al, 1991). Total hydralazine absorption, however, is similar in both cases, although absorption is delayed by a bolus meal.

Gastric emptying of drugs is delayed when they are administered with a meal. Gastric emptying of drugs is about 15 minutes for fasted dogs, but may take up to three hours if given to

Table 69-3. Recommendations for administering medications with or without food.*

Drugs that can be administered with food		
Allopurinol	Hydrocortisone	Mitotane
Amantadine	Isotretinoin	Nitrofurantoin
Aspirin	Itraconazole (capsules)	Olsalazine
Azathioprine	Ketoconazole	Pancrelipase
Betamethasone	Ketoprofen	Paromomycin
Carprofen	Ketorolac	Pentoxifylline
Cefadroxil	Lithium	Phenylbutazone
Cimetidine	Lufenuron	Piroxicam
Clofazimine	Meclofenamate	Praziquantel
Clomipramine	Meloxicam	Prednisolone
Deracoxib	Metformin	Prednisone
Dexamethasone	Methocarbamol (not high fat)	Quinacrine
Diethylcarbamazine	Methylprednisolone	Sulfasalazine
Etodolac	Metoprolol	Tepoxalin
Flunixin	Mexiletine	Triamcinolone
Glyburide	Misoprostol	Ursodiol
Griseofulvin		
Drugs that should not be administered with food (one hour before or three hours after)		
Acetaminophen	Digitoxin	Omeprazole
Ampicillin	Digoxin	Oxacillin
Bethanechol	Dipyridamole	Oxytetracycline
Captopril	Etidronate	Penicillamine
Carbenicillin	Itraconazole (suspension)	Penicillin V
Chlortetracycline	Levodopa	Procainamide
Cloxacillin	Levothyroxine	Quinidine
Codeine	Lincomycin	Rifampin
Cyclophosphamide	Minocycline	Tetracycline
Difloxacin		
No effect = no *clinical* effect, can give to either fed or fasted animals (some of these drugs may have increased absorption in the fasted state but the clinical outcome is unaffected)		
Acepromazine	Diphenoxylate	Methotrexate
Aminophylline	Disopyramide	Metronidazole
Amitriptyline	Dolasetron	Mibolerone
Amlodipine	Doxepin	Milbemycin
Amoxicillin	Doxycycline	Moxidectin
Amoxicillin/clavulanate	Enalapril	Naltrexone
Amprolium	Enrofloxacin	Nandrolone
Atenolol	Ephedrine	Neomycin
Azithromycin	Epsiprantel	Nifedipine
Benazepril	Ergocalciferol	Ondansetron
Bismuth subsalicylate	Erythromycin	Orbifloxacin
Bromide	Famotidine	Ormetoprim/ sulfadimethoxine
Bunamidine	Felbamate	
Buspirone	Fenbendazole	Pamidronate
Busulfan	Finasteride	Paroxetine

dogs fed a full meal. Because the majority of drug absorption occurs in the small intestine, drug administration with food typically results in delayed drug absorption and may or may not affect the extent of absorption. Feeding also stimulates acid secretion in dogs, which markedly increases the absorption of drugs with low pKa (e.g., weak acids, ketoconazole). The rate and extent of absorption of cephalexin are decreased in dogs when this antibiotic is administered with food, but this decrease is clinically irrelevant (a similar example is amoxicillin). In contrast, the extent of absorption of cefadroxil is increased in fed dogs, but its rate of absorption is decreased. Because cefadroxil is a time-dependent antimicrobial, its efficacy is expected to increase when it is administered with food, but this increase may or may not be clinically relevant (Campbell and Rosin, 1998). Feeding also tends to increase GI tract blood flow, increasing both food and drug absorption.

Studies of penicillin absorption in dogs after oral administration have yielded conflicting results. In a study of greyhounds receiving 20 mg/kg body weight ampicillin or amoxicillin per os with no food, moist food or dry food, ampicillin absorption was impeded 60 to 80% by feeding, whereas amoxicillin absorption was unaffected (Watson and Egerton, 1977). In a more recent study involving a variety of breeds, absorption was impaired about 30% when ampicillin (20 mg/kg body weight) was administered immediately or two hours after feeding a dry food as compared with ampicillin administered to fasting dogs or one hour before feeding (Kung et al, 1995). Absorption of ampicillin (20 mg/kg body weight) administered immediately after feeding a moist food was similarly impaired, whereas administration two hours after feeding a moist food had a lesser effect on absorption.

In a comparative study of different penicillin preparations given to dogs, peak plasma concentrations of ampicillin, amoxicillin, penicillin V, phenethicillin and cloxacillin were decreased 40 to 50% by feeding immediately before drug administration; however, time to maximal concentrations was increased 0.5 to 1.5 hours only for ampicillin and amoxicillin (Watson et al, 1986). From these studies, it is recommended that ampicillin be given to fasted dogs and at least one hour before feeding to ensure adequate drug absorption.

Physical Incompatibilities

Specific nutrients (e.g., dietary fiber) can impede drug absorption across the GI mucosa by adsorbing the agent or increasing the unstirred water layer on the mucosal surface (Reppas et al, 1991). Some of these interactions are predictable, based on the behavior of fiber in binding substances such as bile acids or decreasing the absorptive rate of solutes such as monosaccharides. Psyllium mucilloid decreases the absorption of riboflavin, β-carotene, iron, zinc and other trace elements (Roe, 1989).

Both nutritive and non-nutritive cytoprotective agents adsorb drugs and inhibit their absorption. For example, sucralfate binds tetracycline, phenytoin, cimetidine, digoxin and levothyroxine (Havrankova and Lahaie, 1992; McCarthy, 1991). Antacids (e.g., aluminum hydroxide) can precipitate tetracyclines, iron salts, warfarin, digoxin, quinidine, phenothiazines, indomethacin, isoniazid, sulfadiazine, prednisone and levothyroxine (Roe, 1989; Liel et al, 1994). Mineral sup-

Butorphanol	Firocoxib	Phenobarbital
Calcitriol	Florfenicol	Phenoxybenzamine
Carbimazole	Flucytosine	Phenylpropanolamine
Cefaclor	Fludrocortisone	Phytonadione (vitamin K)
Cefdinir	Fluoxetine	Piperazine
Cefixime	Fluconazole	Ponazuril
Cefpodoxime	Furosemide	Potassium
Cephalexin	Gabapentin	Prazosin
Chlorambucil	Granisetron	Primidone
Chloramphenicol	Hydralazine	Promethazine
Chlorothiazide	Hydrochlorothiazide	Propranolol
Chlorpheniramine	Hydrocodone	Pyrantel
Chlorpromazine	Hydroxyurea	Pyridostigmine
Ciprofloxacin	Hydroxyzine	Pyrimethamine
Clenbuterol	Imipramine	Selegiline
Clindamycin	Ipodate	Sotalol
Clonazepam	Isosorbide	Spironolactone
Clorazepate	Ivermectin	Stanozolol
Colchicine	Levamisole	Sulfadiazine
Cyproheptadine	Linezolid	Sulfadimethoxine
Danazol	Lisinopril	Sulfamethazine
Dantrolene	Loperamide	Sulfamethoxazole
Dapsone	Marbofloxacin	Taurine
Dextromethorphan	Mebendazole	Terbutaline
Diazepam	Meclizine	Theophylline
Dichlorvos	Megestrol	Tocainide
Dichlorphenamide	Melphalan	Toltrazuril
Diclazuril	Mercaptopurine	Trimeprazine
Diethylstilbestrol	Mesalamine	Trimethoprim
Dihydrotachysterol	Metaproterenol	Tripelennamine
Diltiazem	Methazolamide	Tylosin
Dimenhydrinate	Methenamine	Valproic acid
Diphenhydramine	Methimazole	Vancomycin
		Warfarin

Prior to = administer 30 to 60 minutes before feeding

Cisapride	Liothyronine	Ranitidine
Domperidone	Metoclopramide	Sucralfate
Gemfibrozil	Propantheline	Trimethobenzamide
Glipizide		

Consistent = can be given to fed or fasted animals, but give in a consistent manner

Cyclosporine

Unknown = data were not available for recommendation

Acetylcysteine

*For no effects, although some of these drugs may have increased absorption in the fasted state, the clinical outcome may be unaffected.

plements, including iron salts such as ferrous sulfate, can decrease the absorption of methyldopa, penicillamine, tetracycline, levothyroxine and quinolone antibiotics (Roe, 1989; Campbell et al, 1992). When orbifloxacin was mixed with a vitamin-mineral supplement in vitro, within four days orbifloxacin concentration was decreased by about 50% of what was expected (KuKanich and Papich, 2003). Calcium salts and calcium-containing foods (e.g., milk, 1 to 2 mg calcium/ml) can precipitate insoluble tetracycline chelates (Williams et al, 1993). Foods of plant origin may contain phytic acid, which inhibits zinc and calcium absorption, and tannins, which inhibit iron uptake. Gelatinization of liquid drug formulations following mixing with enteral formulas has been observed for certain expectorants, elixirs, syrups, concentrates and suspensions.

The potential binding of pharmaceutical agents to equipment used for administration should also be considered. Adsorption of vitamin A and drugs such as phenytoin and insulin to plastic polymers used in nasogastric, gastrostomy and enterostomy tubing has been reported (Fleisher et al, 1990; Spence and Camishion, 1995). Furthermore, precipitation or gelatinization of drugs by nutrients can block feeding tubes. Diazepam binding to intravenous fluid lines is a good example of drugs binding to equipment (Parker and MacCara, 1980). Approximately 45% of diazepam will adsorb to fluid bags within two hours and about 48% of diazepam will bind to intravenous fluid lines during a constant rate infusion.

Physical Factors Affecting GI Absorption of Drugs

The cephalic phase of digestion is normally initiated by the perception, visualization, smell and taste of food. This phenomenon contributes to normal GI motility, secretion, digestion and absorption of food and pharmaceutical agents. For example, when acetaminophen is administered by nasogastric tube postoperatively, its absorption is significantly reduced compared with its absorption following oral administration (Elfant et al, 1992). Decreased GI motility due to stress, pain, luminal obstruction and postsurgical ileus may also contribute to reduced absorption.

Commercial moist and dry foods similarly affect gastric emptying; however, solid food may decrease the emptying of liquids and liquids may decrease the rate and pattern of solid emptying (Burrows et al, 1985; Horowitz et al, 1989). Specific dietary components that affect the rate of GI transit can also alter oral drug assimilation. In dogs, meals containing cellulose or wheat bran increase the frequency of postprandial contractions; yet, only cellulose decreases duodenojejunal flow and prolongs transit time (Bueno et al, 1981). However, bran increases mixing and onward propulsion of ingesta. Addition of guar gum induces continuous low-amplitude contractions in dogs and increases jejunal flow, but still increases transit time because of water adsorption and luminal distention. Soluble fibers (e.g., methylcellulose) increase luminal viscosity, resulting in delayed gastric emptying and increased thickness of the unstirred water layer (Reppas et al, 1991). Thus, both delivery of drug to the intestine and contact with the mucosal surface are impeded.

Addition of fat to a meal changes intragastric distribution of solid material, induces segmental changes in antral and pyloric

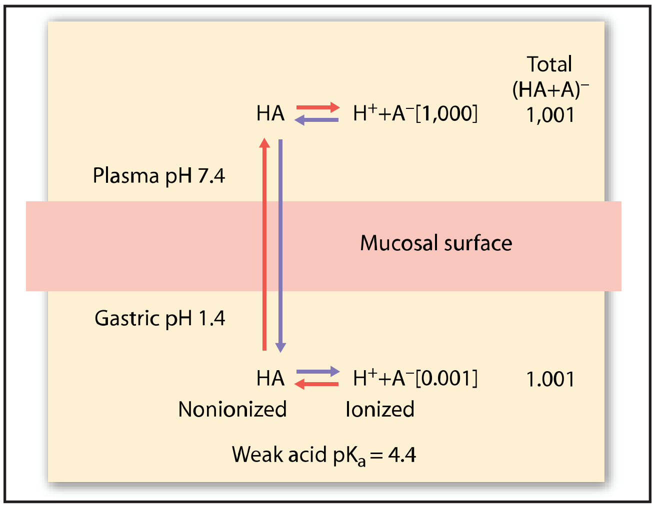

Figure 69-2. Influence of pH on the distribution of a weak acid between gastric contents and blood plasma across the gastric mucosa. The nonionized form of the drug predominates at low pH following gastric acid release. Only the nonionized form has sufficient lipid solubility to diffuse across the gastric mucosa. The ratio of ionized to nonionized drug may be calculated from the Henderson-Hasselbalch equation, and is determined by the pH on either side of the mucosa relative to the pKa of the drug. Dietary factors that increase or decrease gastric acid secretion will promote or inhibit acidic drug absorption. (Adapted from Benet LZ, Kroetz DL, Sheiner LB. The dynamics of drug absorption, distribution, and elimination. In: Hardman JA, Limbird LE, eds. Goodman and Gilman's The Pharmacological Basis of Therapeutics, 9th ed. New York, NY: McGraw-Hill, 1996.)

Table 69-4. Dietary factors that may affect drug metabolism and excretion, principally through induction of phase I biotransformation.

Macronutrients	**Micronutrients**	**Non-nutrients**
Protein	Vitamins	Antioxidants (BHA, BHT)
Carbohydrate	Minerals	Coumarins
Fat	Essential fatty acids	Flavonoids
Fiber		Indoles
		Methylxanthines
		Organonitriles
		Phenols
		Pyrolysis by-products
		Terpenoids

Examples of drugs whose metabolism and excretion is altered by these dietary factors

Acetaminophen	Morphine
Allopurinol	Oxazepam
Aminophylline	Penicillin
Cefoxitin	Pentobarbital

Chloroquine	Phenytoin
Diazepam	Prednisolone
Estradiol	Propranolol
Hexobarbital	Theophylline
Isoniazid	Zoxazolamine
Meperidine	

motility and retards gastric emptying (Heddle et al, 1989). Intraduodenal instillation of dilute glucose solutions at a rate in excess of approximately 2 kcal (8.4 kJ)/min., regardless of tonicity, stimulates both phasic and tonic pyloric contractions, thereby inhibiting gastric emptying and delaying oral drug absorption. Propranolol and metoprolol are affected in this manner (Chow and Lalka, 1993; Heddle et al, 1988). Enterohepatic cycling of drugs (e.g., doxycycline) may be affected by rate of passage and by portal blood flow and hepatic metabolism.

Chemical Factors Affecting GI Absorption of Drugs

Beyond the effects of drug binding or precipitation, specific nutrients may compete for absorption by the intestinal mucosa. For instance, phenytoin absorption is impaired by concurrent administration of the B vitamins folic acid and pyridoxine (Roe, 1989). Concurrent food intake and particular food ingredients can alter gastric or intestinal pH, thereby altering drug dissolution, ionization and absorption. In addition to the effect of milk calcium content on tetracycline absorption, milk can increase gastric pH, inducing premature dissolution of enteric-coated tablets, resulting in gastric irritation, altered absorption or both.

Gastric acid secretion associated with food ingestion can assist in the dissolution and ionization of alkaline drugs. Gastric acid secretion, however, limits the rate of absorption of alkaline drugs, while promoting the absorption of dissolved, unionized acidic drugs (**Figure 69-2**). The subsequent release of bicarbonate-rich pancreatic secretions promotes ionization of acidic drugs, but facilitates absorption of dissolved, unionized alkaline drugs. Release of hydrochloric acid in the stomach typically leads to alkalinization of the blood and the postprandial "alkaline tide," establishing an ionization gradient that can affect diffusion of ionizable compounds across the GI mucosa.

By affecting the food's acidification potential, dietary cation-anion balance can alter mineral absorption and drug availability through changes in ionization. Concurrent consumption of fats can affect drug absorption, depending on the polarity and lipid solubility of the individual agent. For example, it has been well documented that lipid-soluble vitamins and the antifungal agent griseofulvin are better absorbed when taken with whole milk or a meal with fat. High-fat foods may promote the absorption of nitrofurantoin, chlorothiazide and riboflavin by delaying gastric emptying, which facilitates dissolution in the stomach before passage into the small intestine for uptake (Roe, 1989).

TRANSPORT FROM THE GI TRACT TO THE SITE OF ACTION OR METABOLISM

Dietary factors that affect blood flow will alter the rate of delivery of absorbed drugs to their site of action or metabolism. Dehydration not only may reduce GI blood flow and absorption, but may also reduce the absorbed drug's subsequent delivery to or removal from particular tissues. Hypovolemia and reduced tissue perfusion may result in target tissue concentrations below the effective concentration. Decreased blood flow may reduce hepatic extraction for metabolism and excretion. Decreased urine formation may increase drug accumulation and toxicity in various organs; aminoglycoside accumulation in

the renal proximal tubules is an example. Other dietary ingredients may affect cardiac output (methylxanthines), renal blood flow (protein) or intestinal reperfusion following ischemia (antioxidants), thereby altering drug distribution.

Like many metabolites and hormones, drugs may be transported in the blood in free form or bound to plasma proteins. Thus, changes in nutritional status that affect plasma protein synthesis will likely affect drug binding and distribution. For example, hypoalbuminemia due to low dietary protein quantity or quality can affect the distribution of antibiotics, barbiturates, cardiac glycosides and analgesics. Drugs and nutrients may influence one another's disposition because binding to plasma proteins is competitive. Recent protein-binding interaction studies indicate that drug-drug competition for protein binding sites occurs rarely; the only drug expected to result in an adverse effect is lidocaine administered as an IV infusion (Benet and Hoener, 2002). However, hypoproteinemia may have marked effects that can result in toxicity due to increased free drug (e.g., lidocaine) or decreased efficacy (e.g., cefpodoxime) due to increased elimination by glomerular filtration (i.e., protein-bound drugs are excluded from glomerular filtration). High postprandial free fatty acid levels can displace anionic compounds from cationic binding sites on plasma proteins. Drugs and nutrients that are competitively transported into erythrocytes may be similarly affected. This effect has been documented for the interaction between folic acid and the loop diuretics furosemide and ethacrynic acid (Roe, 1989). Dietary factors that influence acid-base metabolism can alter blood pH and intraerythrocytic pH, thereby affecting drug ionization, protein binding and cell uptake.

DIETARY EFFECTS ON DRUG METABOLISM

The clearance of many drugs from the circulation depends on their biotransformation in the liver, kidneys and other organs with xenobiotic-metabolizing enzymes (**Table 69-4**) (Williams et al, 1993; Anderson and Kappas, 1991). For drugs that are metabolized rapidly, extraction is determined principally by organ blood flow. For example, the rate-limiting step for clearance of indocyanine green and sulfobromophthalein sodium is hepatic blood flow. Lidocaine and fentanyl are examples of currently used drugs, whereas sulfobromophthalein and indocyanine green are typically used for physiologic measurements. For drugs that are metabolized relatively slowly, clearance from the circulation is determined primarily by the quantity and affinity of enzymes responsible for their metabolism.

Hepatic drug metabolism occurs through two predominant biotransformation pathways: 1) phase I (oxidation, reduction and hydrolysis) and 2) phase II (glutathione or glucuronide conjugation, acetylation and sulfation). Phase I reactions are catalyzed principally by a family of cytochrome P-450 enzymes in the microsomal mixed-function oxidase system. Phase I reactions alter the functional groups of a compound (**Figure 69-3**). Phase I reactions increase water solubility. However, phase I reactions do not always alter functional groups (e.g., diazepam→nordiazepam, oxazepam). Furthermore, metabolism increases the conversion of prodrugs to active drugs (e.g., cyclophosphamide→4-hydroxyphosphamide→acrolein, phosphoramide mustard).

Phase II reactions are catalyzed by families of glutathione-S-transferase, glucuronyl transferase and N-acetyltransferase isoenzymes. Phase II reactions result in conjugation and altered water solubility (**Figure 69-4**). The outcome of phase I and II reactions is reduced activity and enhanced drug excretion. Phase I reactions may increase the activity or toxicity of drugs; phase II reactions may alter tissue distribution and subsequent target organs for toxicity or mutagenicity of the drug's metabolites (Guengerich, 1984; Parke and Ioannides, 1981).

Macronutrient Effects on Drug Metabolism

Inappetence due to disease is a common cause of decreased macronutrient intake that can affect drug action. Furthermore,

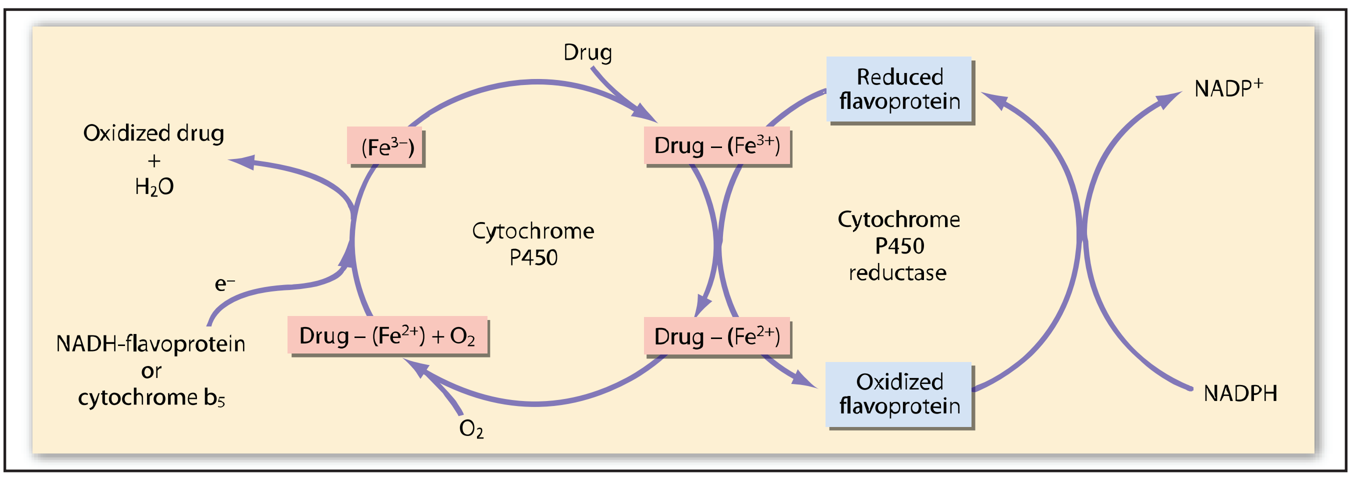

Figure 69-3. The hepatic phase I microsomal mixed-function oxidase system for drug metabolism. (Adapted from Benet LZ, Sheiner LB. Pharmacokinetics: The dynamics of drug absorption, distribution, and elimination. In: The Pharmacological Basis of Therapeutics, 7th ed. New York, NY: McGraw-Hill, 1985.) Key: Fe = iron, $NADP^+$ = the oxidized form of nicotinamide-adenine dinucleotide phosphate, NADPH = the reduced form of NADP.

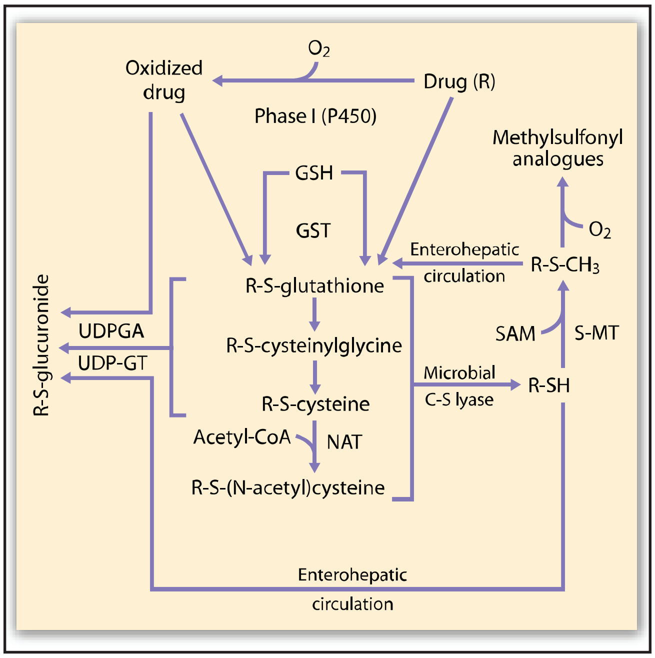

Figure 69-4. The hepatic phase II biotransformation system for drug metabolism. (Adapted from Fettman MJ, Butler RN, McMichael AJ, et al. Metabolic phenotypes and colorectal neoplasia. Journal of Gastroenterology and Hepatology 1991; 6: 81-90.) Key: P-450 = cytochrome P-450, GSH = reduced glutathione, GST = glutathione-S-transferase, acetyl-CoA = acetyl-coenzyme A, NAT = N-acetyltransferase, UDPGA = uridine diphosphoglucuronic acid, UDP-GT = UDP-glucuronyl transferase, SAM = adenosylmethionine, S-MT = S-methyltransferase.

changes in the macronutrient composition of the diet can significantly alter hepatic drug metabolism.

Dietary Protein Intake

In experimental studies in rats, low dietary protein intake reduced the metabolism and increased the toxicity of pentobarbital, strychnine and zoxazolamine (Guengerich, 1984). The activities of the mixed-function oxidase enzymes flavoprotein reductase and cytochrome b5 are decreased by dietary protein restriction. Inducibility of cytochrome P-450 by phenobarbital in rats is also decreased by feeding less dietary protein (Guengerich, 1995).

High-protein (e.g., 44 vs. 10% of kcal, as fed), low-carbohydrate foods (e.g., 35 vs. 70% of kcal, as fed) enhance the hepatic metabolism and excretion of many different drugs in people, including acetaminophen, oxazepam, theophylline, propranolol and estradiol (Guengerich, 1995; Fagan et al, 1987; Pantuck et al, 1991). Conversely, consumption of protein-restricted foods for as few as 10 days significantly decreases elimination of these drugs.

Certain essential amino acids may stimulate hepatic protein synthesis and thereby induce the hepatic mixed-function oxidase system. Sulfur-containing amino acids can promote hepatic drug metabolism by increasing glutathione synthesis and subsequent conjugation reactions (Fettman, 1991). Starvation can reduce the activity of glutathione-S-transferase and the synthesis of glutathione for conjugation; events that also participate in the development of fasting hyperbilirubinemia.

Dietary protein-related changes in renal blood flow and renal tubular transport can simultaneously affect the clearance of drugs eliminated in urine (Park et al, 1989). Increased dietary protein intake in dogs (from 9.4 to 27.3% on a dry matter basis) increases the elimination of gentamicin and reduces the potential for nephrotoxicity, presumably by stimulating renal blood flow (Behrend et al, 1994; Grauer et al, 1994). In people, low-protein diets (19 vs. 268 g/day) decrease the hepatic metabolism of allopurinol to oxypurinol, and decrease renal excretion of oxypurinol (Berlinger et al, 1985). The pharmacokinetics of allopurinol and oxypurinol in dogs do not appear to be affected by dietary protein (Bartges et al, 1997).

One canine study determined the effects of various foods on the pharmacokinetics of phenobarbital and the interactive effects of changes in body composition and metabolic rate (Maguire et al, 2000). Phenobarbital pharmacokinetic studies were performed in 27 healthy, adult, sexually intact female beagles before and two months after they were fed one of three commercially available foods: 1) a maintenance food, 2) a low-protein veterinary therapeutic food for renal failure patients or 3) a low-fat veterinary therapeutic food for weight loss. Phenobarbital, 3 mg/kg body weight orally, twice daily was administered to all three groups. Volume of distribution, mean residence time and half-life ($t_{1/2}$) decreased significantly, whereas clearance rate and elimination rate increased significantly with time in all groups. Dietary protein or fat restriction induced significantly greater changes: $t_{1/2}$ (hours) was lower in dogs fed the renal food (25.9 ± 6.1) and the weight-loss food (24.0 ± 4.7) compared to results from dogs fed the maintenance food (32.9 ± 5.2). Phenobarbital clearance rate (ml/kg/min.) was significantly higher in dogs fed the weight-loss food (0.22 ± 0.05) compared to clearance rates in dogs fed the maintenance food (0.17 ± 0.03) or the renal food (0.18 ± 0.03). Induction of serum alkaline phosphatase activity (IU/l) was greater in dogs fed the renal food (192.4 ± 47.5) and the weight-loss food (202.0 ± 98.2) than in dogs fed the maintenance food (125.0 ± 47.5). The authors concluded that phenobarbital dosage should be reevaluated if a dog's diet, body weight or body composition changes during treatment. Veterinarians in clinical practice, researchers evaluating drug pharmacokinetics (phenobarbital and other drugs) and pet food companies that market veterinary therapeutic foods with nutrient profiles that differ from typical commercial maintenance foods should be aware that a dietary change may markedly affect the pharmacokinetics of concurrent drug therapy.

Dietary Carbohydrate Intake

High carbohydrate intake (70 vs. 35% on a dry matter basis) in people depresses oxidative drug metabolism (Fagan et al, 1987). High dietary fructose, glucose and sucrose levels increase barbiturate sleeping time and decrease in vitro metabolism of barbiturates in mice (Guengerich, 1995). Parenteral glucose has the same effect in dogs and cats; thus, high dietary intake of these carbohydrates may likely modify barbiturate responses in these

species as well. Supplemental carbohydrate administration in rats increases liver weight, hepatic fat and glycogen deposition, but decreases hepatic mixed-function oxidase activities. Carbohydrate feeding in rats can similarly decrease the microsomal activation of carcinogens such as benzo(a)pyrene and aflatoxin B_1.

In people, long-term consumption of 70 vs. 35% carbohydrate diets depresses antipyrine and theophylline clearance (Pantuck et al, 1991). The proposed mechanism involves inhibition of the synthesis of d-aminolevulinic acid synthetase, a key enzyme in the synthesis of heme for cytochrome P-450 (Pantuck et al, 1991). However, carbohydrate is also required for UDP-glucuronyl transferase activity for glucuronidation of oxidized drug metabolites; short-term deprivation of carbohydrates can decrease rates of conjugation. This, too, contributes to the hyperbilirubinemia of fasting.

Dietary Fat Intake

In addition to the effects of dietary fat intake on drug absorption and plasma protein binding, lipid intake can affect hepatic xenobiotic-metabolizing enzyme activities (Guengerich, 1995). Foods deficient in essential fatty acids result in decreased rates of drug metabolism. Dietary lipids have been reported to be essential for optimal induction of P-450 enzymes by phenobarbital. Rats fed a 20% corn-oil diet for four days had twofold increases in the activities of several hepatic P-450 isoenzymes (P-450 2, 2A1, 2B1, 2C11, 2E1 and 3A) as compared with enzyme activities in rats fed a fat-free diet (Yoo et al, 1992). However, there is an inverse relationship between lung P-450 2B1 activity and dietary fat intake. In one study in which rats were fed 6% dietary lipid for 40 days as coconut, peanut, corn or fish oil, cytochrome P-450 and epoxide hydrolase activities were highest in the fish-oil group (Mounie et al, 1986). In this same study, UDP-glucuronyl transferase type I activity was increased by fish-oil or corn-oil supplementation, but reduced by coconut oil.

In another study, rats fed 10% dietary lipid for two weeks as soybean oil, lard or fish oil were exposed to pentachlorobenzene (PECB). Blood concentrations of the metabolite pentachlorophenol were highest and tissue concentrations of PECB were lowest after feeding fish oil (Umegaki et al, 1995).

Fish oils are relatively high in polyunsaturated fatty acids, particularly of the omega-3 (n-3) family (eicosapentaenoic and docosahexaenoic acids), but contain relatively less omega-6 (n-6) fatty acids than other sources. Effects of fish-oil supplementation may be due to: 1) altered cell and organelle membrane fluidity, 2) increased propensity towards oxidative damage and/or 3) specific induction of enzyme synthesis. In people, the degree of dietary fatty acid saturation has had little effect on oxidation of antipyrine or theophylline; however, the principal cytochrome P-450 isoenzyme, 3A4, is sensitive to microsomal membrane characteristics (Guengerich, 1995). A dietary deficiency of labile methyl donors (e.g., choline or methionine) increases spontaneous and chemically induced hepatocarcinogenesis in rats because of decreased microsomal enzyme activity (Rogers, 1995). Lipotrope deficiency also impairs methylation of DNA and RNA; however, a considerable portion of microsomal lipid can be removed in vitro without adversely affecting P-450 activity.

Dietary fat restriction alters phenobarbital pharmacokinetics in dogs, as discussed in more detail in the Dietary Protein Intake section (above). Restriction of dietary fat resulted in a significantly shorter phenobarbital half-life, a significantly higher phenobarbital clearance rate and an increased induction of alkaline phosphatase activity vs. the fat levels in the control, maintenance type food (Maguire et al, 2000).

Effects of Feeding Route

The route of nutrient administration may also affect hepatic drug metabolism. Decreased hepatic clearance of indocyanine green in pigs fasted for 12 days returns to normal after enteral feeding for 12 days (Waters et al, 1994). However, intravenous feeding with an identical formula did not improve hepatic clearance despite similar weight gains. Hepatic hydroxylation of pentobarbital and demethylation of meperidine by rats are significantly impaired following seven days of parenteral feeding with a formula that otherwise maintains hepatic drug clearance when administered enterally (Knodell et al, 1984). Lipid-free total parenteral nutrition depresses hepatic phase I and II drug metabolism. Parenteral lipid-free nutrition for 10 days in rats decreased the hepatic activities of cytochrome P-450 oxidase, p-nitroanisole demethylase and p-nitrophenol glutathione-S-transferase by one-half (Raftogianis et al, 1995). Thus, the intake of macronutrients, composition of the food and route of nutritional support interact to modify drug metabolism.

Micronutrient Effects on Drug Metabolism

Dietary Vitamin Intake

The hepatic mixed-function oxidase system requires several vitamins (Anderson and Kappas, 1991; Yang et al, 1992). Niacin and riboflavin participate directly as the principal components of the electron carriers $NADP^+$, NAD^+, FAD and FMN, which are coenzymes for cytochrome P-450 reductase, DT-diaphorase and NADH-cytochrome b_5 reductase (Anderson and Kappas, 1991). Dietary deficiency can lead to a generalized decrease in total P-450 and associated monooxygenase activities (Guengerich, 1984; Catz et al, 1970).

Folate deficiency blocks the induction of cytochrome P-450 by phenobarbital, and pyridoxine (vitamin B_6) deficiency may alter cysteine conjugate β-lyase activity (Guengerich, 1984). Excessive dietary folate can antagonize methotrexate activity, whereas increased pyridoxine intake can increase the metabolism of levodopa, thereby reducing its effectiveness. Thiamin deficiency increases the levels of cytochrome P-450 2E1, NADH-P-450 reductase and cytochrome b5, but decreases the oxidation of N-nitrosodimethylamine, acetaminophen, aminopyrine, ethylmorphine, zoxazolamine and benzo(a)pyrene (Anderson and Kappas, 1991).

The antioxidant vitamins (A, C and E) are required for normal membrane synthesis and stability. Vitamin A deficiency decreases hepatic mixed-function oxidase system activity and depresses oxidation of aminopyrine, ethylmorphine, aniline,

benzo(a)pyrene and 7-ethoxycoumarin (Anderson and Kappas, 1991). Vitamin C deficiency decreases NADPH-P-450 reductase activity and prolongs the half-life of antipyrine, acetaminophen and salicylamide. Vitamin E deficiency decreases microsomal metabolism of ethylmorphine, codeine and benzo(a)pyrene (Anderson and Kappas, 1991). Effects of vitamin E deficiency occur without decreases in cytochrome P-450 activity, and probably relate to the antioxidant properties of tocopherol, which may prevent oxidative damage to membrane lipids. Vitamins A and D are substrates for cytochrome P-450 and can competitively block the metabolism of other P-450 substrates.

Dietary Mineral Intake

Many minerals modulate hepatic drug metabolism. Iron is required for heme synthesis in cytochromes and for metal ion-catalyzed oxidative reactions (Parke and Ioannides, 1981). Iron deficiency results in decreased metabolism of hexobarbital and aminopyrine (Anderson and Kappas, 1991). Selenium is a cofactor for glutathione peroxidase; selenium deficiency may promote oxidative damage to the microsomal system. Hypothyroidism resulting from iodide deficiency increases flavoprotein synthesis and cytochrome P-450 oxidative activity (Danforth and Burger, 1989). Deficiencies of zinc, magnesium and potassium decrease drug metabolism, whereas high concentrations of metals (e.g., cobalt and cadmium) may block heme synthesis and thereby lower cytochrome P-450 levels (Anderson and Kappas, 1991).

Non-Nutrient Effects on Drug Metabolism

Non-nutrient dietary factors can profoundly influence drug metabolism by inducing the activity of many hepatic biotransformation enzymes (Guengerich, 1995). Phenols (e.g., hydroxycinnamic, dihydroxycinnamic and ferulic acids) are antioxidants that block chemical carcinogenesis. Methylxanthines, including caffeine, theobromine and theophylline, competitively bind to cytochrome P-450 to block oxidation of other compounds. Coumarin derivatives in vegetables and fruits induce glutathione-S-transferase activity. Organonitriles (1-cyano-2-hydroxy-3-butene, 1-cyano-3,4-epithiobutane) and indole derivatives (indole-3-carbinol, 3,3'-diindolmethane, indole-3-acetonitrile) in cruciferous plants (e.g., broccoli, cauliflower and cabbage) increase hepatic and renal glutathione concentrations and induce hepatic and renal glutathione-S-transferase activities (Fettman, 1991).

Excessive organonitrile exposure induces hepatic and renal toxicity, which may impair drug metabolism, whereas small amounts may have anti-carcinogenic properties (Guengerich, 1995; Fettman, 1991). Flavonoids and terpenoids from citrus fruits can either induce or block cytochrome P-450-related oxidative reactions, and can exert mutagenic or anti-tumorigenic effects, depending on the dose administered (Guengerich, 1995). Flavonoids in grapefruit juice can significantly prolong the half-life of dihydropyridine calcium channel blockers (e.g., nifedipine, felodipine and nisoldipine) and inhibit the metabolism of cyclosporin. St. John's wort is a potent inhibitor of cytochrome P-450 3 families (CYP3A); therefore, it can inhibit metabolism, cause toxicity or lead to decreased efficacy.

Butylated hydroxytoluene (BHT) and butylated hydroxyanisole (BHA) are added to certain processed food products to inhibit lipid oxidation (Guengerich, 1995). These food additives competitively inhibit cytochrome P-450-related oxidases, but induce other enzymes, including glutathione-S-transferase, glucuronyl transferase, DT-diaphorase and quinone reductase. In some experimental systems, they have demonstrated anti-carcinogenic properties, presumably by blocking activation of chemical carcinogens (DeLong et al, 1985). In other systems, a hydroperoxide derivative has been shown to have a tumor-promoting effect (Guyton et al, 1991). Polycyclic hydrocarbons and related pyrolysis products of charbroiling are reported to increase cytochrome P-450 oxidase activities and to increase the clearance of such drugs as theophylline, bufuralol, acetaminophen, tacrine and warfarin (Guengerich, 1995). Induction of cytochrome P-450 hydroxylase can lead to activation of arylamine and heterocyclic amines, which are also consumed with food, and have been linked to stimulation of carcinogenesis.

DIETARY EFFECTS ON DRUG EXCRETION

Following P-450 hydroxylation, heterocyclic amines may subsequently undergo N-acetylation, the metabolic phenotype and activity of which affects the organ and route of excretion of the metabolite (Fettman et al, 1991). If there is "slow" N-acetyltransferase activity, most of the hydroxylated amine undergoes hepatic glucuronidation and is returned to the blood for excretion in the urine. In people, so called "slow acetylators" are predisposed to urinary bladder cancer. Those individuals with "fast" N-acetyltransferase activity appear to be predisposed to colorectal cancer, presumably through preferential colonocytic metabolism to mutagenic arylamides and acetoxyarylamines. Thus, metabolic phenotype as determined by genetics, or from enzyme induction due to dietary effects, can influence the site, route and rate of drug excretion. In veterinary patients, dogs are poor acetylators whereas cats are good acetylators.

Because many of the drugs excreted by the kidneys undergo active transport by anion- or cation-specific mechanisms in the renal tubular epithelium, their elimination can be altered through competitive inhibition by other charged solutes. Pharmacologically, this effect has been purposely employed by the co-administration of probenecid with penicillins to block elimination by the anion-specific renal tubular transport mechanism. Nutritionally, this effect may result from consumption of divalent cations (e.g., calcium and magnesium), which decreases renal tubular transport and accumulation of aminoglycosides such as gentamicin (Brinker et al, 1981; Quarum et al, 1984; Schumacher et al, 1991; Wong et al, 1989). As a result, urinary elimination of the antibiotic is increased and nephrotoxicity thereby reduced.

Furthermore, dietary alterations in urinary pH can affect the ionization and trapping of drugs secreted into the tubular lumina. The relatively common practice of formulating commercial feline foods to promote urinary acidification in the prevention and treatment of lower urinary tract diseases (e.g., struvite crys-

talluria and urolithiasis) may also affect the elimination of pharmaceutical agents excreted in the urine (Fettman et al, 1992). Examples include ion trapping in urine as a treatment for aspirin (salicylate) and amphetamine toxicities. Urine alkalinization increases the elimination of aspirin and urine acidification increases the elimination of amphetamine. However, acid/alkaline changes for these treatments typically occur through fluid and fluid supplementation.

Food ingredients that stimulate bile, fecal or urine flow may affect the excretion of drugs by these routes. For example, dietary fats with choleretic properties will enhance the excretion of drug metabolites in the bile and the return of enterohepatically recycled drugs such as doxycycline. Salts of divalent cations (e.g., magnesium oxide and magnesium hydroxide) can exert a laxative effect that may increase fecal elimination of poorly absorbed oral drugs and enterohepatically recycled drugs. High dietary salt content and other naturally occurring diuretics, including active loop diuretics, can enhance the excretion of drugs and their metabolites in urine.

BENEFICIAL EFFECTS OF NUTRIENTS ON DRUG ACTION

The presence of food need not impair drug absorption, and within limits may be indicated to facilitate safe GI uptake of drugs (**Table 69-3**). Food may prevent GI irritation, modify drug-induced nausea or delay drug uptake, increasing the ultimate amount of drug absorbed (**Table 69-5**). For example, food can promote gastric acid secretion to enhance the uptake of an acidic drug such as aspirin while simultaneously protecting the mucosa from irritation by the drug.

Consumption of food can minimize nausea induced by the concurrent administration of hypertonic salt and carbohydrate solutions. In people, micronized preparations of phenytoin are actually better absorbed in the fed rather than the fasted state (Fleisher et al, 1990). In other cases, dietary supplementation with a specific nutrient may be indicated to counteract adverse drug side effects, to prevent drug-induced nutrient imbalances or to potentiate therapeutic effects.

Provision of Nutrients to Prevent Drug-Induced Imbalances

Additional energy and protein may be indicated to combat alterations in drug metabolism associated with prolonged decreases in food intake. A critical example would be the provision of nutrients during enteral- or parenteral-assisted feeding of patients incapable of voluntary food consumption. Effects of individual nutrient deficiencies have already been described. In addition, studies of prolonged starvation and of kwashiorkor in people have demonstrated significant reductions in the metabolism of numerous drugs by phase I and phase II hepatic biotransformation systems (Guengerich, 1995). These drugs include chloroquine, isoniazid, penicillin, chloramphenicol, tobramycin and cefoxitin. In addition, hypoalbuminemia-related decreases in drug binding alter the clearance of cloxacillin, streptomycin, sulfamethoxazole, sulfadiazine, digoxin, thiopental and phenylbutazone (Roe, 1989). Malnutrition-related decreases in renal blood flow and glomerular filtration rate have caused gentamicin toxicity.

Most commercial pet foods are adequately fortified with micronutrients; therefore, supplementation is not necessary unless a homemade food is fed, nutrient intake is decreased or a specific medical indication for prescription of a nutrient as a "neutraceutical" exists. Vitamin supplementation may be indicated to counteract the effects of drugs that specifically antagonize vitamin absorption or function. These include: 1) the use of folacin to manage deficiency induced by folic acid antagonists such as methotrexate, 2) vitamin K vs. antagonists in the coumarin family, 3) tocopherol, retinol and/or ascorbic acid to counter losses due to oxidative drug damage, 4) cholecalciferol for deficiency induced by anticonvulsants such as phenytoin, 5) thiamin to replace that lost to thiaminase activity in raw fish and 6) B vitamins to replace those lost following antibiotic-induced alterations in the GI microflora.

Specific minerals may also become deficient because of binding or precipitation in the GI tract, or following enhanced fecal losses due to laxatives or urinary loss due to diuretics. Urinary electrolyte losses due to loop diuretics can lead to significant physiologic abnormalities. Trace elements such as zinc may bind to fiber or be precipitated by phytates. Oral calcium supplements may block iron absorption. Excessive use of antacids, laxatives and binding resins can result in macroelement deficiencies.

Table 69-5. Examples of the effects of nutrients on drug action.

Beneficial effects	Examples
Enhanced GI drug absorption	Fatty foods enhance absorption of griseofulvin
Prevention of undesirable drug effects	Foods minimize nausea induced by metronidazole
Enhancement of desirable drug effects	Water enhances laxative effects of psyllium
Improved drug metabolism	Enteral feeding supports metabolism of cefoxitin
Altered drug excretion	Protein promotes renal excretion of gentamicin
Detrimental effects	**Examples**
Impaired GI drug absorption	Food interferes with absorption of ampicillin
Antagonism of desirable drug effects	Folate opposes chemotherapeutic effects of methotrexate
	Increased plasma potassium decreases digoxin activity
Potentiation of undesirable drug effects	Potassium increases potential toxicity of captopril
	Decreased plasma potassium increases digoxin activity
Impaired drug metabolism	Fish oil enhances hepatic oxidation of phenobarbital
Altered drug excretion	Calcium increases urinary excretion of gentamicin
	High-chloride diets increase bromide clearance and decrease its half-life

Glutathione precursors (e.g., cysteine or N-acetylcysteine) may be indicated to counter the oxidative damage induced by pharmaceutical agents such as the: 1) analgesic acetaminophen (e.g., S-adenosyl-L-methionine [SAMe] is recommended for oxidative damage in cats caused by acetaminophen as well as hepatotoxicity due to other origins, although definitive efficacy is lacking), 2) urinary antiseptic methylene blue, 3) injectable anesthetic propofol and 4) antitumor agent doxorubicin (Fettman, 1991; Webb et al, 2003). Oxidative damage resulting from administration of oxidized lipid supplements or excessive use of omega-3 fatty acid sources may also necessitate treatment with glutathione precursors or antioxidant vitamins.

Provision of additional water may be indicated for the prevention or treatment of renal damage resulting from nephrotoxic drug administration. Examples of drugs whose administration should routinely be coupled to increased water intake include cisplatin, aminoglycosides, nonsteroidal antiinflammatory drugs, analgesics and diuretics.

Provision of Nutrients to Enhance Drug Effects

Certain nutrients may be prescribed to facilitate a drug's intended effect or to synergistically promote the target physiologic functions. Additional energy or protein can generally facilitate therapeutic drug effects by promoting optimal distribution and hepatic biotransformation activities. These additions will tend to normalize pharmacokinetics to ensure the individual patient's dose response may more closely approximate the anticipated response.

Providing adequate energy and protein to patients receiving exogenous thyroid hormones plays an integral role in the physiologic response to that supplementation (Danforth and Burger, 1989). Undernutrition may result in reduced synthesis of thyroid-binding plasma proteins and subsequent changes in thyroid pharmacokinetics. Reductions in energy or protein intake suppress target tissue monodeiodination of thyroxine to the physiologically active triiodothyronine. Triiodothyronine levels decrease within 24 hours of fasting or caloric restriction, and may decline by 40 to 50% within three days. Should fasting induce increased adrenal glucocorticoid secretion, depressed target tissue triiodothyronine receptor levels may also be observed. Although these reductions in target-cell responsiveness to thyroid hormones represent an appropriate adaptation to conserve energy during starvation, the effect on exogenous thyroid hormone pharmacotherapy may be undesirable.

It is important to maintain a regular feeding schedule and consistent food for animals with diabetes mellitus to stabilize intermediary metabolism. The administration of exogenous insulin to insulin-dependent diabetics and the administration of oral hypoglycemic agents to non-insulin-dependent diabetics should be timed relative to feeding. For both forms of diabetes mellitus, specific dietary formulations are indicated to: 1) modulate GI carbohydrate uptake, 2) meet protein requirements without adversely affecting renal function and 3) moderate overall lipid metabolism to prevent ketoacidosis (Chapter 29).

Dietary intake of specific minerals that modulate hormonal axes should be considered, including calcium and phosphorus intake when cholecalciferol is administered for chronic renal failure, and sodium and potassium when mineralocorticoids are replaced in hypoadrenocorticism. The trace minerals chromium and vanadium may improve glucose tolerance and facilitate management of diabetics with insulin or oral hypoglycemic agents (Anderson et al, 1991; Boden et al, 1996). Specific omega-3 fatty acid therapy may be used to potentiate the effects of antiinflammatory drugs, anticoagulants and antineoplastic agents (Meydani, 1996). Arginine may be provided to improve nitric oxide production and to enhance immune function (Kirk and Barbul, 1990), glutamine to promote enterocyte metabolism (Hall et al, 1996), cysteine to enhance glutathione synthesis (Sellke et al, 1991), carnitine to improve digoxin responsiveness in congestive heart failure (Pepine, 1991) and antioxidant vitamins to protect against oxidative damage.

Dietary fiber may be indicated along with drug therapy for a number of diseases. Increased dietary fiber intake has proved beneficial in the treatment of insulin-dependent and non-insulin-dependent diabetes mellitus by moderating glucose absorption from the GI tract. Fermentable dietary fiber increases colonic short-chain fatty acid concentrations and decreases luminal pH. As a result, these fibers may be used as the primary treatment for canine and feline colitis or as an ancillary therapy to sulfasalazine or metronidazole treatment. Soluble fibers (e.g., psyllium mucilloid) may act in this way in conjunction with other antidiarrheal treatments, or as stool softeners for use with laxatives to treat constipation (Fettman, 1992). Hepatic cytochrome P-450 concentrations and UDP-glucuronyl transferase activities appear to be altered by the type and quantity of fiber in the food (Nugon-Boudon et al, 1996).

Dietary buffers may be indicated in conjunction with other therapies for chronic renal failure to correct metabolic acidosis or to facilitate activity of replacement pancreatic enzymes in exocrine pancreatic disease. They may be used to enhance alkaline drug absorption from the GI tract and to promote acidic drug excretion in the urine. Alkalinization of the urine has been used clinically to reduce the ionization, renal accumulation and toxicity of aminoglycosides (Brown and Riviere, 1991). Finally, buffers (e.g., sodium bicarbonate, aluminum hydroxide) can be used with H_2-receptor antagonists (e.g., cimetidine, ranitidine) or as laxatives (e.g., magnesium oxide, magnesium hydroxide).

ADVERSE EFFECTS OF NUTRIENTS ON DRUG ACTION

In addition to ameliorating undesirable effects on drug absorption or metabolism, specific nutrients may antagonize desired drug effects (**Table 69-5**). Excess caloric intake will complicate weight management in obese patients. Excess protein intake can adversely affect renal handling of drugs by increasing renal blood flow and drug excretion, or by promoting intraglomerular hypertension and reducing glomerular filtration in chronic renal failure. High protein intake can increase the hepatic

metabolism of drugs such as the methylxanthines, resulting in reduced therapeutic efficacy.

High mineral intake can complicate drug therapy of specific disorders: 1) sodium and hypertension, 2) potassium and hypoadrenocorticism, 3) magnesium and feline lower urinary tract disease and 4) phosphorus and chronic renal failure.

Excessive dietary intake of iodine can lead to a paradoxical “iodine toxicosis goiter” through what is referred to as the “Wolff-Chaikoff effect.” As iodide accumulation by the thyroid gland increases, so does iodination of tyrosyl residues of thyroglobulin. However, very high iodine levels appear to cause auto-inhibition of iodide organification and thyroglobulin proteolysis, leading to thyroid hormone deficiency. This phenomenon has been observed in foals born to mares that received excessive iodine supplementation during gestation, as well as in other species (Drew et al, 1975; Driscoll et al, 1978).

Naturally occurring non-nutritive dietary factors that may influence drug responses include methylxanthines, which may complicate aminophylline therapy, histamine in certain types of fish, which may interfere with antihistamine treatment and tyramine in chicken livers and aged cheeses, which confound the action of monoamine oxidase inhibitors. Alcohols and antioxidants added to certain nutrient sources as preservatives and humectants may have adverse effects as well. Benzoic acid and benzoyl alcohol in commercial fluid and drug preparations, propylene glycol in semi-moist commercial cat food and onion powder in commercial human baby foods may induce oxidative erythrocyte damage and Heinz body anemia in cats (Bedford and Clarke, 1971; Wilkie and Kirby, 1988; Christopher et al, 1989; Kaplan, 1995). These substances are no longer commonly used in commercial product manufacturing.

EFFECTS OF OBESITY ON DRUG DISPOSITION

Although complicated by the metabolic effects of overnutrition during weight gain or restricted food intake during weight loss, numerous studies have documented a significant effect of obesity on drug metabolism in people and other animals (Reidenberg, 1977). Changes in the apparent volume of distribution have been observed because of alterations in the quantity of body fat. Obesity increases the volume distribution of lipophilic drugs such as alprazolam, carbamazepine, diazepam, methotrexate, oxazepam, sufentanil and vancomycin. Increased volume distribution for lipophilic drugs (e.g., thiobarbiturates) necessitates administration of a higher dose to achieve the desired clinical response. Sequestration in body fat may prolong the drug’s action. Obesity decreases the volume distribution of polar compounds including acetaminophen, ciprofloxacin, furosemide, gentamicin, isoniazid, sulfisoxazole and tolbutamide (Ducharme et al, 1994; Dunn et al, 1991; Caraco et al, 1992; Abernethy et al, 1984; Shum and Jusko, 1984; Yuk et al, 1988; Fleming et al, 1991; Schwartz et al, 1991; Allard et al, 1993).

Drug clearance may be affected following changes in hepatic microsomal enzyme induction, as well as alterations in the predominant pathways used for phase II conjugation reactions. Several investigations have demonstrated enhanced biotransformation of volatile anesthetics in obese patients, resulting in increased production of the reactive intermediates typically responsible for organ toxicity (Bentley et al, 1982). Enhanced hepatic oxidative metabolism of halothane in obese people has resulted in increased serum levels of fluoride and bromide ions; the former is associated with increased hepatotoxicity. Half-life elimination of triazolam is prolonged in obese subjects, and clearance following oral administration is reduced, presumably because of decreases in hepatic extraction.

Drug toxicity may be enhanced when the dose administered is based on total body mass, but distribution is restricted to lean body mass, resulting in higher plasma drug concentrations and greater exposure to susceptible organs (Corcoran et al, 1989; Corcoran and Salazar, 1989). Obese rats appear to be at increased risk for gentamicin and furosemide nephrotoxicity by this mechanism (Corcoran et al, 1989; Corcoran and Salazar, 1989). Susceptibility to the toxic affects of these drugs remains even when the dose is decreased to reflect lean body mass and to equalize drug exposure. Studies of acetaminophen toxicity in rats have shown that when obese animals are dosed according to fat-free mass, toxicity is increased because of a metabolic shift toward less sulfation and more glucuronidation (Corcoran and Wong, 1987). Obesity likewise appears to increase drug glucuronidation in people. Furthermore, target organs may be predisposed to drug toxicity by pre-existing obesity-related lesions such as hepatic lipidosis.

Obesity increases steroid hormone clearance in people because of enhanced aromatization and interconversion of androgens to estrogens by adipose tissue (Dunn et al, 1991). Prednisolone and methylprednisolone succinate clearance in obese people is also increased, although potential contributions by increased cardiac output, hepatic blood flow, liver size and hydrolysis by extrahepatic carboxyesterases have not been resolved. On the other hand, methylprednisolone clearance appears to be decreased, suggesting that obesity may affect specific oxidative pathways very differently (Dunn et al, 1991).

Although similar studies have not been conducted in companion animals, certain generalizations can be made. Obesity will result in changes in the effective dose administered for drugs given according to total body weight, whether it is increased because of poor lipid solubility or decreased because of lipophilicity. Drug dose or dosing interval may need to be adjusted to maintain therapeutic effect and protect against toxicity. Alterations in body composition concurrent with drug administration may have significant effects on clinical efficacy and margin of safety, and must be considered whenever a patient’s body weight changes markedly (Caraco et al, 1992).

SUMMARY

Quantitatively and qualitatively, ingested nutrients have major effects on the biologic activity of pharmacologic agents. This is true not just for orally administered drugs in the GI tract, but also for drugs administered parenterally. Ingested nutrients may

modify hepatic and renal metabolic processes, thus altering the action of parenterally administered drugs. Inappetence associated with many chronic diseases may significantly modify drug absorption, metabolism and action.

Specific macronutrients and micronutrients not only support normal physiologic processes necessary for drug delivery and action, but may also modify specific metabolic processes integral to drug activity. For instance, dietary protein must be sufficient to ensure adequate plasma protein synthesis and maintenance of plasma volume for the delivery and action of most systemically administered drugs. Dietary protein may also specifically affect the hepatic metabolism of some drugs, the renal elimination of others and the modification by target tissues of yet others. Specific amino acids can play a role in drug metabolism and action as well. Food is a major modulator of drug activity and food-drug interrelationships must be considered when designing treatment regimens.

Because few studies to determine the effects of food on drug metabolism have been conducted in dogs and cats, it is difficult to delineate specific feeding recommendations for drugs commonly used in veterinary practice. However, it is important to consider potential nutrient-drug interactions whenever the expected action of a prescribed drug is not seen in an individual patient. One may alter the dosing schedule relative to meals or adjust the dietary composition or dose to correct overt nutrient imbalances. Alternatively, one may determine circulating drug concentrations to detect changes in pharmacokinetics and to establish the need for a change in drug type or dose. It is clear that a standardized food, consistent feeding schedule and balanced nutrient intake are prerequisites to successful pharmacologic management of disease.

FOR MORE INFORMATION

See Chapters 25 and 26 for lists of drugs that may affect taste and smell perception, stimulate appetite, are incompatible with B-complex vitamins and are compatible with total nutrient admixtures.

CASE 69-1

Epilepsy in a Dachshund

Lauren Trepanier, DVM, Dipl. ACVIM (Internal Medicine)
School of Veterinary Medicine
University of Wisconsin-Madison
Madison, Wisconsin, USA

Patient Assessment

An 11-year-old, neutered female dachshund weighing 10 kg was presented for evaluation of poorly controlled seizures. Idiopathic epilepsy had been diagnosed when the dog was six months old. The dog had received phenobarbital, phenytoin or a combination of both drugs for the past nine years. During the past few months, the dog had been having clusters of seizures each month, despite treatment with phenobarbital. Trough serum phenobarbital concentrations (20.4 µg/ml) were within the therapeutic range (15 to 45 µg/ml).

The results of physical and neurologic examinations were normal. The dog's body condition was 3/5. Serum biochemistry analysis revealed increases in liver enzyme activity (alkaline phosphatase, gamma-glutamyl transferase) and abnormal pre- and postprandial bile acid concentrations. Abdominal ultrasonography revealed mild hepatomegaly with normal hepatic echogenicity. Two small cystic calculi were evident in the urinary bladder.

The presumptive diagnosis was subclinical anticonvulsant-associated hepatopathy. Treatment was initiated with another anticonvulsant, potassium bromide (20 mg/kg body weight, per os, q24h), to control the seizures and allow the dose of phenobarbital to be reduced. The dog had no seizures during the two months after initiation of potassium bromide treatment. Serum bromide concentration had reached 1,100 mg/l (therapeutic range 1,000 to 2,000 mg/l). Alkaline phosphatase and gamma-glutamyl transferase activities had decreased markedly.

On re-examination one month later, the dog was still free from seizures, but had persistent cystic calculi. In the past, the dog had been treated for recurrent struvite crystalluria and cystic calculi with antibiotics and a veterinary therapeutic food. A struvite calculolytic food (Prescription Diet s/d Canine[a]) and antibiotic (Clavamox[b]) were prescribed. Two weeks later, the dog had a cluster of five seizures over a 36-hour period.

Assess the Food and Feeding Method

For the past three years, the dog had been fed a moist veterinary therapeutic food (Prescription Diet c/d Canine[a]) that contains reduced levels of struvite precursor substances and produces an acidic urinary pH. These nutritional characteristics help keep struvite crystalluria and urolithiasis from recurring. Because of the recurrent cystic calculi, the food was changed two weeks ago to a

moist veterinary therapeutic food (Prescription Diet s/d Canine[a]) shown to help dissolve struvite uroliths. Nutrient profiles of the two foods are summarized in **Table 1**.

Questions

1. What potential food-drug interactions could be causing the recent increased seizure activity in this dog?
2. What other diagnostic tests should be performed in this patient?
3. How should the treatment and feeding plan be modified?

Answers and Discussion

1. The most likely food-drug interaction in this dog is between the potassium bromide anticonvulsant and the dietary chloride load. Bromide is excreted slowly, but almost exclusively by the kidneys. The amount of bromide excreted depends on the total body halide (i.e., fluorine, chlorine, bromine, iodine) concentration. Bromide and chloride compete for renal tubular reabsorption. An increase in chloride load, in the form of dietary sodium chloride or ammonium chloride, will markedly increase urinary excretion of bromide in several species, including dogs. In addition, high-chloride foods fed experimentally to dogs will significantly shorten the elimination half-life of bromide and lead to decreases in serum bromide concentrations. The veterinary therapeutic food being fed to the dog to help dissolve the cystic uroliths contains increased levels of sodium chloride to increase urine volume thereby decreasing the concentration of struvite-forming constituents in the urine.
2. Serum bromide concentrations can be measured to determine whether therapeutic levels are being maintained. In this patient, the serum bromide concentration the day after the seizures was 410 mg/l, which was much lower than the concentration measured one month earlier (1,100 mg/l) and below the normal therapeutic range (1,000 to 2,000 mg/l). The anticonvulsant dosage or formulation had not been changed, and the owner was adamant that doses of potassium bromide had not been missed.
3. Because high chloride intake enhances bromide elimination and may have reduced the serum bromide concentration, the owner was instructed to discontinue feeding the moist calculolytic food and to resume feeding the moist struvite-preventive food, with the lower chloride content. The dog was fed to maintain a weight of 10 kg (520 kcal [2.18 MJ]; 1.1 cans/day).

   Seven weeks after being fed the lower chloride food again and with daily potassium bromide treatment (20 mg/kg body weight), the dog's serum bromide concentration was 990 mg/l. If a change to a higher chloride food or a food of unknown chloride content is necessary, serum bromide concentrations should be monitored frequently during the weeks to months after the dietary change, and the dosage of potassium bromide should be adjusted as needed to maintain therapeutic bromide concentrations. Eradication of urinary tract infection and monitoring urinary pH to ensure that the urine is continuously acidic are required for successful treatment and prevention of struvite urolithiasis. Serial radiographs and urinalyses should be performed to monitor the cystic uroliths. Surgical removal of uroliths may be indicated if they persist, increase in size or cause clinical problems.

Table 1. Nutrient profiles of veterinary therapeutic foods fed to the patient.

Nutrient (% DM)	c/d Canine, canned[a]	s/d Canine, canned[a]
Protein	23.6	7.9
Fat	24.0	26.0
Carbohydrate (NFE)	46.6	58.9
Crude fiber	1.4	2.1
Calcium	0.68	0.31
Phosphorus	0.51	0.10
Potassium	0.62	0.45
Magnesium	0.08	0.02
Sodium	0.27	1.30
Chloride	0.65	2.41

Key: DM = dry matter, NFE = nitrogen-free extract.

Progress Notes

Serum bromide concentrations remained stable between 1,200 and 1,250 mg/l over the next 21 months. Seizures were not observed since the cluster of seizures that occurred after the change to the high-chloride food.

CASE 69-2

Hyperadrenocorticism in a Dachshund

Philip Roudebush, DVM, Dipl. ACVIM (Small Animal Internal Medicine)
Hill's Scientific Affairs
Topeka, Kansas, USA

Patient Assessment

An eight-year-old neutered female dachshund was examined for chronic dermatitis. The owners reported a slowly progressive, nonpruritic dermatopathy and polydipsia and polyuria of three to four months' duration. The dermatitis had been treated with antibiotics and griseofulvin with no response. To the owners' knowledge, the dog had received no corticosteroids.

Physical examination revealed an alert, active 10-kg dog with normal body condition (3/5), a dry coat and a "pot-bellied" appearance. The abdomen was distended and totally devoid of hair. The skin on the abdomen was markedly thinned. Bilateral alopecia and hyperpigmentation were evident on the dorsum, extending from the shoulders to the flank. Focal, circumscribed plaques with peripheral erythema were present in the inguinal and axillary regions. The remainder of the physical examination was normal.

Diagnostic evaluation included a complete blood count (lymphopenia, eosinopenia), serum biochemistry profile (hypercholesterolemia [1,414 mg/dl, normal = 125 to 250 mg/dl] and increased alkaline phosphatase activity [491 IU/l, normal <50 IU/l]), urinalysis (dilute urine with hematuria and bacteriuria) and thoracic and abdominal radiographs (calcification of subcutaneous tissues along the back). Subsequent urine culture yielded large numbers of *Escherichia coli*. Histologic evaluation of skin biopsy specimens confirmed calcinosis cutis. Water consumption in the hospital exceeded 120 ml/kg body weight/24 hours (normal = 40 to 60 ml/kg body weight).

The tentative diagnosis was pituitary-dependent hyperadrenocorticism with secondary calcinosis cutis and bacterial urinary tract infection. Hyperadrenocorticism was confirmed by excessive plasma cortisol response to intramuscular injection of ACTH gel (cortisol, pre 27 mg/dl and cortisol, two hours post-ACTH 60.0 mg/dl; normal pre-cortisol 0.5 to 4.0 mg/dl and post-ACTH 8.0 to 20.0 mg/dl).

Assess the Food and Feeding Method

The dog was fed a combination of a commercial grocery store brand dry food and a grocery store brand moist food. The dry food was available free choice and the moist food was fed once daily in the morning.

Question

Mitotane[a] (o,p'-DDD) was used to treat this patient's hyperadrenocorticism. What food-drug interactions are important to consider in the treatment and feeding plans?

Answer and Discussion

Mitotane is a commonly used drug for treatment of canine hyperadrenocorticism. Mitotane exerts a direct cytotoxic effect on the adrenal cortex, resulting in selective, progressive necrosis and atrophy of the zonae fasciculata and reticularis.

The efficacy of mitotane therapy in patients with hyperadrenocorticism can be improved markedly by dosing with food. Studies have shown that the systemic availability of mitotane is very poor when intact tablets are administered to fasting dogs, whereas availability is much better from intact or powdered tablets given with food (**Table 1**). Mitotane is soluble in fat but poorly soluble in water. The presence of dietary fat during drug administration could assist in dissolution and absorption of lipophilic drugs such as mitotane. Based on these studies, mitotane should always be administered with meals.

The interaction between food and drug probably explains some of the variation in response of pituitary-dependent hyperadrenocorticism patients to mitotane, in relation to the time required to gain initial control with daily administration and the efficacy of weekly maintenance doses. Failure to administer the drug with food may contribute to the apparent "resistance" to the effects of the drug seen in some dogs with hyperadrenocorticism.

Interactions between drugs and ingested food are common. The most common outcome is reduced or delayed absorption of the drug, although absorption is sometimes increased or unaffected by food. In many instances the changes in drug availability are modest and their clinical significance is not great. However, the substantial effect of food on mitotane availability is almost certainly clinically important and should be considered when prescribing adrenolytic therapy with this drug.

Clinical signs that owners should monitor include the dog's attitude, appetite and water intake. A common, early adverse sign of mitotane toxicity is diminished appetite, which usually occurs before other adverse clinical signs develop such as vomiting, weakness and complete anorexia. Therefore, the owners should observe the dog's appetite closely before administering the daily mitotane dose. If the food is consumed rapidly, the owner should administer the mitotane immediately after the dog finishes the meal. If the food is consumed slowly or not at all, the owners should contact the veterinarian before administering the drug.

Progress Notes

Therapy was initiated at home with an induction or loading dose of mitotane (42 mg/kg body weight/day for seven to 10 days). One 500-mg tablet was given each day following the morning meal of moist food. The dog ate the morning meal rapidly over the next 10 days; mitotane was administered each day. By Day 10 of treatment, daily water consumption had decreased from more than 120 ml/kg body weight/day to 31 ml/kg body weight/day. Daily mitotane administration was stopped and weekly therapy initiated. The dog was also treated with sulfisoxazole for the concurrent cystitis.

CASE 69-3

Traumatic Injury in a Mixed-Breed Dog

Craig D. Thatcher, DVM, MS, PhD, Dipl. ACVN (Veterinary Nutrition)
College of Veterinary Medicine
Virginia-Maryland Regional College of Veterinary Medicine
Blacksburg, Virginia, USA

Patient Assessment

A 10-year-old, female mixed-breed dog weighing 22.2 kg was presented after being attacked by two dogs. Physical examination revealed a temperature of 37.4°C (99.3°F), pulse of 120 beats/min. and a thready, respiratory rate of 140 breaths/min. (panting) and multiple bite wounds associated with severe tearing of the subcutaneous tissues and crushing injuries to the deep musculature of the flank, lumbar and cervical regions. The dog had a flail chest, rib fractures and subcutaneous emphysema over the flank, chest, neck and head. The abdomen was painful on palpation and bruising was noticeable throughout the wound regions. The dog's body condition score was normal (3/5).

Results of a complete blood count and biochemistry profile included marked leukopenia and neutropenia with a degenerative left shift. The dog had panhypoproteinemia and moderate thrombocytopenia, which were consistent with severe sepsis and a poor prognosis. A coagulation panel demonstrated increased activated partial thromboplastin and prothrombin times with a significant decrease in platelet numbers, suggesting disseminated intravascular coagulation. Thoracic radiographs revealed a pneumomediastinum, mild pneumothorax, contusion of the left cranial lung lobe, disseminated emphysema and fractures of the right 11th and 12th ribs. Abdominal radiographs were within normal limits. No fluid was aspirated during abdominocentesis.

Initial treatment consisted of 400 ml of hetastarch (50 ml/hr) followed by lactated Ringer's solution + 20 mEq KCl/l (IV, 80 ml/hr), eurofloxacin (IV, 5 mg/kg b.i.d.), ampicillin (IV, 22 mg/kg t.i.d.), metronidazole (IV, 10 mg/kg t.i.d.), plasma (IV, 36 ml/hr administered by pump), sodium heparin (SQ, 1,500 IU t.i.d.), diazepam (IV, 2.1 mg) and 250 ml morphine (3.0 ml/45.6 mg)/lido-

caine (27.4 ml/547.2 mg) in 0.9% NaCl at a constant infusion rate (IV, 10 ml/hr). Additionally, one dose of oxymorphone (IV, 1-mg vial) was administered; morphine (IV, 0.2 mg/kg) was provided as needed to control pain.

While the dog was anesthetized, its wounds were surgically débrided, explored and covered. Devitalized tissue and skin were removed, wounds were irrigated, suction tubing was placed in linear incisions over each wound and continuous suction applied. A 20-Fr., 16-in. Argyle thoracostomy tube was placed in the 11th intercostal space because one wound communicated with the thoracic cavity. During surgery, a percutaneous gastrostomy (PEG) tube was placed for nutritional support. The dog was placed in an oxygen cage in the intensive care unit.

Assess the Food and Feeding Method

The dog had been NPO for three days before presenting to the hospital. The dietary goals were to feed a highly digestible, calorically dense diet, with high quality and quantity of protein and high fat content to support wound healing and immune cell function and decrease body catabolism. Because the patient had not eaten for the previous three days, enteral nutritional support was initiated at 75% of the dog's calculated resting energy requirement (510 kcal/day). One 6-oz. can of Maximum-Calorie[a] diet was blended with 60 ml of warm water, which provided 1.4 kcal/ml. The feeding schedule was initiated on Day 1; the dog was fed 63 ml of the blended diet q4h through the PEG tube. Four hours after the first feeding, but before the next scheduled feeding, more than 40 ml of a dark brown granular material was aspirated from the feeding tube. Enteral feeding was discontinued.

Questions

1. What food-drug interaction in this patient resulted in discontinuation of enteral feeding?
2. What alternative feeding route could be used to feed this dog?

Answers and Discussion

1. Morphine is a plant-derived alkaloid of opium and is the most widely used opioid throughout the world. Oxymorphone is produced by modifying the morphine molecule. Both of these opioids produce multiple, major effects on the central nervous, respiratory, cardiovascular and gastrointestinal (GI) systems. Opioids are excellent analgesics but poor to moderately effective sedatives and muscle relaxants. Central nervous system depression occurs in dogs after systemic administration of morphine.

   The dog's first response to morphine is to empty the GI tract. Opioid receptors are found in the myenteric plexus of the GI tract and when stimulated result in constipation. Opioids induce GI stasis, which is associated with increased tone of smooth muscle throughout the GI tract. Morphine decreases biliary and pancreatic secretions, resulting in delayed digestion in the small intestine. Propulsive contractions are markedly decreased throughout the intestinal tract.

   The opioids used to control severe pain in this patient were responsible for GI tract stasis. The enteral feeding route was unsuitable for this patient because food was retained within the stomach and digestion was delayed. The dog may have had GI bleeding as evidenced by the dark brown color of the aspirated material from the PEG tube.
2. Parenteral feeding was selected for this patient.

Progress Notes

Three days after presentation, the dog underwent cardiac arrest and died. Necropsy findings revealed massive trauma, congestion of the heart and lungs and myocardial necrosis. The bite wounds caused severe sepsis that likely led to the death of this patient.

Chapter 70

Feeding Small Pet Mammals

James W. Carpenter

Karen N. Wolf

Christine Kolmstetter

"All the thoughts of a turtle are turtles, and of a rabbit, rabbits."
The Natural History of Intellect, 1893

CLINICAL IMPORTANCE

Ferrets, rabbits and rodents are popular pets that are often presented to veterinarians for advice about their care, including diet and feeding management and treatment of medical disorders. Each species presents nutritional challenges. Dietary management of ferrets, rabbits and rodents may be modified by lifestage, level of physical activity and state of health. Owners may need advice about feeding healthy pets to meet needs for maintenance, growth, reproduction or stress. Patients may present with disorders caused by an imbalanced diet or improper feeding practices. In addition, nutritional support is used for rehabilitation of debilitated animals. This chapter covers the nutritional needs of healthy pet ferrets, rabbits and rodents and those with common disease processes.

Dietary management begins with assessment of the animal, food and feeding method. A feeding plan is formulated based on the results of this assessment (Chapter 1). Although data are lacking for specific exotic species, assessment is similar to that for other mammals. It begins with a thorough history of the animal, including diet, husbandry and environment. Physical examination includes recording body weight and assessing body condition, using body condition scores. Details about body condition scoring systems are unavailable for most small mammals; however, a five-point system (where 1 = cachectic, 3 = optimal, and 5 = obese) can be applied to all species. Body condition scores qualitatively assess amounts of body fat and muscle. Excessive loss of body fat suggests starvation (due to husbandry, diet, or disease), whereas excessive loss of muscling suggests advanced starvation, forced inactivity or altered metabolic states (often due to disease).

Other factors may become part of overall nutritional assessment. Small mammals, for example, can also be evaluated for the condition of their skin and fur and their behavior and attitude. As for other species, serum biochemistry profiles are of limited use in nutritional assessment.

DOMESTIC FERRETS

Husbandry

The domestic or European ferret (*Mustela putorius furo*) is a member of the family Mustelidae, order Carnivora. Other mustelids include the mink (*Mustela vison*) and weasel (*Mustela* spp.). Pet ferrets were domesticated from the wild European polecat and were probably brought to North America by English settlers 300 years ago (Fox, 1988). Two variations are recognized, based on coloration: 1) the fitch ferret is pale yellow buff with black mask, legs and tail, and 2) the albino ferret is white with pink eyes.

Ferrets have become increasingly popular as companion animals due to their small size, ease of care and maintenance and inquisitive personality (Carpenter et al, 1994; Brown, 1993, 2004; Fox, 1988; Bernard et al, 1984; Ryland and Bernard, 1983; McLain et al, 1988).

Key Nutritional Factors

Ferrets are strict carnivores that eat whole, small prey items in the wild. They have a very short, simple gastrointestinal (GI) tract lacking a cecum and ileocolic valve. Ingesta have a rapid intestinal transit time of approximately three to six hours (Bell, 1999; Brown, 2004). Because of the relatively inefficient GI tract, ferrets thrive on highly digestible foods containing large amounts of protein and fat, with minimal digestible (soluble) carbohydrate and fiber (Bell, 1999; Brown, 2004). In nature, the only significant sources of carbohydrates are those obtained from ingesting the gut contents of prey items (Bell, 1999). Although the most appropriate diet for a ferret is whole prey or a balanced fresh or freeze-dried carnivorous diet, this is impractical. Ferrets raised on ranches are often fed pelleted mink diets, which consist of 30 to 35% meat-based protein and 20% animal fat. However, diets for mink depend heavily on fish; mink diets are less palatable to ferrets because mink are naturally fond of fish whereas ferrets are not (Bell, 1999). Because the exact nutritional requirements of pet ferrets are unknown, recommendations for the best food for this species cannot be adequately determined. When evaluating a diet, review the list of ingredients on the package: the crude protein of a maintenance diet should be 30 to 35% and based on high quality meat, not grains; the fat content should be 15 to 20% (Bell, 1999; Brown, 2004). A comparison of constituent nutritional values of some North American commercial foods used for ferrets has been previously published (Bell, 1999; Lewington, 2000).

Commercial foods marketed specifically for ferrets mirror the formulations known to be successful in mink and cats (NRC, 2006, 1982; AAFCO, 2007). Guidelines for cat foods may be used when assessing the completeness and balance of foods intended for ferrets (AAFCO, 2007). Grocery store cat foods are very palatable because of their coating with animal fat and digest, but they are nutritionally inadequate for any stage of ferret's life. Minimally stressed ferrets may live on these foods for years, but nutritional deficiencies may occur especially in breeding animals (Bell, 1999). Pelleted ferret food is the preferred diet, although premium dry kitten food is generally acceptable for meeting the ferret's nutritional requirements for growth and reproduction (Kupersmith, 1998). Canned food should be avoided as the main diet because ferrets may be unable to consume enough protein and fat on a dry matter (DM) basis. Furthermore, periodontal disease may occur earlier if ferrets are fed a moist diet because of the lack of friction to help prevent plaque buildup on the teeth (Bell, 1999; Crossley and Aiken, 2004).

Protein and Amino Acids

Ferrets require foods containing 30 to 35% protein on a DM and metabolizable energy (ME) basis. These levels correspond to label guaranteed analyses of about 27 to 32% for dry food and 6.5 to 8.0% for moist cat food (Bell, 1999; Brown, 2004). Protein quality is as important as quantity. Digestibility must be considered when determining the amount of protein. Poorly digestible protein will not satisfy the animal's nutrient requirements. Premium brands tend to have more digestible protein from meat sources rather than from cereal-based sources. Ferrets fed low-quality cat or dog food have a much higher incidence of struvite urolithiasis and may be susceptible to other complications such as GI diseases, respiratory infections, reproductive failure and poor growth (Bell, 1999; Orcutt, 2003).

Specific amino acid requirements are unknown for ferrets, but are assumed to be similar to requirements for cats. For example, young ferrets fed a single meal of an arginine-free food developed hyperammonemia, as do young cats (Deshmukh and Rusk, 1989). Likewise, cats and other strict carnivores need the high biologic value of proteins found in meat. To ensure high biologic value and maintain high food digestibility, dietary protein for ferrets should originate primarily from animal-based ingredients (poultry meal, meat by-products, eggs).

Fat and Fatty Acids

Ferrets thrive when fed commercial foods containing 15 to 20% DM fat (Bell, 1999; Brown, 2004). These levels correspond to label guaranteed analyses of about 14 to 18% for dry and 3 to 5% for moist cat food.

Specific fatty acid requirements are unknown, but it is assumed that ferrets require linoleic and arachidonic acids. The former is abundant in vegetable oils, whereas the latter is abundant in animal-based ingredients (especially nerve tissue). Fatty acid requirements should be met by providing meat-based commercial cat or mink foods.

Digestible Carbohydrates and Fiber

Other strictly carnivorous species, such as cats and mink, have no dietary requirement for carbohydrates, including fiber. Glucose is provided by hepatic gluconeogenesis, using amino acids. Dietary fiber may play a role in weight control and reduction, and in certain specific GI disorders.

The simple, short digestive tract of strict carnivores dictates hydrolysis of most dietary fuels, with little or no hindgut fermentation of fiber. The ferret intestinal tract is comparatively deficient in brush-border enzymes, thus ferrets are less able to absorb calories from carbohydrates (Bell, 1999). Generally, foods with added fiber should not be fed to healthy ferrets and those in above-maintenance physiologic states, such as growth and lactation, but may be considered for patients with fiber-responsive disorders.

Energy

Metabolic rates for mustelids vary, but generally those with a long thin body shape, short fur, strict carnivorous behavior and high activity (e.g., ferrets and mink) have high metabolic rates, hence high caloric needs, relative to cats and other mustelids with different body shapes and activity levels (Knudsen and Kilgore, 1990). Seasonal metabolic cycles complicate predic-

tions of energy needs. Generally, autumn (shortening daylight) signals fat deposition and weight gain, whereas spring (lengthening daylight) signals fat mobilization and weight loss (Robbins, 1993). Pet ferrets that aren't exposed to variations in photoperiod may not undergo physiologic fluctuations in weight (Bell, 1999).

Ferrets reportedly consume 200 to 300 kcal (837 to 1,255 kJ) ME/kg body weight daily for adult maintenance (**Table 70-1**) (McLain et al, 1988). This amount equals about one-half to three-quarters cup of dry cat food containing about 400 kcal (1,674 kJ) ME per cup (standard eight-oz. measuring cup). This is about three times greater than the food intake of an average cat.

Energy needs increase for growth and reproduction (**Table 70-1**). Caloric requirements may be met by increased intake of an adult maintenance food or by consumption of a diet with increased caloric density. Increasing food intake works to a point, but foods with higher caloric density should be offered in demanding situations. Thus, growing and lactating ferrets should be fed cat foods formulated for growth and reproduction.

A ration with a caloric density of about 5.0 kcal/g (20.9 kJ/g) DM has been recommended for ferrets (McLain et al, 1988). Generally, dry cat foods contain 4.0 to 5.0 kcal ME/g (16.7 to 20.9 kJ ME/g) DM, or about 360 to 450 kcal ME/100 g (1,506 to 1,883 kJ ME/100 g) (about 1 cup). Moist cat foods usually contain 4.0 to 5.0 kcal ME/g (16.7 to 20.9 kJ ME/g) DM, or about 360 to 450 kcal ME/400 g (1,506 to 1,883 kJ ME/400 g) (about one 13-oz. can). Dry foods are generally preferred for ferrets because their texture may help prevent periodontal disease. Furthermore, although moist food may contain more DM protein and fat, ferrets may be unable to consume enough of this formulation to meet their requirements, because the bulk of the high moisture content in the food limits consumption (Bell, 1999).

Obesity is uncommon in ferrets, but may occur in later years as activity decreases. Most ferrets, therefore, are fed successfully by free-choice access to a high quality commercial ferret (or kitten) food. Although ferrets do not need treats, an occasional, judicious addition of natural treats (selected fruits and even vegetables) may be used. Food intake should be regulated for overweight ferrets.

Vitamins and Minerals

Dietary guidelines for cats and mink have been established by controlled comparative trials and thus are followed for pet ferrets because of limited research data in this species. Most published reports suggest that ferrets require vitamins and minerals in amounts similar to other carnivores. For example, research suggests that ferrets grow well when fed calcium (0.6 to 0.8% DM) and phosphorus (0.4 to 1.0% DM) in ranges fed to other mammalian carnivores (Edfors et al, 1990). Unlike cats, however, ferrets absorb β-carotene (the plant-based precursor of vitamin A) (Ribaya-Mercado et al, 1989). Despite this interesting finding, the conversion process is inefficient in ferrets: therefore, foods for pet ferrets should contain preformed vitamin A (e.g., retinyl palmitate) and not rely on carotenoids (Lederman et al, 1998).

Generally, deficiencies of specific vitamins and minerals are unlikely to occur in ferrets fed commercial foods formulated for cats, ferrets or mink. Deficiencies are more likely to occur in ferrets fed poorly formulated homemade foods. Imbalanced homemade foods for carnivores are most likely to be deficient in calcium and iodine. Both nutrients are deficient in common ingredients such as meats, most dairy products, rice and vegetables. Homemade foods should contain sources of calcium (bone meal, calcium carbonate) and iodine (iodized salt, kelp). Chapter 10 contains recipes for balanced homemade foods for cats that may be given to owners who insist on cooking for their ferrets (Donoghue and Kronfeld, 1994).

Deficiencies may also occur when excessive amounts of table foods or supplements are added to commercial ferret, cat or mink foods. Supplementation with table foods or single ingredients above about 10% of DM may imbalance previously balanced foods. For example, adding large amounts of corn oil reduces protein and other essential nutrients to deficient levels (on an energy basis). Deficiencies may also arise when large amounts of calcium are added to balanced foods because excess calcium interferes with absorption of trace minerals such as zinc and copper.

Vitamin and mineral toxicities may occur in ferrets overdosed with commercial supplements (e.g., chewable vitamin-mineral preparations given as treats) or with specific ingredients (e.g., vitamin A intoxication from an all-liver diet).

Table 70-1. Average daily metabolizable energy (ME) intakes for ferrets at maintenance (M) and above-maintenance states, based on the recommendation of 200 to 300 kcal ME/kg body weight. For this table, 250 kcal/kg was used. Much variation between individuals should be expected.*

Body weight (g)	Daily energy intake (kcal ME) M	1.5M	2M	2.5M	3M
200	50	75	100	125	150
300	75	112	150	188	225
400	100	150	200	250	300
500	125	188	250	312	375
600	150	225	300	375	450
700	175	262	350	438	525
800	200	300	400	500	600
900	225	338	450	562	675
1,000	250	375	500	625	750
1,200	300	450	600	750	900
1,400	350	525	700	875	1,050
1,600	400	600	800	1,000	1,200
1,800	450	675	900	1,125	1,350
2,000	500	750	1,000	1,250	1,500
2,200	550	825	1,100	1,375	1,650

*To convert to kJ, multiply kcal by 4.184.

Special Nutritional Needs

Kits from six weeks (weaning) to about 14 weeks of age require a soft, moist food. Growing kits require 35% protein and 20%

fat (Bell, 1999; Brown, 2004). Although a ferret kibble may be most appropriate, a premium quality cat food (formulated for all lifestages or for growth and reproduction) soaked with water may also be adequate for growth. Goat's milk added to softened cat food has been recommended for slow-growing kits (Morton and Morton, 1985). Ferrets achieve 90% of their adult size by 14 weeks of age, thus food consumption is very high.

Providing protein at levels greater than 35% improves the conception rate in jills (Bell, 1999). Pregnant and lactating ferrets also require above-maintenance levels of food. Generally, pregnant animals need about twice the maintenance level, whereas animals at peak lactation need three to four times maintenance amounts. Unrestricted access to premium quality food and a constant supply of water are required during these periods of high metabolic demand.

Food intake varies seasonally. Under natural lighting conditions, ferrets eat more and gain weight in the fall in preparation for the cold winter months (Morton and Morton, 1985). As the photoperiod increases in the spring, ferrets tend to lose most of their body fat, thereby preparing them for summer heat. Weight cycling may occur at other times as a result of unnatural photoperiods (Morton and Morton, 1985). Pet ferrets may not experience these fluctuations if they are not exposed to natural photoperiods.

Selected Nutritional Diseases

Although the prevalence of nutrient deficiencies and toxicities in ferrets is largely unknown, specific diet-related problems are rarely seen in practice. Like dogs and cats, some ferrets with dermatologic problems respond to dietary supplementation with fatty acids (Chapter 32), but direct causal links between diet and disease remain to be established.

Anecdotal reports suggest that some, but not all, ferrets with dermatologic problems may respond to adding meat or liver to their usual diet of commercial cat food. This finding suggests that ferrets may be responding to arachidonic acid in meat or perhaps additional protein. When feeding liver, care must be taken to avoid inducing vitamin A intoxication. Generally, no more than 30 g of liver should be added per 800 kcal (3,347 kJ).

Ferrets fed excessive dietary fat risk protein deficiency. Protein deficiency manifests as slow growth in the young, low conception rates and failed lactation in breeding females and impaired immunity and generalized unthriftiness in ferrets of all ages. The problem may be corrected by feeding a commercial ferret chow or premium kitten chow.

Quality commercial ferret, kitten or cat foods appear to provide adequate levels of vitamins and minerals for ferrets. Most published reports of clinical problems have occurred in large breeding operations or under laboratory conditions.

Vitamin E deficiency results in yellow discoloration of body fat, hemolytic anemia, anorexia and a progressively impaired gait leading to paralysis (McLain et al, 1988). Affected young growing kits are found dead or depressed, cry when handled and are reluctant to move. Diffuse firm swellings under the skin and prominent subcutaneous lumps in the inguinal areas are clinical manifestations of the deficiency (McLain et al, 1988). This disease has been termed yellow fat disease, fatty degeneration of the liver and steatitis. It results from feeding foods containing high levels of polyunsaturated fatty acids with inadequate dietary vitamin E (McLain et al, 1988). Diagnosis is based on clinical signs and a history of feeding a food containing high levels of polyunsaturated fatty acids, deficient levels of vitamin E or both.

Thiamin deficiency resulting from feeding fish containing thiaminase has been reported to occur on ferret farms in New Zealand (McLain et al, 1988). The disease was seen in weanling animals and adults. Clinical signs included anorexia and lethargy followed by dyspnea, prostration and convulsions.

Zinc toxicity has also been reported to occur in ferrets on farms in New Zealand (McLain et al, 1988). The toxicosis resulted from excessive intake of dietary zinc that had leached from galvanized feeding pans and water dishes. Presumptive zinc toxicity was based on clinical signs (anemia, posterior weakness and lethargy), gross pathology and histologic examination of kidney and liver specimens and demonstration of elevated levels of zinc in these tissues.

Copper toxicosis has been reported to occur in sibling pet ferrets (Fox et al, 1994). Signs referred to liver disease; tissue copper concentrations confirmed the diagnosis. A genetic predisposition to copper intoxication was proposed.

Ferrets also can develop lower urinary tract disease similar to that seen in domestic cats. Diet is thought to play an important role. Ferrets fed a diet containing poor quality protein have a higher incidence of struvite urolithiasis (Orcutt, 2003). Metabolism of plant protein creates more alkaline urine, which enhances formation of struvite crystals. Suggestions for prevention mirror recommendations for feline lower urinary tract disease (Chapter 46); however, the disease in ferrets is not well documented.

Feeding Plan

Ferrets require a high-protein, high-fat, low-carbohydrate diet. Foods for ferrets should be a premium quality kibble or chow and should be formulated for strict carnivores–ferrets or kittens (and possibly even adult cats). The diet must contain a high quality animal-source, not plant-source protein, to ensure high digestibility, palatability and protein quality. Protein and fat levels should preferably be 30 to 35% and 20% DM, respectively (Bell, 1999).

Foods may be fed free choice unless the ferret is overweight. Because of their high metabolic rate, ferrets consume more calories, hence more food, than cats.

Healthy ferrets should not be fed high-fiber foods. Dietary fiber, though, may play a role in weight control and in fiber-responsive disorders.

Other dietary recommendations for ferrets include:

- Vitamin-mineral supplements are generally unnecessary for healthy ferrets fed well-formulated commercial ferret or kitten/cat foods. Supplementing foods that are already balanced increases the risk of creating an imbalance and subsequent deficiencies or intoxications.
- Although it was a common practice to supplement a ferret's

diet with table foods such as cooked meat, fish, poultry, and eggs or fresh liver (Bernard et al, 1984; Ryland and Bernard, 1983), this practice is seldom indicated. Foods containing lactose or simple sugars should be avoided to prevent digestive upsets. Fruits and vegetables have also been offered in limited quantities; however, ferrets do not digest the fiber in these foods; therefore, they are generally not required. If a client insists on supplementing a ferret's diet, selected supplements should be used judiciously. Supplements should be limited to no more than 10% of the daily caloric intake. One ml of Linotone[a] or Ferretone[a] is acceptable, and soft-moist meat or liver snacks manufactured for ferrets or cats make good treats (Bell, 1999). Other acceptable snacks include baby food meats that contain no carbohydrates, egg yolk or whole cooked egg or small amounts of raw meat or liver. Pureed raw liver or hamburger mixed with egg yolk is especially appealing to kits and contains amino and fatty acids that may correct deficiencies associated with inadequate diets (Bell, 1999). Ferrets should not be offered carrots or nuts (may rarely cause intestinal obstruction), raisins (high sugar content) and bananas in amounts larger than 1 tsp (Purcell and Brown, 1999).

- Dry foods are generally recommended for ferrets because they may help keep the animal's teeth and gums in good condition, are more energy efficient, cost less and are easier to store and feed than moist foods.
- Ferrets do not need to eat mice or other rodents.
- Because hairballs occasionally occur in ferrets, feline hairball laxatives may be given every other day, following label dosage recommendations for cats (Brown, 1993).
- Bones should be avoided to prevent obstructions in the oral cavity and GI tract.
- Fresh water, in either a heavy crock-type bowl or drinking bottle, should be available free choice.
- Because ferrets are finicky, any food changes should be made gradually.
- Ferrets with insulinomas need constant access to a high-quality protein-based food. If a sugar-based syrup is used for emergency treatment of a hypoglycemic episode, it should be followed by a meat-based supplement after the patient is able to swallow to prevent dramatic fluctuations in glucose concentrations.
- Sick ferrets may be reluctant to eat and often require frequent hand feedings of warmed, moist, highly palatable foods. Examples include meat baby foods or a mixture of meat baby food, premium-quality moist cat food and a high-calorie supplement (e.g., Ensure Plus[b]) blended with the preferred dry diet (ground into a powder) and made into a warm gruel (Bell, 1999).

RABBITS

Husbandry

The domestic rabbit (*Oryctolagus cuniculus*) (Order Lagomorpha) is a descendent of the old world rabbit of western Europe and northwestern Africa (Fox, 1994; Donnelly, 2004a). It has become a popular pet, resulting in an increased demand for veterinary care for this species. Although domestic rabbits are used for commercial meat and fur production, teaching and biomedical research, exhibition by rabbit fanciers and as outdoor pets, most now are probably household pets. As pets, rabbits are small, relatively easy to care for, fastidious, quiet mannered and can be litter-box trained.

Figure 70-1. Overgrown, maloccluded incisor teeth frequently result in malnutrition or anorexia in rabbits.

As noted by their dental formula (I2/1, C0/0, P3/2, M3/3), lagomorphs can be distinguished from rodents by the presence of two pairs of upper incisor teeth. The smaller, second upper incisors, known as peg teeth, are located directly behind the first and lack a cutting edge. Rabbit teeth are hypsodont or open-rooted (continuously growing). Malocclusion and overgrowth are most likely to occur with the incisor teeth (**Figure 70-1**), which grow 10 to 12 cm a year throughout life, although malocclusion and overgrowth of the molar teeth may also occur (Harkness and Wagner, 1989). Rabbit teeth are developed for a high-fiber, herbivorous diet (Davies and Davies, 2003; Brooks, 2004). Chewing is characterized by up to 120 jaw movements per minute, with a lateral motion, which helps wear the teeth down to the proper occlusal surfaces.

As herbivorous hindgut fermenters, rabbits have a GI system resembling that of horses (Cheeke, 1994). Both species possess a non-compartmentalized stomach and a large cecum. The simple stomach has thin walls and indistinctly separated glandular and nonglandular areas. Rabbits are unable to vomit because of a well-developed cardiac sphincter (Davies and Davies, 2003; Brooks, 2004). The stomach is normally never fully devoid of food and fecal pellets. The terminal ileum expands and forms a thin-walled structure unique to lagomorphs known as the sacculus rotundus. Large amounts of lymphatic tissue are located in the wall of the sacculus, giving it a "honeycomb" external appearance. The thin-walled cecum is

Figure 70-2. A ventrodorsal radiograph of the abdomen of a rabbit with a gastric trichobezoar. Note the tubular distention of the stomach. (Reprinted with permission from Veterinary Medicine 1995; 90: 365-372.)

Figure 70-3. A ventrodorsal radiograph of the abdomen of the rabbit in **Figure 70-2** following a barium swallow. Note the contrast medium outlining the mass filling the gastric lumen. (Reprinted with permission from Veterinary Medicine 1995; 90: 365-372.)

a spiral structure and the largest and most prominent organ in the abdominal cavity of rabbits. The cecum has approximately 10-fold the stomach capacity and makes up 40 to 60% of the total volume of the GI tract (Jenkins, 1999). Antiperistaltic action moves small particles and solubles into the cecum, where cellulose is digested and fermented. The GI transit time for fiber is approximately four to five hours.

Instead of chewing cud for improved digestion, as would ruminants, rabbits use cecotrophy or pseudorumination (Brooks, 2004). Muscular contractions in the colon cause indigestible fiber particles to separate from nonfiber components of the gut contents. The fusus coli, another structure unique to lagomorphs, separates the proximal from the distal colon. The fusus coli functions as a pacemaker to control colonic contractions. Peristaltic contractions move fiber through the colon for excretion in hard feces. Antiperistaltic contractions move fluids and particles retrograde through the colon into the cecum for fermentation. After fermentation, the cecal contents are expelled through the colon (Brooks, 2004; Cheeke, 1994; Jenkins, 1999; Irelbeck, 2001). The fermented pellets produced in the cecum are called cecotrophs. Cecotrophs are excreted during the night and early morning, approximately eight hours after consumption of the original food item, as clusters of grapelike material and are consumed (cecotrophy) directly from the anus. Cecotrophs contain twice the protein (25 to 30% DM) of usual fecal pellets, more B vitamins and much less fiber (Tobin, 1996; Lowe, 1998; Brooks, 2004; Davies and Davies, 2003). Cecotrophy is particularly important for efficient digestion of forage proteins. The process also provides the rabbit with microbially synthesized B-complex vitamins, microbial protein and small quantities of volatile fatty acids. The pH of the rabbit's stomach is extremely acidic (<2.0), which may neutralize large num-

bers of bacteria ingested with cecotrophs.

The most clinically relevant feature, however, of the rabbit's GI system may be that the myoelectrical initiation of peristalsis occurs distal to the stomach. This feature allows hair to accumulate in the stomach and may account for the common occurrence of gastric trichobezoars in rabbits (**Figures 70-2** through **70-4**) (Gentz et al, 1995).

Key Nutritional Factors

Energy

Daily caloric needs for maintenance of healthy adult rabbits are estimated to be $100(BW_{kg})^{0.75}$ (**Table 70-2**) (Tobin, 1996). Thus, a healthy adult rabbit weighing 4 kg consumes almost 300 kcal/day (1,255 kJ). Because energy needs relate to metabolic body size, smaller breeds require a higher caloric intake per unit of body weight.

Daily energy needs increase for growth (190 to $210[BW_{kg}]^{0.75}$), early gestation ($135[BW_{kg}]^{0.75}$), late gestation ($200[BW_{kg}]^{0.75}$) and lactation ($300[BW_{kg}]^{0.75}$) (**Table 70-2**) (Tobin, 1996). Thus, there are two- to threefold increases in energy needs; therefore, food consumption correspondingly increases during growth and lactation (Harkness, 1987; Collins, 1988). Energy needs also increase in cold environmental temperatures.

Production rabbits often adjust feed intake to meet energy needs, when appropriate feed is available. Pet rabbits, however, occasionally overeat and risk obesity.

Protein and Fat

Rabbits require 13 to 18% DM dietary crude protein (**Table 70-3**). Research suggests that 13% is adequate for maintenance, 15 to 16% for maximum growth and 18% for gestating or lactating does. These levels are allowable minimums determined for laboratory and production rabbits. Protein levels of 12 to 16% should be adequate for healthy household rabbits. Protein provided at levels used for production may be excessive for pet rabbits and may lead to reduced appetite for cecotrophs (Harcourt-Brown, 2002).

Rabbits require adequate amounts of relatively high-protein, high-quality foods, which is achieved by efficient use of plant proteins, such as those found in alfalfa and clover (**Table 70-4**). Low-protein foods and nonprotein nitrogen are used poorly. Bacterial protein from the lower bowel contributes little to the amino acid needs of growing rabbits, but may benefit adults fed poor-quality protein at maintenance. Excess dietary protein may allow the proliferation of *Clostridium* spp., which could lead to enteritis (Lebas et al, 1998).

Rabbits require no added dietary fat. Most foods contain 2 to 5% fat, which is sufficient (**Table 70-3**). Excess dietary fat may increase the incidence of arteriosclerosis, although some strains of rabbits may develop arteriosclerotic plaques even on a fat-free diet (Brooks, 2004).

Fiber

Dietary fiber can be divided into indigestible fiber (passes through the digestive tract without entering the cecum) and fermentable fiber (enters the cecum for fermentation). Both indigestible and fermentable fiber are critical to optimal rabbit nutrition. The indigestible fiber stimulates gut motility, provides optimal dental wear and stimulates ingestion of cecotrophs. Fermentable fiber provides a substrate for cecal microflora, allows for volatile fatty acid production and prevents proliferation of pathogenic bacteria in the cecum (Harcourt-Brown, 2002; Brooks, 2004). Rabbits need a minimum of about 12 to 16% dietary crude fiber. The low end of the range, 12%,

Figure 70-4. The gastric trichobezoar removed in pieces from the rabbit in **Figures 70-2** and **70-3** weighed 102 g. Trichobezoars are frequently associated with a low-fiber diet. (Reprinted with permission from Veterinary Medicine 1995; 90: 365-372.)

has been recommended for lactating does, 14% for growth and gestation and 15 to 16% for maintenance (**Table 70-3**) (Cheeke, 1995). These levels are minimums established for production rabbits; higher fiber levels may benefit pets. Dietary fiber levels of 18 to 25% have been recommended to maintain optimal GI health and help prevent obesity in pet rabbits (Lowe, 1998; Irlbeck, 2001; Brooks, 2004).

Adequate insoluble dietary fiber is important for rabbit health. In studies, growth rates were reduced in young rabbits fed low-fiber foods. Growth rates of production rabbits are optimal when foods containing 10 to 15% DM crude fiber are fed. Enteritis is more common in rabbits fed less than 10% crude fiber (Cheeke, 1994). Dietary fiber primarily stimulates gut motility rather than serves as a source of nutrition. Fiber promotes intestinal motility, provides nutrition for intestinal microorganisms and minimizes susceptibility to enteritis. Cecal fermentation of fiber produces volatile fatty acids (acetate, butyrate, and propionate), which are absorbed and used for energy. Volatile fatty acids aid in the control of pathogenic organisms by helping to maintain a low cecal pH. Foods with adequate fiber help to prevent obesity and hair chewing (**Table 70-4**) (Harkness, 1987). Diets low in indigestible fiber can lead to decreased GI motility and retention of food and hair in the stomach. Slowed gut motility and increased retention time of food can lead to alterations in the gut flora and development of enterotoxemia (Harcourt-Brown, 2002; Brooks, 2004).

Vitamins

A dietary supply of vitamins A, D and E is an integral part of rabbit nutrition. Bacteria in the gut synthesize B vitamins in adequate quantities. Thus, addition of B vitamins to commercial foods may be unnecessary, although it often occurs. The adequacy of vitamin K synthesis in the gut is questionable; therefore, manufacturers often add this fat-soluble vitamin to commercial foods.

Because vitamins A and E are readily destroyed by oxidation, food preparation and storage methods should prevent losses from excess light or heat. Optimally, feed should be stored at 15°C (60°F) in a vermin proof area and fed within 90 days of milling (Brooks, 2004). Foods containing more than 30% alfalfa meal may provide sufficient vitamin A in the form of the precursor β-carotene (Fraser, 1991). Deficiency may occur, however, if old (more than one year postharvest) alfalfa is fed.

Table 70-3 lists recommended levels of dietary vitamin A for production rabbits. Recommendations for pet rabbits include 7,000 to 18,000 IU vitamin A/kg food, 40 to 70 mg vitamin E/kg food and 2 mg vitamin K/kg food (Tobin, 1996; Lowe, 1998; Harcourt-Brown, 2002). The role of vitamin D in calcium regulation in rabbits differs from that in other species. Intestinal absorption of calcium does not require the presence of vitamin D. In rabbits, vitamin D is important for phosphorus metabolism and deficiencies can lead to hypophosphatemia and osteomalacia (Harcourt-Brown, 2002). Sunlight is necessary for endogenous synthesis of vitamin D in rabbits. Commercial rabbit pellets are also supplemented with vitamin D. A level of 800 to 1,200 IU/kg is recommended for pet rabbits (Lowe, 1998; Harcourt-Brown, 2002).

Minerals

Calcium requirements for rabbits appear to be similar to those for other species (i.e., 0.5 to 1.0 % DM [**Table 70-3**]). Rabbits absorb calcium very efficiently and the excess is excreted in urine, rather than in bile as typically occurs in other species (Cheeke, 1994; Norris, 2001). Normal rabbit urine may have a thick milky appearance due to the excretion of calcium carbonate. Interestingly, rabbits have a higher than normal serum calcium level (12 to 13 mg/dl) compared to that of other mammals. Excess calcium supplementation with certain types of greens or vitamin-mineral mixes may cause urolithiasis or excessive calciuria in some pet rabbits (Irlbeck, 2001; Harcourt-Brown, 2002; Brooks, 2004). Urinary calculi can form in the kidneys, ureters and urinary bladder. **Table 70-5** lists calcium

Table 70-4. Protein and fiber contents (dry matter basis) of forages commonly fed to rabbits.*

Forages	Crude protein (%)	Cellulose (%)	Hemicellulose (%)	Lignin (%)	ADF (%)	Crude fiber (%)
Alfalfa hay	14	26	12	12	39	32
Alfalfa meal	18	24	-	11	35	26
Clover hay	16	26	9	10	-	29

and phosphorus contents of commonly fed forages.

Most rabbit foods contain adequate calcium because the formulations include alfalfa meal, which averages about 1.4% calcium, 0.2% phosphorus and at least 300 IU vitamin D_2 (ergocalciferol) per g (DM) (United States–Canadian Tables of Feed Composition, 1982). Prolonged intake of high-calcium foods (4% DM) may cause calcification of soft tissues such as the aorta and kidneys; hypervitaminosis D most likely exacerbates the effect because it aids calcium absorption (Cheeke, 1994). Feeding a food (e.g., possibly a diet lower in alfalfa or alfalfa meal) containing 0.5% calcium prevents soft-tissue calcification.

Table 70-5. Calcium, phosphorus and vitamin D_2 contents (dry matter basis) of forages commonly fed to rabbits.*

Forages	Calcium (%)	Phosphorus (%)	Vitamin D_2 (IU/g)

Special Nutritional Needs

The energy requirements of production rabbits fed free choice have been met by feeding dry foods containing 2.2 kcal/g (9.2 kJ/g) of food during maintenance, 2.5 kcal/g (10.5 kJ/g) of food during growth and gestation and 2.7 kcal/g (11.3 kJ/g) during lactation (Cheeke, 1995). Alternatively, feeding a single pelleted commercial rabbit food (hence a single energy density, often about 2.5 kcal/g [10.5 kJ/g] DM) and varying food intake, instead of the food itself, can be used to meet energy goals above maintenance needs.

Ideally, specific foods could be used for different functions: creep, starter, grower, finisher, lactation and maintenance (Cheeke, 1994). In most instances, however, commercial rabbit producers find it impractical to use more than one food. Thus, a single commercial pellet is typically fed to the entire rabbit colony. Adjustments for increased consumption of food above normal must be made for pregnant and lactating animals. Similar techniques may be used for pet rabbits.

Compared with many other mammals, rabbits have a high water intake. Rabbits drink about 120 ml/kg body weight daily (Cheeke, 1994), and even more during lactation and hot weather.

Selected Nutritional Diseases

Although nutrient requirements of rabbits have been summarized in numerous studies (Cheeke, 1987, 1994, 1995; Cheeke et al, 1987; Lebas, 1987; Fraser, 1991), data about specific requirements are limited. However, the major nutritional problems of rabbits are not specific nutrient deficiencies or imbalances, but rather disturbances in digestive tract function (enteric disease) associated with dietary factors (Cheeke, 1994; Harcourt-Brown, 2002; Brooks, 2004) or with malocclusion of teeth.

Malocclusion

Anorexia is a common clinical presentation of pet rabbits. Malocclusion of the teeth is a likely cause. Because rabbit incisor teeth are open-rooted, a developmental defect in the normal appositional anatomy precludes normal wear; thus, overgrowth of the teeth occurs (**Figure 70-1**). Overgrown incisor teeth may limit or prevent prehension of food and can traumatize the oral mucosa. A complete physical examination of rabbits should always include an evaluation of the oral cavity, including the molar teeth. Maloccluded incisor teeth need to be trimmed using either a high- or low-speed dental handpiece every four to six weeks or may need to be extracted (Crossley and Aiken, 2004). Specialized dental equipment, including speculums, mouth gags and long-shank dental burrs are available for use in rabbits. Endoscopic equipment can also be used to examine the oral cavity and teeth (Crossley and Aiken, 2004).

Rabbit molar and premolar teeth may also be maloccluded. Although maloccluded molar teeth are often floated with a fine file or their sharp points clipped off with a rongeur, ideally dental drills (low speed) should be used to remove the points (Crossley, 2003).

Trichobezoars

Gastric obstruction by a trichobezoar is another common cause of anorexia in rabbits (**Figures 70-2** through **70-4**). Hairballs are common incidental findings in rabbit necropsies, even among shorthaired breeds. The rabbit's inability to vomit and the small pyloric lumen predispose to hair accumulation in the stomach. The primary inciting factor for development of trichobezoars is intestinal hypomotility. Diets low in indigestible

fiber and high in carbohydrates predispose to GI hypomotility and retention of hair and food in the stomach (Harcourt-Brown, 2002; Jenkins, 2004). A definitive diagnosis can be difficult. Occasionally, the stomach can be palpated in the cranial abdomen as a large, doughy mass. Fecal pellet production is frequently reduced or absent, and those that are passed are smaller than normal. Survey radiography may reveal an enlarged stomach with displaced intestines. Contrast radiography may aid the diagnosis. A large, ingesta-filled stomach in a rabbit that has been anorectic for four to seven days suggests gastric stasis. A definitive diagnosis requires exploratory laparotomy; however, given the risk of surgery in these compromised patients, a presumptive diagnosis is often made based on response to treatment (Jenkins, 2004).

Medical treatment strategies emphasizing rehydration of the patient and stimulation of gastric motility have been developed with very good results (Hernandez-Divers, 2005). Force-feeding fluids, vegetable purees or commercial products (Critical Care for Herbivores[c]) is often indicated, as is administration of subcutaneous fluids, or if the patient is hospitalized, intravenous fluids (Jenkins, 2004). Additional treatments may include administration of an appropriate systemic antibiotic, gastric motility stimulants and surgery if the rabbit fails to respond to medical management. Although feeding fresh pineapple juice (10 ml/day) (which contains the enzyme bromelain), papaya tablets (which contain papain) or proteolytic enzymes have been reported to aid breakdown and passage of trichobezoars, the response to such treatments is equivocal (Jenkins, 2004) and no longer recommended as a treatment strategy. Hairballs or gastric stasis in rabbits can generally be prevented by feeding foods with adequate fiber (>14% DM crude fiber), minimizing stress and boredom, frequent grooming and providing adequate exercise (Carpenter et al, 1995).

Mucoid Enteropathy

Pet rabbits are also commonly presented with diarrhea, for which there are several differential diagnoses. Mucoid enteropathy is a GI disorder that is paradoxically characterized by constipation and diarrhea (Gentz et al, 1995; Jenkins, 2004), and by anorexia, lethargy, weight loss, cecal impaction and excessive production of mucus in the digestive tract (Lelkes and Chang, 1987). The cause of mucoid enteropathy is still under investigation, but the disease appears to be caused by changes in cecal pH that result from disruptions in the normal cecal flora (Lelkes and Chang, 1987; Jenkins, 1993). It likely occurs secondary to microbial alterations caused by hyperacidic cecal pH (Lelkes and Chang, 1987). A food containing about 20% crude fiber seems to maintain an optimal cecal pH to prevent changes in the normal microbial flora.

Mucoid enteropathy generally occurs in young rabbits, typically those just beyond weaning age (seven to 14 weeks) (Jenkins, 1993, 2004). It is rarely encountered in rabbitries that feed a high-fiber ration and avoid grains, simple carbohydrates and excesses of proteins or fats. Treatment includes feeding a high-fiber food (alfalfa hay) or syringe feeding a vegetable baby food (Jenkins, 1993) containing no additional sugars. In some cases, metoclopramide stimulates gastric emptying and apparently improves cecal activity. Fluid therapy to correct fluid and electrolyte imbalances is a priority to counteract losses that accompany the diarrhea (Gentz et al, 1995). Other treatment recommendations have been previously reported (Gentz et al, 1995; Jenkins, 2004).

Enterotoxemia

Enterotoxemia is one of the most common diseases of rabbits seen in clinical practice. Enterotoxemia is caused by the toxin produced by *Clostridium spiroforme* (Jenkins, 2004). Rabbits, particularly those recently weaned, are sensitive to foods high in sugars and starches (Gentz et al, 1995). Feeding these foods has been associated with at least some cases of enterotoxemia. Weanlings have an undeveloped population of normal GI flora and a high gastric pH, which allows proliferation of *C. spiroforme*. Nutritional counseling, therefore, is an important part of rabbit medicine, especially because many rabbit owners think lettuce, carrots and sugary treats are an appropriate diet for their animals.

Obesity

Many household rabbits have limited opportunities for exercise with almost unlimited access to palatable foods. Therefore, obesity is common in pet rabbits.

Because rabbits vary widely in body size, optimal body weights are difficult to estimate. Frequent weighing of each rabbit and recording the results in the medical record are important components of a preventive medicine program. Owners can be shown gradual increases in their rabbit's weight from medical records and the need for intervention. Systems for body condition scoring have not been published for rabbits and would be a welcome addition to preventive medicine programs.

Because rabbits use fiber efficiently, obesity may occur even when high-fiber foods are fed. However, weight control may be achieved by limiting the quantity of food offered. The amount of food offered should be reduced gradually, perhaps 10% every two weeks, until the amount fed maintains the desired body weight and condition.

Vitamin Deficiency and Toxicosis

Although cecal microbes synthesize B-complex vitamins and vitamin K and the rabbit obtains them via cecotrophy, manufacturers may add all of the essential vitamins to commercial foods. The requirement for vitamin D may be low because rabbits readily absorb calcium and phosphorus (Cheeke, 1995).

Signs of vitamin D toxicity include progressive emaciation and weakness, loss of appetite, diarrhea and paralysis. Soft tissues (i.e., liver, kidneys, artery walls and muscle) may become extensively calcified (Cheeke, 1995).

Vitamin A deficiency and excess may lead to reproductive disturbances. Low conception rates, fetal resorption, low survival of newborn kits and hydrocephalus in fetuses occur with toxic levels. Toxicosis is generally associated with adding synthetic vitamin A to foods that contain high levels of good-quality alfalfa

Table 70-6. Energy and nutrient contents of foods commonly fed as snacks to rabbits and rodents.*

Food items	Weight (g)	Water (%)	Energy (kcal/g)**		Protein	Fat	Carbohydrate	Fiber	Ca	P
			(As fed)	(DM)

(Cheeke, 1995). Vitamin A-deficient rabbits exhibit poor growth, leg deformities, increased susceptibility to disease (e.g., enteritis) and hydrocephalus (Cheeke, 1995; Brooks, 2004).

Little information is available about the vitamin E requirements of rabbits. Signs of deficiency include muscular dystrophy, with paralysis of the hind legs, reproductive failure and neonatal death (Cheeke, 1995).

Feeding Plan

A diet commonly recommended by veterinarians for pet rabbits is a commercial high-fiber (at least 18 to 22% DM), pelleted food containing 12 to 16% DM crude protein, fed at the rate of one-fourth cup/2.3 kg body weight, divided into two daily meals (Carpenter, 2003; Cheeke, 1995; Jenkins, 1991). Although alfalfa-based pellets may be appropriate for growing rabbits, timothy hay-based pellets are recommended for adult rabbits because they contain less protein and calcium than alfalfa. Although some rabbits may be offered pellets free choice, many adult rabbits fed in this manner may become obese or fail to consume an adequate amount of loose hay.

Loose hay (mixed grass hay, timothy hay or dried grass clippings), should be provided free choice (Jenkins, 1991; Kupersmith, 1998). Alfalfa hay can be offered throughout the growth stages, but then should be discontinued because it contains higher than needed protein and calcium levels.

The diet should be supplemented with judicious amounts of thoroughly washed leafy greens (romaine lettuce, kale, mustard greens, carrot tops, parsley and dandelion greens) and fresh vegetables (carrots, broccoli, green peppers, cauliflower and cabbage). Dark greens with a low oxalate content should be selected (Kupersmith, 1998). In addition, rabbits may be fed a small amount (up to one tablespoon/2.3 kg body weight) of fresh fruit (strawberries, other berries, apples) daily or several times per week. Amounts of these palatable snacks should be limited because all are nutritionally incomplete and may cause a dietary imbalance (**Table 70-6**). Rabbits should not receive sugary treats, crackers, bread, rolled oats or breakfast cereals, which can cause abnormal fermentation in the gut and an overgrowth of certain bacteria resulting in serious, often fatal diarrhea.

Because rabbits are perhaps the most efficient converters of poorly digestible materials to animal flesh, their nutritional requirements can be met with any good quality hay supplemented with fresh greens (Jenkins, 1999). Therefore, some veterinarians are proposing that a diet of hay and fresh greens may satisfy the nutritional needs of house rabbits and minimizes the chance of diet-induced disease (Jenkins, 1999).

Practitioners often receive telephone calls regarding the feeding of wild orphaned bunnies. Ideally, if the orphaned bunny is deemed healthy, it should be returned to its environment if at all possible. Exceptions to this include if the bunny is smaller than the size of a tennis ball and its mother is known to be dead, or if the patient is not in good health. If hand-rearing is required, the patient should be thoroughly examined and medical problems such as hypothermia and dehydration should be rectified before feeding (Taylor, 2002). Hand-raising of wild bunnies should be done by licensed, trained rehabilitators. Feeding guidelines for orphaned bunnies are available (Sleeman, 2005; Taylor, 2002).

Other dietary recommendations for rabbits include:

- Because of the rabbit's intestinal microflora, food changes should be introduced gradually (over four to five days). For some rabbits with sensitive GI tracts, food changes may need to be made over a 10-day period (Harkness and Wagner, 1989). This is especially true for four- to 12-week-old rabbits. Current and new foods should be mixed 75:25 to begin the conversion. Quantities of the new food can then be increased gradually every few days.
- High-energy foods may increase susceptibility to mucoid enterotoxemia.
- Purchase small quantities of pellets at a time to prevent nutrient losses. Use pellets within 90 days of milling. Pellets can be stored in the freezer to reduce nutrient loss and spoilage.
- Clean, fresh water should be available at all times.

RODENTS

Introduction

The approximately 1,700 species of rodents in existence today represent over one-half of the total species of living mammals. The order Rodentia is divided into three suborders (sciuro-

morph, myomorph and hystricomorph) based primarily on variations in the origin of the masseter muscle. The word rodent originates from the Latin verb "rodere," to gnaw. Rodents are identified by their four prominent continuously erupting (hypsodontic) incisor teeth, which are frequently orange or yellow. Canine teeth are absent, and a gap, or diastema, exists between the incisor and cheek teeth. All rodents have six upper and six lower molar teeth, which may be either open- or closed-rooted, depending on the species. The presence or absence of premolar teeth is also species dependent.

Understanding rodent dentition is important because malocclusion and overgrowth of open-rooted teeth are common clinical problems, with sequelae such as weight loss, malnutrition and oral mucosal ulcerations. Normal gnawing behavior occurs when a rodent holds an object, frequently with the assistance of the forefeet, against the immobile upper incisor teeth and then shears with lateral to medial movements of the lower incisor teeth and jaw. During the gnawing process, the rodent moves the lower jaw forward, allowing apposition of incisor teeth but preventing occlusion and abrasion of cheek teeth. By withdrawing the cheek into the diastema, the rodent can compartmentalize the gnawed material into the cranial portion of the oral cavity, thus allowing for lengthy periods of gnawing without necessarily swallowing the gnawed material. During the chewing process, the lower jaw moves caudally to bring upper and lower cheek teeth into apposition. The complex muscles and anatomic variations in the associated skull bones, which allow for such specialized jaw movements, are a primary means of classifying rodent species (Sainsbury, 2003).

Although veterinarians may be presented with some very unusual pet rodents for examination, diagnosis and treatment of health problems, the most commonly seen pet rodents are guinea pigs (*Cavia porcellus*), chinchillas (*Chinchilla laniger*), hamsters (multiple species), Mongolian gerbils (*Meriones unguiculatus)*, rats (*Rattus norvegicus*) and mice (*Mus musculus*). Rodents are intelligent, relatively inexpensive to purchase and maintain and require little space. Unfortunately, however, owners are frequently unaware of specific husbandry requirements until problems resulting from conditions such as improper caging, poor nutrition and water deprivation become evident. A thorough history about husbandry practices can provide invaluable clues to the clinician when trying to address an owner's concerns.

Cage Requirements

Proper caging is a critical aspect of rodent husbandry. This requirement should be considered when assessing suspected nutritional problems. Inadequate housing, poorly positioned food and water dispensers, dirty cages and a stressful environment can contribute to problems such as anorexia and dehydration. A variety of cages are available in pet stores, and one should be selected carefully, keeping in mind the characteristics of the species for which it will be used. In general, cages must be escape-proof and predator-proof, provide adequate ventilation, minimize the possibility of trauma, have mounted sipper bottles and provide adequate floor space.

Cages are typically constructed of metal, glass or plastic. Wood should not be used for caging rodents because it can be gnawed and is difficult to disinfect. Solid flooring is preferred to wire because it minimizes potential limb trauma and pododermatitis; however, it is more difficult to keep clean. Wire flooring can be used successfully if it is of proper mesh size and a portion of the cage contains solid flooring.

Bedding should be nonabrasive, nontoxic, clean, absorbent, inedible, dust-free and capable of being made into nests. Various medical problems have been associated with some frequently used bedding materials. Cedar shavings have been associated with dermatopathies and pulmonary and hepatic changes. Pine may affect hepatic enzyme activity. Hardwood shavings such as aspen and shredded nontoxic paper are the most commonly recommended bedding materials. Gerbils, hamsters and mice apparently prefer larger amounts of bedding than do guinea pigs, chinchillas and rats (Harkness, 1993). Frequency of cage cleaning and replacement of bedding varies with rodent type and cage.

Environmental enrichment in the form of nesting material, cage toys and different food items can be used to enhance the lives of laboratory and pet rodents, again keeping in mind the behavioral characteristics of the particular animal. Providing opportunities to forage allows animals to engage in natural behavior and can prevent boredom and provide exercise (Baumans, 2005).

Common Aspects of Rodent Nutrition

Although little research has concerned pet rodents specifically, the popularity of rodents as laboratory animals has led to extensive nutritional studies. Nutrient requirements for laboratory rodents serve as initial guides to the nutrient requirements of pet rodents (**Table 70-7**) (NRC, 1978).

Coprophagy

Most rodents are coprophagous, and fecal pellets are frequently ingested directly from the anus. Generally lighter, softer feces (cecotrophs) are selectively ingested. These feces are produced in the cecum and contain important B-complex vitamins and protein. Young rodents ingest maternal feces, thereby inoculating their own intestinal tracts with autochthonous flora (Clark, 1984; Manning et al, 1984).

Anorexia, Weight Loss and Dehydration

Clinical problems related to anorexia, weight loss, dehydration or a combination of these factors are frequently observed in pet rodents. Common etiologies include husbandry-related factors such food and/or water deprivation, inability to reach or manipulate food or water utensils, inappropriate diet, sudden dietary changes, poor hygiene, overcrowding, inadequate temperatures and other environmental stressors (Harkness, 1993).

Careful and tactful questioning by the clinician is necessary for the client to realize or admit to the presence and significance of inadequate husbandry practices. If possible, the client should bring the rodent and its entire cage to the veterinary visit for a more thorough assessment of the animal's environment.

Following a complete physical examination, basic diagnostic

Table 70-7. Estimated nutrient requirements of laboratory rodents.* Some of these values were determined by rigorous comparative trials, others by examination of foods known to suffice for specific species. The data presented here are intended to be used only as starting points. The literature cited should be consulted for more information.

**Minimum protein requirements were determined with animals fed purified and semi-purified diets containing casein as a protein source. For animals fed commercial foods comprised of complex ingredients and relatively lower digestibilities, dietary protein should be higher.
***To convert to kJ, multiply kcal by 4.184.

studies such as complete blood counts, biochemistry profiles, radiographs and fecal examinations should be conducted whenever possible to rule out malocclusion, GI disease and other primary disease problems. Fecal culture and abdominal ultrasound are also often useful.

The prognosis for an anorectic, dehydrated rodent with significant weight loss is guarded. Supportive care includes administering oral, subcutaneous, and/or intraperitoneal fluids and offering a variety of sweetened foods or treats to encourage food intake. Many rodents will also tolerate gentle force-feeding. Pelleted rodent feed may be blenderized with water and appropriate supplements such as yogurt, vegetable baby foods or both. Alternatively, liquid enteral products formulated for people or pets may be fed without supplementation.

Feeding is best accomplished by wrapping the animal gently in a towel, placing the feeding syringe into the diastema, expressing small volumes into the oral cavity and allowing the animal to swallow. One-ml syringes can be used to feed mice, and 3- to 10-ml catheter-tipped syringes used to feed larger rodents. Owners can be shown how to feed their pets at home; however, they must be able to recognize when the animal is responsive enough to allow force feeding, to minimize potential problems with aspiration. Small meals should be fed several times throughout the day.

Malocclusion

Malocclusion is another common clinical problem in pet rodents. The incisor teeth are usually involved, although the cheek teeth may also be maloccluded, depending on the species. Etiologies include genetic, dietary, infectious and traumatic factors. Overgrown teeth can result in tongue and oral ulcers, ptyalism, anorexia and weight loss. An oral examination is an important but often difficult component of a rodent physical examination. An otoscope may help visualize cheek teeth, but the patient may require sedation for the procedure. Skull radiographs are also useful for assessing severe malocclusion and tooth root abscesses. Specialized equipment, including specula, mouth gags and long-shank dental burrs, are available for use in rodents.

Inhalant anesthesia, preferably isoflurane administered through a facemask, is adequate for short dental procedures, such as trimming incisor teeth. The animal is masked down and the mask is removed when the animal attains an appropriate level of anesthesia. Its mouth is held open with a specialized speculum or gauze strips around the upper and lower incisors, and the incisor teeth are cut quickly, preferably with a high-speed dental drill. A variable-speed, rotary power tool with a circular cutting blade (Dremel Moto-Tool[d]) can also be used. Care should be used not to injure the tongue and surrounding tissues. Although sharp clippers have been used to trim the teeth of smaller rodents, teeth may split or shatter with this method; therefore, this technique is not recommended. Inhalant anesthesia delivered by facemask may be challenging for lengthier dental procedures on cheek teeth, which may require clipping with bone rongeurs or, preferably, using a guarded flat or taper fissure burr in a straight, low-speed dental handpiece (Quesenberry, 1994; Harkness and Wagner, 1995; Crossley and Aiken, 2004). Injectable anesthesia may be required for these procedures because small rodents are very difficult to intubate.

Rodents with chronic malocclusion problems may need teeth trimming every few months. Owners should monitor animals for anorexia and drooling. Breeding rodents with malocclusion problems should be discouraged.

Guinea Pigs

Husbandry

Domestic guinea pigs belong in the Caviidae family, which consists of short-tailed or tailless rodents that have one pair of mammary glands, four digits on the forefeet and three digits on the hindfeet. The most commonly seen breeds are: 1) the Shorthair or English, which has very uniform short hair, 2) the Abyssinian, which has a coat arranged in whorls or rosettes and 3) the Peruvian, which can have a coat several inches long. Various coat colors and multicolored patterns also exist for each species. Pet guinea pigs live for five to seven years and weigh 450 to 750 g. Gestation averages 68 days, and litter size ranges from two to four young (Clark, 1984; Anderson, 1987; Quesenberry et al, 2004).

Guinea pigs are herbivores with simple stomachs. Their teeth are open-rooted and erupt continuously. The dental formula is I1/1, C0/0, P1/1 and M3/3. The incisors are white unlike that of other rodents, which normally have yellow incisors. Guinea pigs have a long digestive tract with a gastric emptying time of approximately two hours and a total GI transit time from eight to 20 hours. Normal GI flora consists primarily of *Lactobacillus* and occasionally *Streptococcus* spp., yeast and soil bacteria (Manning et al, 1984; Harkness and Wagner, 1995a). Much of the digestive process occurs in the cecum, which is a thin-walled sac divided into numerous lateral pouches by smooth muscle bands (taenia coli). The cecum is normally found on the central and left side of the abdomen and may contain as much as 65% of the GI contents (Richardson, 1992; Quesenberry et al, 2004). Guinea pigs are coprophagous.

Special Nutritional Needs

Guinea pigs, people and other primates are unable to synthesize vitamin C (ascorbic acid) because they lack the enzyme L-gluconolactone oxidase, which is needed to convert glucose to ascorbic acid. Adequate dietary supplementation is, therefore, critical to prevent hypovitaminosis C (scurvy), as detailed below. (See Feeding Plan.)

Guinea pigs display behavioral characteristics that influence their overall nutritional status. For example, they are extremely susceptible to stressful situations such as inadequate housing, moving into a new household or different cage and changing feeding schedules. Stressed guinea pigs may become anorectic and lose weight. Furthermore, guinea pigs do not tolerate dietary or environmental changes well. Guinea pigs develop dietary preferences early in life and do not adapt readily to change. For this reason, young guinea pigs should be exposed to different dietary items to allow them to become accustomed to variety (Quesenbery et al, 2004).

Proper housing accommodations can be provided by an open-topped enclosure at least 10 inches high, with a floor space of at least 101 square inches for an adult animal, and twice this floor space for a breeding sow. Either solid or wire flooring can be provided. Wire flooring allows for feces and urine to drop to the bottom of the cage. However, it may cause foot injuries and subsequent pododermatitis. Wire flooring should consist of a rectangular mesh 38 by 12 mm. At least a portion of the cage should have a solid bottom (Quesenberry, 1994). Solid floors with a substrate of shredded paper or hardwood shavings generally require more frequent cleaning but are preferable for pet guinea pigs.

Because guinea pigs are easily startled, the cage should be placed in a quiet area in the home to minimize exposure to sudden movements and loud noises. Ideally, a relatively constant

temperature between 18 to 24°C (65 to 75°F), and humidity between 40 and 70% should be maintained (Harkness and Wagner, 1995a). Elevated temperatures may cause heat stress. A cool, damp environment can predispose guinea pigs to respiratory diseases.

Additional behavioral characteristics of guinea pigs include their tendency to contaminate food and water dishes with excreta. Sipper bottles are preferred to minimize contamination of drinking water. However, guinea pigs can pass ingesta into sipper tubes. Guinea pigs also play with the end of the sipper tube, which may cause leaks, resulting in wet bedding and an empty water bottle. All food and water utensils should be cleaned and soiled bedding removed daily.

Any changes in access to food and water should be made gradually, over five to 10 days. Owners should also be cautioned to monitor for any signs of anorexia or decreased water intake when husbandry changes are recommended (Peters, 1991).

Common Nutritional Disorders

HYPOVITAMINOSIS C

Although quality commercial guinea pig foods are formulated with adequate vitamin C, hypovitaminosis C (scurvy) is still a common clinical problem because of this nutrient's lability during storage. Also, feeding guinea pigs rabbit food without providing additional vitamin C may cause scurvy. Because guinea pigs are incapable of storing vitamin C, scurvy appears within one to two weeks after a vitamin C deficient diet is fed. Death usually occurs within three weeks (Tobin, 1996; O'Rourke, 2004).

Guinea pigs with scurvy present with anorexia, bruxism, weight loss, an unkempt appearance and gingivitis. Affected animals are reluctant to move because of joint and muscle pain. Discomfort is apparent when limbs are palpated. Ascorbic acid is required for normal collagen formation; therefore, deficiencies primarily affect the musculoskeletal system. Sequelae include enlarged costochondral junctions, hemorrhage into muscles and joints and abnormalities in epiphyseal growth centers with subsequent pathologic fractures. Secondary infections, delayed wound healing and diarrhea may also be present. Subclinical vitamin C deficiency should be considered in any guinea pig presented with generalized illness. Young animals and pregnant sows are most severely affected (Harkness and Wagner, 1995; Peters, 1991).

Diagnosis of vitamin C deficiency is based on the history and clinical signs. Radiographs may reveal enlargement of long bone epiphyses and costochondral junctions.

Treatment involves parenteral supplementation with 50 to 100 mg vitamin C/kg body weight until clinical signs resolve (Quesenberry, 1994) one to two weeks after a vitamin C deficient diet is fed. Death usually occurs within three weeks (Tobin, 1996; O'Rourke, 2004). Oral vitamin C can then be initiated at the same dosage. Owners can supplement the diet with liquid pediatric vitamin C products obtained over-the-counter from pharmacies and supermarkets. (Appropriate dietary supplements are discussed in the Feeding Plan section.) Anorectic and dehydrated animals should receive supportive care such as fluids and forced alimentation as discussed in the Introduction to Rodents section. Client education about dietary requirements of guinea pigs plays a critical role in preventing this disease.

PREGNANCY TOXEMIA

Pregnancy toxemia or ketosis occurs primarily in obese, primiparous, anorectic, stressed guinea pig sows. Boars are also susceptible to ketosis, although obviously pregnancy is not a factor. Obesity and anorexia are the most critical inciting factors for the development of ketosis. Genetics may also play a role. The onset of clinical signs is abrupt and occurs within about five days (before and after) of parturition. Clinical signs include lethargy, ruffled coat, anorexia, prostration, muscle spasms and death.

Diagnostic tests may reveal hypoglycemia (perhaps terminal hyperglycemia), hyperlipidemia, ketonemia, hyperkalemia, hyponatremia, hypochloremia, proteinuria and urinary pH less than six.

Supportive care includes administration of fluids, 5% glucose given orally or intravenously, antibiotics and judicious use of corticosteroids if the animal is in shock. Caesarean section may be attempted to save the fetuses. Prognosis, however, is poor and treatment is generally unsuccessful. Preventing obesity in sows (preferably body weight <500 g), providing a good food, minimizing stress and avoiding fasting or undernutrition in late pregnancy will reduce the risk of pregnancy toxemia.

CECAL IMPACTION

Low fiber intakes (perhaps <10% DM crude fiber) predispose guinea pigs to cecal impaction. Prevention is best accomplished by providing adequate long-stem fiber in the form of chopped grass hay. Hay should be offered free choice, even when fiber-containing guinea pig pellets are fed.

SOFT-TISSUE CALCIFICATION

Guinea pigs are reportedly susceptible to a syndrome involving calcification of soft tissues, especially in the forelimbs. The syndrome is thought to be related to dietary levels of calcium, phosphorus, magnesium, potassium and vitamin D (Tobin, 1996). Means of prevention are unknown, but efforts should be made to restrict use of supplements and to maintain DM vitamin D levels below 2,000 IU/kg (Tobin, 1996).

Feeding Plan

FEEDING ADULTS

Guinea pigs are strict herbivores and should be maintained on a feed specifically labeled for the species. Commercial dry rabbit food, although similar in appearance, should not be used because it contains inadequate levels of protein and vitamin C.

Vitamin C

Adequate dietary vitamin C levels are critical for overall good health, and although commercial guinea pig foods are formulated with approximately 800 mg DM vitamin C/kg, low vitamin C intake is still a common problem due to the vitamin's lability. Heat, moisture and contact with metals hasten its deterioration

during storage. Ideally, guinea pig pellets should be stored at 22°C (72°F) and used within 90 days of milling (Quesenberry, 1994; Quesenberry et al, 2004). Consumers may have difficulty determining how long the product has been on the shelf at the time of purchase because: 1) the milling date is frequently not stated on the food container and 2) many pet stores buy feed in bulk and then repackage product for resale. Owners should therefore be encouraged to buy food in small quantities from a reputable pet store that has a relatively high turnover of food products and to store the food properly at home.

Guinea pigs require approximately 10 mg vitamin C/kg body weight daily for maintenance and 30 mg/kg body weight daily for gestation. If the freshness of guinea pig pellets is unknown, 200 mg/ml vitamin C can be added to the drinking water. However, the half life of this nutrient in clean, fresh water is only 24 hours, and shorter if organic debris is present or if metal containers are used. Vitamin C can also be given orally on a daily basis using human pediatric vitamin C formulations (Quesenberry, 1994). Daily feeding small amounts of vegetables with a high vitamin C content such as red or green peppers, tomatoes, spinach and asparagus can augment vitamin C intake. Excess ingested vitamin C is excreted rapidly in the urine, with 80% of the ingested amount being eliminated in three days. Fresh vegetables should be thoroughly rinsed to minimize potential pesticide contaminants and bacterial pathogens such as *Salmonella* spp. (Harkness, 1993a).

Protein, Fiber and Water

Commercial guinea pig pellets contain approximately 20% DM crude protein and 9 to 18% DM crude fiber. For an adult guinea pig, average daily food consumption is 6 g/100 g body weight and average daily water consumption is 10 ml/100 g body weight (Harkness, 1993a). Because guinea pigs are such fastidious eaters, owners should be discouraged from frequently changing brands of food to avoid anorexia. High-quality timothy or grass hay should be available at all times (Quesenberry et al, 2004). Oral lesions may occur if the hay is too coarse. Secondary infection of these lesions with beta-hemolytic *Streptococcus* spp. can lead to cervical lymphadenitis and abscess formation. Owners who allow their guinea pigs access to the yard should also be forewarned about possible herbicide/pesticide exposure. Overgrazing on lush lawns or fresh grass clippings can result in diarrhea. The recommended diet for guinea pigs is comprised of guinea pig pellets and high-quality grass hay supplemented with fresh vegetables.

FEEDING NEONATES

Newborn guinea pigs are precocious, with teeth, a full coat and open eyes. Birth weights vary from 60 to 100 g. Neonates weighing less than 50 to 60 g rarely survive. Birth weight is related to genetic characteristics and maternal nutritional status, and is directly proportional to gestation length and inversely proportional to litter size. Neonatal guinea pigs remain close to the sow but generally will not nurse for the first 12 to 24 hours and, therefore, should not be force fed during this time. Neonates usually begin eating solid food at four to five days of age (i.e., guinea pig chow softened with cow's milk or water). If several lactating sows are present, the young may nurse alternately among them. In this case, the smaller piglets must be monitored to ensure that they nurse adequately. Weaning age varies from 14 to 28 days when body weight reaches 150 to 200 g. Average daily weight gain should be 2.5 to 3.5 g daily until 60 days of age (Manning et al, 1984).

Chinchillas

Husbandry

Chinchillas belong in the Chinchillidae family and are closely related to guinea pigs. Chinchillas originate from the rocky slopes of the South American Andes, where they were nearly hunted to extinction in the early part of the 1900s because of their prized pelts. A small group of chinchillas brought to the United States at that time were successfully bred in captivity and are progenitors for the majority of today's pet population.

Chinchilla breeds are characterized by their coat color, which in the wild is a smoky blue-gray. Other color variations represent mutations. The normal coat is thick and soft, an attribute that often masks problems such as weight loss. Adult chinchillas weigh from 400 to 600 g and have an average life span of 10 years, with a maximum up to 20 years. The average gestation period is 111 days, and average litter size is two, with a range of one to six. The dental formula is I1/1, C0/0, P1/1 and M3/3. All teeth are open-rooted. Incisor teeth grow 6.2 to 7.6 cm per year (Hoefer, 1994; Quesenberry et al, 2004).

Chinchillas are hindgut fermenters and have a long alimentary tract, measuring more than 3.5 m in adult animals. The proximal colon is sacculated and communicates with the large thin-coiled cecum. The longer distal colon is smooth (Williams, 1979). Chinchillas are also coprophagic. Chinchillas ingest more than 70% of their total food intake at night (Quesenberry et al, 2004).

Proper housing is a critical factor for a chinchilla's overall well being. The animal's native environment includes a relatively low temperature and humidity and a sloping, hard, rocky habitat that requires that chinchillas jump from one crevice to another. Chinchillas should therefore be housed in a large (minimum of 1,650 cm^2 floor area per animal), multilevel cage to accommodate normal, active behavior. If wire mesh flooring is used, the mesh size should be small enough to prevent leg entrapment. Some areas of solid flooring should be provided to minimize foot lesions. The optimal temperature range is 16 to 21°C (60 to 70°F). Temperatures as low as 0°C (32°F) can be tolerated if the animal has been acclimated. Temperatures greater than 27°C (80°F) can result in heatstroke, particularly in the presence of high humidity (Quesenberry et al, 2004).

Chinchillas are fastidious groomers and should be provided with a dust bath for a short time (30 to 60 minutes) each day. Keeping the dustpan dish in the cage continuously results in fecal contamination of the dish and subsequently of the coat, and can lead to conjunctivitis. Dust can be obtained commercially and consists of a mixture of 9:1 silver sand to Fuller's earth (Jenkins, 1992; Hoefer, 1994).

Because chinchillas are hindgut fermenters, they have complex digestive processes for fermenting dietary fiber. Any disruption of these processes can result in diarrhea, constipation, mucoid enteritis, bloat, intussusception and rectal prolapse. Inappropriate foods and sudden food changes are common causes of these problems. Inappropriate foods include those that contain high levels of simple carbohydrates and protein or not enough fiber. Such foods alter cecal fermentation processes with subsequent changes in pH, motility and flora, resulting in enteritis. Any change in the normally gram-positive GI flora can lead to overgrowth of bacteria such as *Escherichia coli* and *Clostridium, Proteus* and *Pseudomonas* spp. Therefore, antibiotics such as ampicillin, amoxicillin, penicillin, cephalosporins, clindamycin, lincomycin and erythromycin should be avoided (Ness, 2005). Other causes of enteritis include *Salmonella* spp., *Giardia lamblia, Cryptosporidium* spp., coccidia and nematodes (Williams, 1979; Jenkins, 1992; Hoefer, 1994; Donnelly, 2004b). Unfortunately, the exact cause of gastroenteritis frequently remains undetermined, thus subsequent treatment is symptomatic, including administration of fluids, dietary changes (adding fiber) and appropriate antibiotics.

Few integumentary disorders of chinchillas are directly associated with specific nutrients. Fatty acid deficiency leads to a poor coat, skin flaking and possibly cutaneous ulcers. Zinc deficiency can result in alopecia (Scott et al, 1995).

Feeding Plan

FEEDING ADULTS

Specific nutrient requirements for chinchillas have not been well established. With the exception of being placentophagic, chinchillas are considered to be strict herbivores and subsist in the wild on shrubs and grasses. Controversy exists among various authors as to what type of feeding plan is most suitable for captive animals. All recommendations reflect a high overall dietary fiber requirement. Experts generally agree that good nutritional status can be achieved by feeding a combination of pellets and free-choice, good-quality grass or timothy hay. Commercially available chinchilla pellets are preferred to guinea pig and rabbit pellets because of formulation and size differences. Because chinchillas often use their forefeet to hold their food, the shape and size of the pellets affect ease of food handling and amount of wastage. Pellets should consist of 18 to 20% DM crude protein, 15 to 35% DM crude fiber and 4% DM fat.

Adult chinchillas eat an average of 21 g of food per day. Only one to two tbs of pellets should be fed per day, because overfeeding may cause enteritis. High-quality grass hay should be available free choice. Treats such as fresh fruits, vegetables and nuts can be offered occasionally but should be limited to not more than 1 tsp per day (Harkness, 1993b; Hoefer, 1994; Quesenberry et al, 2004). Fresh water in clean sipper bottles should always be available.

FEEDING NEONATES

Newborn chinchillas are precocious and weigh 30 to 50 g. They generally begin eating pelleted food at one week of age, and are completely weaned by six to eight weeks. Orphaned neonates can be hand-reared or fostered onto other chinchillas, and can survive independently after two to three weeks of age. Two reportedly successful hand-feeding formulas vary markedly. One is a mixture of one part unsweetened condensed milk and two parts water. The other is a mixture of one-half water, one-half evaporated milk, with glucose added to achieve a final concentration of 25% (Williams, 1979; Kraft, 1987). Milk replacers, however, may be a better alternative to condensed or evaporated milk.

Hamsters

Husbandry

Hamsters are rodents in the Cricetidae family. There are many species of hamsters. The most commonly seen are the golden or Syrian hamster (*Mesocricetus auratus*), the Chinese hamster (*Cricetulus griseus*) and the dwarf hamster (*Phodopus sungorus*). Hamsters were introduced into the United States in 1938 for research purposes.

Although hamster species vary markedly, male and female adults weigh 85 to 130 g and 95 to 150 g, respectively. Females tend to be larger and more aggressive than males. Life spans are relatively short and average from 18 to 24 months. The gestation period is 15 to 16 days. Litter size ranges from five to nine. Young are born without hair, with eyes and ears closed, but with erupted incisor teeth. The dental formula is I1/1, C0/0, P0/0 and M3/3. Incisor teeth grow throughout life; however, molar teeth are closed-rooted. Hamsters possess large cheek pouches that are used to transport and store food. When alarmed, hamsters will also temporarily store their young in these pouches. The stomach is divided into glandular and nonglandular portions. The nonglandular forestomach is lined with keratinized epithelium and is the site of pregastric fermentation (Van Hoosier and Ladiges, 1984; Battles, 1991). Like rabbits and many rodents, hamsters are coprophagic.

Hamsters are nocturnal animals. Although they are not true hibernators, hamsters enter a period of "pseudohibernation" from which they can be aroused, when exposed to shorter day lengths and temperatures below 4.4°C (40°F). In the wild, hamsters are solitary animals that live in burrows. Hamsters are very active at gnawing and escape by chewing through cages or by pushing open cage lids. Subsequent ingestion of inappropriate household items can lead to serious GI problems. Therefore, proper caging, as with other rodents, is critical to the overall well being of these animals.

Cages for adult hamsters should have a floor space of at least 125 cm^2 and a height of at least 15 cm. The traditional slotted metal food hoppers that are placed on top of the cage and frequently used for rats and mice are generally inappropriate for hamsters. The flat face of these pets makes it difficult for them to retrieve food items. If slotted metal food hoppers are used, the slots should be at least 7/16 in. wide. Clean water in a sipper bottle should always be available and the bottle should be placed low enough for the hamster to reach. The recommended environmental temperatures for hamsters are 18.3 to 21.1°C (65 to 70°F). Relative humidity should be between 30 and 70%

(Wagner and Farrar, 1987; Harkness, 1993c).

Acute enteric diseases are common problems among hamsters, especially weanlings. Underlying causes often remain unknown; however, stress, inadequate diet and improperly positioned feeders are often contributing factors. Processed feed should have a minimum of 8% crude fiber content to prevent diarrhea. An intracellular bacterium, *Lawsonia intracellularis*, is the causative agent of proliferative ileitis diarrhea or "wet tail;" however, *Escherichia coli*, *Clostridium* spp. or *Bacillus* spp. may also be involved. Rapid weight loss, dehydration and staining of the perineal region are present clinically. Other possible sequelae include intestinal blockage, prolapse and intussusception. Administration of inappropriate antibiotics (e.g., penicillin, ampicillin, lincomycin and bacitracin) can result in overgrowth of *Clostridium difficile* and a subsequent fatal enterocolitis (Harkness, 1993c).

The prognosis for hamsters presenting with signs of enteritis is generally guarded. Treatment involves supportive care such as administration of fluids subcutaneously or intraperitoneally, appropriate antibiotics (e.g., trimethoprim-sulfadiazine, chloramphenicol or enrofloxacin) and oral bismuth salicylate. Hamsters with enteritis should be hand-fed and placed in a warm environment.

Few reports document specific nutrient deficiencies in hamsters. Generalized alopecia and skin problems have been associated with low protein (<16%) and with deficiencies in pantothenic acid, riboflavin, pyridoxine, niacin, fatty acids and copper. Vitamin E deficiency can lead to muscular weakness, ocular secretions and death. Hamsters fed foods high in polyunsaturated fat are more susceptible to vitamin E deficiency and subsequent muscular dystrophy (Harkness, 1993c; Scott et al, 1995).

Feeding Plan

Specific nutrient requirements for hamsters have not been well established. In the wild, hamsters are omnivorous, ingesting a variety of plants, seeds, fruits and meats. Pelleted rodent foods that provide 16 to 20% crude protein appear to provide good growth rates, whereas those containing 8 to 12% crude protein appear to be inadequate. Hamsters tend to ingest fruits, nuts, cereals and prepackaged "rodent treats" preferentially to the more nutritionally balanced rodent foods; therefore, these items should be provided in limited quantities. Adult food consumption averages 15 to 20 g/day (Harkness, 1993c).

Pregnant and lactating females have markedly increased food consumption. A one-week supply of food should be placed in the cage at about the Day 13 of gestation to minimize disturbances during parturition. Food should be placed on the cage floor rather than in a hopper to minimize the dam's distraction with food gathering, which may result in neglect of the young. This practice also allows easier access to food for pups as they approach weaning. Pups should also have easy access to the water bottle, and they should be observed closely to ensure that they can pull hard enough on the sipper tube to obtain water. Neonatal hamsters are altricial, and have birth weights from 2 to 3 g. Young begin gnawing on solid food at seven to 10 days of age and are weaned around 21 days. Weaning weights average 35 g. Attempts at hand raising or cross-fostering of orphaned hamster neonates onto other rodent species are generally unsuccessful (Wagner and Farrar, 1987).

Gerbils

Husbandry

Gerbils are rodents in the Cricetidae family. The Mongolian gerbil is the most common pet species. A frequent color pattern is agouti or brown; however, other color variations such as black, white and cinnamon also exist. Gerbils are social, burrowing animals native to the desert regions of central Asia. As pets, they are generally friendly and easily handled. Because of their water conservation mechanisms, they produce only a few drops of urine daily and are, therefore, virtually odor free. Adult gerbils weigh from 55 to 100 g and have a life span of three to four years. Gerbils generally form monogamous pairs, which is unique among rodents. Gestation length is 24 to 26 days, with a litter of size of four to seven. Neonates are altricial. Approximately half of the pet gerbil population exhibits spontaneous, convulsive seizures that are induced by strange environments or excitement. Fatalities are uncommon and anticonvulsant therapy has not been recommended (Harkness, 1993d, Harkness, 1995a; Donnelly, 2004c).

Gerbils can be housed as described for hamsters. They also actively gnaw so cages need to be escape-proof. Adult gerbils should be provided with a minimum floor space of 230 cm^2 with sides at least 15 cm high. Temperatures should be maintained between 18 to 29°C (65 to 85°F) and humidity levels between 30 and 50%. Gerbils do not tolerate high temperatures and their coat appears greasy under conditions of high humidity (Wagner and Farrar, 1987).

Diarrhea can result from food changes, contaminants or deprivation and protozoal or bacterial infections, such as salmonellosis. Treatment is symptomatic as described for hamsters, because the specific etiology frequently remains undetermined.

Specific nutrient deficiencies are uncommon in gerbils fed commercial dry rodent food. Animals maintained on high-fat diets such as excessive amounts of sunflower seeds develop lipemia and hypercholesteremia with excess fat deposits throughout the body. However, atherosclerosis does not appear to occur under these conditions, which has made gerbils important in cardiac disease research. Weanling animals are especially susceptible to malnutrition and dehydration as a result of poor accessibility to food and water (Wagner and Farrar, 1987).

Feeding Plan

In the wild, gerbils feed on plants, seeds and insects. In captivity, they should be fed a commercial dry rodent food that is suitable for gerbils, offered free choice. Gerbils maintained on a standard rat or mouse diet for longer than six months may develop periodontal disease (Donnelly, 2004c). Gerbils will ingest seeds preferentially, which results in a diet high in fat and low in calcium. Gerbils generally eat about eight meals per day, with a total food consumption of 5 to 8 g/100 g of body weight. Because they eat frequent small meals, rapid weight loss occurs

if food quantities are limited. Clean water in easily accessible sipper bottles should always be available. Young gerbils generally begin eating solid food at 14 to 16 days of age and are weaned at 20 to 26 days. Dry rodent food can be softened with water for weanlings (Harkness, 1993d).

Rats

Husbandry

The common pet rat belongs in the Muridae family and originated in central Asia. Adult female and male rats weigh from 250 to 300 g and 450 to 520 g, respectively. The average life span ranges from 2.5 to 3.5 years. The gestation period is 21 to 23 days, and litter size ranges from six to 12. The rat's dental formula is I1/1, C0/0, P0/0 and M3/3. Incisor teeth erupt continuously, but molar teeth are permanently rooted. Rats have a divided stomach, a large cecum, no gallbladder and a GI transit time of 12 to 24 hours.

A variety of cages, usually constructed of plastic or metal, are available in pet stores. General guidelines for optimal caging were discussed previously. (See Rodents, Cage Requirements.) Cages should be made escape-proof because rats are adept at chewing through cages, lifting lids and opening small cage doors. Adult rats should be provided with a minimum of 250 cm^2 of floor space and a cage height of 18 cm. Ambient temperatures should be 18 to 27°C (65 to 80°F) with an optimum temperature of 22°C (72°F). Relative humidity should be maintained at 40 to 70% (Kohn and Barthold, 1984; Harkness, 1993e).

The formulations of complete rodent diets, including those for rats, have been published, and most animal diet manufacturers have access to computer programs for formulating diets (Knapka, 1999). So, although various nutrient deficiencies have been produced in experimental rats and are described in detail in the literature, they are uncommon in pet rats fed commercial dry rodent food. Protein deficiencies are probably most common and can result in anemia, cataracts, poor growth and impaired reproduction.

Feeding Plan

Rats should be fed a commercial dry rodent food, offered free choice. They are primarily nocturnal feeders. Adult rats consume approximately 10 g of food/100 g of body weight. Treats should not exceed 10% of food intake. Dietary fiber content should be at least 5% to minimize problems with diarrhea. On a dry matter basis, crude protein requirements are approximately 10% for maintenance, and 20% for growth and reproduction. Young rats are weaned at 21 days of age at which time body weight ranges from 40 to 50 g (Harkness, 1993e; Harkness and Wagner, 1995a). Fresh water should be available free choice.

Mice

Husbandry

Mice belong in the Muridae family and originated in Asia. Average life span is 1.5 to 3 years and adult weight ranges from 20 to 40 g. Gestation lasts 19 to 21 days, with litter sizes ranging from 10 to 12. The dental formula is I1/1, C0/0, P0/0 and M3/3. Only the incisor teeth are open-rooted. GI transit time is eight to 14 hours (Jacoby and Fox, 1984; Harkness and Wagner, 1995a).

Cage requirements are similar to those described for rats. (See Rodents, Cage Requirements.) Floor space per adult mouse should be at least 97 cm^2, and 390 cm^2 for breeding females. Ambient temperatures should be maintained between 18 to 29°C (65 to 85°F), with an average of 22°C (72°F). Humidity should range from 30 to 70% (Harkness, 1993f).

Feeding Plan

Mice should be fed a clean, fresh, commercial dry rodent food. Optimal nutrient requirements have not been established and probably vary markedly among various strains of mice. The literature suggests that foods containing 17 to 24% protein, 5% or less fat and 2.5% fiber result in adequate performance levels. Mineral requirements are unknown. Adult mice ingest 4 to 5 g of food daily. Young mice generally begin eating dry food at 10 days of age and are weaned at 21 days (Harkness, 1993f; Harkness and Wagner, 1995a). Clean, fresh water in sipper bottles should always be available.

CASE 70-1

Calciuria in a Rabbit

Karen N. Wolf, MS, DVM
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina, USA

Patient Assessment

A six-year-old, neutered male mini-lop rabbit presented for a one-week history of decreased activity, reduced appetite and spending more time in the litter box. The rabbit was kept indoors, housed in a wire hutch with straw substrate and supervised outdoors one to two hours several times weekly.

On physical examination, the rabbit was overweight, resented abdominal palpation and had gritty material on its fur around the prepuce and on the ventral aspect of its tail. All other physical examination parameters were normal.

Assess the Food and Feeding Method

The diet consisted of free-choice hay and rabbit pellets, one-half cup of leafy green vegetables daily and occasional fruit as a treat. Water was available in a sipper bottle at all times.

Questions

1. What additional questions should be asked about the diet?
2. What is this rabbit's most likely clinical problem?
3. What diagnostic tests should be performed?
4. What are some treatment options?

Answers and Discussion

1. The owner should be asked what type of hay and pellets are being offered to the rabbit. Also, it is important to ask how much the rabbit consumes (proportionately) of each food item offered. Additional information should include how often the water is changed. In this case, the owner was feeding alfalfa hay and alfalfa-based pellets. The rabbit seemed to prefer the pellets but also ate the hay. The water was changed two to three times weekly.
2. The most likely clinical problem based on the dietary history and physical examination is urolithiasis/calciuria. This problem in rabbits is linked to a high concentrate diet, obesity and lack of exercise. Rabbits, unlike most mammals, have a fractional urinary excretion of calcium between 45 to 60%. Increased dietary calcium leads to increased excretion of calcium through the urinary tract. Alfalfa is high in calcium and protein, which contributed to hypercalciuria and obesity in this rabbit. Alfalfa hay and pellets are acceptable for young, growing rabbits but are not recommended for most adult pet rabbits. Chronic, low-grade dehydration may also contribute to the problem. Rabbits have a high water intake (120 ml/kg/day) and need fresh clean water available at all times.
3. Radiographs, urinalyses and blood work (i.e., complete blood counts and serum biochemistry profiles) should be performed to confirm the diagnosis and to assess treatment options. If bacteria are identified, a urine sample collected by cystocentesis should be submitted for culture.
4. The type of treatment is based on the severity of the clinical problem. The presence of large cystic or urethral calculi will mandate either a cystotomy or perineal urethrostomy. If there are nonobstructive calculi or large amounts of dense calcium "sand" filling the bladder, urohydropropulsion or simply administering intravenous or subcutaneous fluid will help flush the bladder. Manual expression of the bladder may aid in the passage of the calcium precipitates. Changing the diet will help prevent recurrence. The diet for an adult pet rabbit should be based on grass hay and green vegetables with limited amounts of timothy hay-based pellets. Fresh water should be available free choice. Ample exercise is also important to prevent obesity.

CASE 70-2

Anorexia in a Guinea Pig

Christine M. Kolmstetter, DVM
Las Vegas, Nevada, USA

Patient Assessment

A one-year-old female Peruvian guinea pig was examined for a two-week history of anorexia and decreased activity. The volume and consistency of the feces were normal. The owner had purchased the guinea pig at two months of age; no other pets were in the household. The animal was housed in a 30-gallon aquarium that contained a shredded paper substrate. The aquarium was located in a quiet area in the living room. The animal was handled daily. No recent changes in environment or husbandry had occurred, and there was no history of trauma.

Physical examination revealed a bright, alert, thin guinea pig with a dull coat. The incisor and cheek teeth and oral mucosa appeared normal. The animal was reluctant to move. Although the guinea pig's joints were not palpably swollen, the animal seemed uncomfortable when the elbow and hock joints were gently flexed and extended. Abdominal palpation was normal.

Assess the Food and Feeding Method

Commercial dry guinea pig food and fresh water in a sipper bottle were provided free choice.

Questions

1. What other questions should be included in the dietary history?
2. What is this patient's most likely nutritional problem?
3. What further diagnostic tests should be offered to the client?
4. What treatment should be recommended?

Answers and Discussion

1. The owner should be questioned about the source of the commercial dry guinea pig food, its length and manner of storage in the home and what other food items the guinea pig consumes. This question revealed that, for the sake of convenience, the owner purchased several bags of food at a local discount grocery store. This supply lasted for two to three months.
2. Hypovitaminosis C is the most likely nutritional problem, based on the history and clinical signs.
3. A complete blood count, serum biochemistry profile and whole body radiographs would reveal the extent of the disease and help disclose other underlying problems that might be present.
4. This patient's food should be supplemented with oral or injectable vitamin C. The client should be educated about proper nutrition and other aspects of husbandry at this time.

CASE 70-3

Dysphagia in a Chinchilla

Karen N. Wolf, MS, DVM
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina, USA

Patient Assessment

A five-year-old female chinchilla was examined for a three-month history of dysphagia, decreased appetite and an unkempt appearance. The owner adopted the chinchilla three years earlier and reported that the patient never had any medical problems. The chinchilla was housed indoors in a multi-tiered cage with predominantly wire flooring although areas with solid flooring were available. The patient was provided with a dust bath several times weekly. The chinchilla appeared interested in the normal pelleted food but seemed to not eat as vigorously as before. No changes had been made in the diet. The owner reported that fecal output seemed reduced.

On physical examination, the patient was bright and alert. However, its mandibular fur was moist, matted and discolored. Oral inspection revealed overgrown incisor teeth and the patient was palpably thin. No other abnormalities were detected.

Assess the Food and Feeding Method

Commercial chinchilla pellets and fresh water in a sipper bottle were available free choice and approximately 1/2 cup of mixed leafy greens was provided once or twice weekly.

Questions

1. What other questions should be asked about housing and diet?
2. What is the most likely cause of this chinchilla's clinical signs?
3. What nutritional deficit is likely to have caused this patient's clinical problems?
4. What diagnostic tests should be performed?
5. What treatment options should be considered?

Answers and Discussion

1. The owner should be asked if hay and chew toys were provided. The owner revealed that hay was offered when the chinchilla was first adopted but the patient showed more interest in the pelleted food; therefore, hay was no longer provided regularly. No chew toys were available.
2. Dental malocclusion is the most likely problem based on clinical signs, dietary history and physical examination findings.
3. A lack of hay is the primary factor contributing to this patient's malocclusion. Mastication of hay or other chew items continuously wears cheek teeth; thus, without items to chew, growing teeth are not adequately worn and will become maloccluded.
4. Anesthesia should be administered and the patient's oral cavity examined. Although the incisor teeth are readily visualized in chinchillas without anesthesia, the narrow opening to the oral cavity and the caudal location of the premolars and molars (cheek teeth) preclude adequate visualization even with instruments such as an otoscope. The mucosal surfaces and tongue should be evaluated for abrasions. The occlusal surfaces of the teeth should be assessed. Skull radiographs should be obtained to better evaluate the teeth, including the roots, and to determine if there is evidence of osteomyelitis or apical abscesses. A complete blood count and serum biochemistry profile should also be performed as part of the clinical workup.
5. Overgrown incisor teeth can be trimmed using a high-speed dental hand-piece equipped with a cutting burr. Modifying the diet to include hay may be curative in uncomplicated cases. Malocclusions of the cheek teeth require leveling, and again, dietary changes may be curative in cases that are detected early and are the direct sequela of a poor diet. Advanced cases may require extractions and trimming of the remaining teeth at regular intervals.

Chapter 71

Nutrition of Reptiles

Scott Stahl
Susan Donoghue

"In the parched path I have seen the good lizard (one drop of crocodile) meditating."
Frederico Garcia Lorca, 1921

INTRODUCTION

Diversity among the more than 6,500 species of reptiles challenges a veterinarian's ability to know the feeding management, estimate the nutritional requirements and recommend appropriate diets for every species presented in practice. With the exception of field studies on free-living reptiles, nutritional research is limited. Thus, recommendations are based on knowledge of natural diets, feeding histories, clinical experience and principles of comparative nutrition.

Identification of different species becomes easier with experience, but is often complicated because owners may know only a common name for their reptile. Common names can be colloquial, or assigned to more than one species. Therefore, misidentification of a patient may result in serious errors in nutritional recommendations. Reference texts help identify species and provide information about natural history and diet (Obst et al, 1988; Mattison, 1987; Zimmerman, 1986; Rossi, 1992; de Vosjoli, 1994, 1996; Boyer, 1996; Frye, 1991). This information can guide recommendations for habitat, including requirements for temperature, light, humidity, substrate, furnishings and social interaction. Failure to provide a suitable environment can lead to stress, causing negative effects on food intake and metabolic status of the patient.

For purposes of clinical nutrition, reptiles may be grouped into herbivores, omnivores and carnivores according to broad generalizations about their natural diet (**Table 71-1**). These distinctions serve as initial guides for making recommendations about diet and feeding management.

PATIENT ASSESSMENT

Signalment

Examination of the patient begins with the signalment. After the reptile presented has been properly identified by species, its age and gender should be estimated. Consider its stage of growth, reproductive status and degree of health, because these factors affect dietary recommendations. For example, certain species of aquatic turtles (e.g., the common sliders often kept as pets) change from eating a primarily carnivorous diet to eating a more herbivorous diet with maturity. Thus, feeding recommendations may differ for juvenile and adult reptiles.

Nutritional needs for reproductively active reptiles tend to be greater than for nonreproductive reptiles. This is especially true for females that need energy for development of ovarian follicles, oviductal eggs and embryos and require calcium for egg laying (often multiple clutches in a breeding season). However, some reptiles may become anorectic during phases of reproduction. For example, male snakes may refuse food during courtship and copulation or during times that seasonally correlate with these activities (e.g., ball pythons may not eat during the "dry season"). Likewise, females may not accept food while gravid. Therefore, for reproductively active reptiles, consider

Table 71-1. Foods and fuel sources vary in reptiles, depending on the carnivorous, omnivorous or herbivorous nature of the species.*

	Carnivores	Omnivores	Herbivores
Common pets	Snakes	Box turtles	Most tortoises
	Aquatic turtles	Bearded dragons	*Iguana* spp.
	Most monitors, tegus	Day geckos	*Uromastyx* spp.
	Most lizards	Forest-dwelling tortoises	*Corucia zebrata*
	Leopard geckos	Anoles	
	Chameleons	Blue tongued skinks	
Foods	Mealworms	Slugs	Greens
	Flies	Snails	Fruits
	Crickets	Crickets	Vegetables
	Mice	Fruits	Clover
	Fish	Vegetables	Dandelions
	Rats	Greens	Grasses
Dietary contents (% kcal metabolizable energy)			
Protein	25-60	15-40	15-35
Fat	30-60	5-40	<10
Carbohydrate	<10	20-75	55-75

Table 71-2. Husbandry questions for reptile owners.

Housing
Description of cage substrate and furniture
Frequency of and routine for cleaning
Location (indoors, outdoors)
Presence of cage mates
Type and size of habitat
Temperature
Measured temperature ranges within habitat (should be gradients of temperature)
Positioning of heat in cage
Safety precautions used to prevent thermal injury
Type of heating (radiant, ventral sources)
Light
Is the light filtered by glass or Plexiglas (these filter out ultraviolet light)
Length of light cycle
Positioning of light source
Type of lighting provided (incandescent, fluorescent, natural sunlight)

recommending heavier feeding during nonreproductive periods to compensate for subsequent nutritional demands.

The nutritional requirements for sick reptiles may also differ from those of healthy reptiles. The overall health status of the patient dictates the need for a change from a traditional diet. Typically, the clinician should recommend diets with greater digestibility and availability (Donoghue and Langenberg, 1996).

History

For reptiles, nutritional disorders are often caused by errors in husbandry; thus, history taking should include specific questions about management. First, a general history is obtained (Boyer, 1996; Divers, 1996). Pertinent information includes the patient's origin (e.g., private breeder, importer, pet shop), whether the patient was born in captivity or caught in the wild, length of ownership, whether there are other reptiles in the home and the disease history for the patient and the entire reptile collection. The history should include specific questions about husbandry (**Table 71-2**).

A dietary history allows the veterinarian to assess the animal's intake of energy and nutrients, and may provide information about the animal's clinical condition and behavior. It also may help in the early detection of nutritional problems before they become serious clinical disorders. Dietary histories may be complex for some reptiles (e.g., iguanas and tortoises) that consume a mix of different foods, including salads and supplements.

One goal of a diet history is to obtain information about all available foods offered to the patient. Foods that may be intentionally offered include commercial foods, homemade salads, snacks, treats and supplements. Foods may also be available unintentionally, such as houseplants for iguanas and tortoises that free range in homes.

Attention should be given to the quality and wholesomeness (absence of potential pathogens) of the food, cleanliness of feeding utensils and the skills and reliability of those responsible for feeding. The veterinarian should also determine whether the reptile has appropriate access to water.

It is best to query those directly responsible for feeding the reptile and not to rely on second-hand information. For complicated feeding programs involving a wide variety of foods, it may be best to ask owners to complete seven- to 10-day diaries, listing all foods offered and estimates of amounts consumed. For both written and oral dietary histories, care must be taken to avoid influencing responses by owners.

When obtaining a dietary history, include specifics about: 1) diet-what is fed, how often and how much, how the food is prepared, where the food is placed in the habitat, when the food is removed and which foods the reptile actually consumes, 2) supplementation-are supplements used, what type, how are they

offered, how often, does the animal eat the food when the supplement is offered and 3) water-how is water offered, frequency of water changes and has the owner observed the animal drinking.

For carnivorous reptiles, dietary histories should concern type, source and health of the prey offered and the frequency of feeding. Look for problems with over- or underfeeding, offering malnourished prey, feeding only or mostly invertebrate prey, failure to provide additional supplementation, etc.

For herbivorous reptiles, dietary histories should especially concern the sources of protein, calcium and fiber. Another concern is whether commercially prepared foods are being diluted by excessive amounts of fruits or vegetables. For those patients fed mixed salads, look for sources of protein (romaine lettuce, legumes), calcium (calcium carbonate), fiber (crumbled hay cubes or fresh grasses). For commercial foods, check labels for ingredients.

Physical Examination

Initially observe the undisturbed patient from a distance. Posture, respiratory rate and movement, activity level, agility, strength and symmetry should be noted and compared with the results of the hands-on examination.

The reptile may be evaluated physically after it is appropriately restrained. The physical examination should be consistent and follow a similar pattern with each patient. This process reduces the likelihood that something will be overlooked. A typical approach is to start at the head and work caudally.

Many signs of malnutrition may be evident during the examination and should be noted in the patient's record. Examples include corneal and conjunctival abnormalities and respiratory disease, which may indicate hypovitaminosis A. Enophthalmos may suggest dehydration or inanition and cachexia. Abnormal color in the oral cavity may be due to anemia or icterus. (Note: This finding may be misleading in the bearded dragon, *Pogona vitticeps*, for example, which naturally has yellow oral mucous membranes.) Increased amounts of mucus in the mouth may indicate hypovitaminosis A. Dysecdysis (abnormal shedding) may suggest dehydration or hypo- or hypervitaminosis A.

After a thorough physical examination, the reptile should be weighed. Patients may also be scored for body condition (fat:lean ratio, degree of emaciation or fat loss) and muscle wasting (cachexia, sarcopenia, protein depletion) (Chapter 1). Average weights and morphometrics have not been established for reptiles, but in-house ranges can be established at a practice.

A general guide for reptiles (and mammals) is that an acute loss of 10% or chronic loss of 20% of body weight indicates the need for nutritional intervention. Body weight, however, provides limited quantitative data about lean body mass. All weight loss, even in healthy reptiles, is accompanied by loss of lean and adipose tissue. Losses of body fat and tissue protein will be accelerated in ill reptiles and those recovering from surgery. Muscle wasting is typically characterized clinically by loss of muscle mass and body weight. Protein catabolism results in cumulative losses of skeletal muscle mass and eventually loss of function of enzyme systems. Tissue proteins usually continue to be depleted during initial recovery from illness and surgery. Weight gain immediately after illness or surgery typically represents water and fat replacement whereas tissue protein is restored later.

Diagnostic Testing

In addition to a thorough physical examination, diagnostic testing helps assess nutritional and overall health status. This is especially important because reptiles, like birds, attempt to hide their illnesses. Diagnostic tests such as hematology and serum biochemistry analyses may be helpful.

Reptile blood is fragile. It is best preserved with heparin and should be processed immediately (Frye, 1991a; Bolten et al, 1992). Reptiles tend to have lower normal hematocrit values than other companion animals. Blood samples should be processed in-house or sent to a commercial clinical laboratory that specializes in reptile blood analysis. This is important to obtain consistently accurate total white blood cell and differential counts. Experienced laboratory technicians can describe the morphology of the cells (i.e., toxic, degranulating, shrunken), which can be just as valuable as the white blood cell total and differential counts. Serial samples are helpful for assessing progression of disease and health status.

Kidney disease is common in reptiles; however, uric acid levels may be affected by the most recent meal eaten by the reptile and may not be a sensitive indicator of renal function. In many cases, elevated serum phosphorus and subsequent decreased serum calcium values (usually in an inverse ratio of phosphorus to calcium) may indicate renal disease much earlier than elevated uric acid concentrations.

Deficiencies of calcium and vitamin D are common in reptiles. Radiographs can be a valuable tool to evaluate quality and density of bones. Additionally, radiography and ultrasonography are useful in assessing fat reserves and evaluating reproductive status of females.

Key Nutritional Factors

Reptiles differ from mammalian and avian patients in the metabolism of energy and nitrogen. These differences affect water balance, intake of essential nutrients, prevalence of diet-related diseases and causes of mortality. This section discusses the key nutritional factors that affect reptiles as well as common diseases caused by nutrient excesses and deficiencies.

Energy

Reptiles are ectothermic and heterothermic. Their body temperature depends on ambient environmental temperatures, rather than on internal metabolism, and varies with fluctuating temperatures. This effect of ambient temperature on body temperature affects metabolic rate (hence caloric needs), activity (e.g., food procurement) and digestion. In most cases, reptiles maintain an appropriate core body temperature if provided with a sufficient temperature gradient within their habitat. However, temperatures that are too cold will limit food consumption and impair digestion. Temperatures that are too hot will lead to excessive stress, decreased food intake and weight loss.

Table 71-3. Estimates of standard metabolic rate (MR) in kcal/day and fractional increases for feeding and activity for reptiles at 30°C (86°F).*

Body weight (g)	MR	1.1 MR	1.25 MR	1.5 MR	2.0 MR	2.5 MR

*$MR = 32(BW_{kg})^{0.77}$ where MR = standard metabolic rate in kcal/day and BW = body weight in kg. To convert to kJ, multiply kcal by 4.184. Adapted from Donoghue S, Langenberg J. Nutrition. In: Mader DR, ed. Reptile Medicine and Surgery. Philadelphia, PA: WB Saunders Co, 1996; 148-174.

Because energy is not used to maintain body temperature, reptiles require fewer calories than birds and mammals. Metabolic rates in reptiles relate to metabolic body size-the smaller the animal, the greater its metabolic rate per unit body weight. The metabolic rates of reptiles average about one-fourth those of mammals. Energy requirements increase with eating, activity, reproduction, growth, protein synthesis (i.e., wound healing) and certain disorders (**Table 71-3**). Daily energy intakes should be calculated by multiplying the metabolic rate by a factor (i.e., 1.1 to 2.5) that accounts for activity and other conditions that increase metabolic rate. Unlike birds and mammals, energy requirements for reptiles do not increase with cold ambient temperatures. Estimates of daily calorie intakes are generally derived from experimental studies using a limited number of species, field work on species not often seen in practice and on clinical experiences of knowledgeable herpetoculturists (Frye, 1991; Donoghue and Langenberg, 1996).

Fuel use varies with the feeding ecology of the species. Generally, assumptions can be made based on the species' food preferences. For carnivores (e.g., snakes, most monitors and many aquatic turtles), exogenous fuel sources are fat (providing 8.5 to 9 kca1/g [35.6 to 37.7 kJ/g]) and protein (providing 3.7 to 4 kcal/g [15.5 to 16.7 kJ/g]). Intake of carbohydrate, including fiber, is minimal (**Table 71-1**). Rates of gluconeogenesis are

likely to stay relatively high in these species.

For herbivores (e.g., tortoises, green iguanas, prehensile tail skinks [*Corucia zebrata*] and spiny tail lizards [*Uromastyx* spp.]), exogenous fuel sources are primarily carbohydrate (about 3.5 kcal/g [14.6 kJ/g]) and protein (about 3.5 kca1/g [14.6 kJ/g]). Dietary fat (providing about 8.5 kcal/g [35.6 kJ/g]) is usually less than 10% of dry matter (DM) (**Table 71-1**). Fermentation of fiber in the lower bowel of herbivores yields short-chain fatty acids that are also used for energy (perhaps providing about 2 kcal/g [8.4 kJ/g] of fiber).

ENERGY DEFICIENCY AND EXCESS

Low calorie intake leads to underweight and cachectic conditions. Ribs and vertebral processes are prominent or palpable in underweight snakes and lizards. Some exhibit longitudinal folds of skin along the lateral body wall. Thin turtles and tortoises lack heft. Poor body condition may be caused by: 1) improper husbandry, 2) stress, 3) improper temperature, 4) inappropriate diets or too little food and 5) underlying diseases that affect appetite and metabolism.

Excessive caloric intake leads to rapid growth in juveniles and overweight and obese conditions in adults. Especially at risk are those species with a sedentary nature, such as large snakes and lizards. Also at risk are reptiles kept in small habitats and fed high-fat diets, such as aquatic turtles maintained in small tanks. Treatment includes decreasing caloric intake and increasing activity. For example, an obese aquatic turtle that is fed commercial pellets daily can, instead, be fed pellets only three times per week and be offered greens on the other days of the week. Tank size should also be increased to encourage activity.

Water

All captive reptiles should have access to fresh water. Proper delivery of water is important. Turtles and snakes generally drink from bowls. Some lizards such as anoles, chameleons and day geckos lap up droplets sprayed or dripped onto foliage. Other lizards, such as iguanas and monitor lizards learn to drink from bowls and smaller reptiles from lids (e.g., plastic caps for pet food cans). Some reptiles may reject water held in plastic containers, presumably because of odor or taste. A switch to glass, ceramic or stainless steel bowls usually corrects the situation. Tortoises and some snakes soak in large, shallow bowls. Soaking enhances water uptake and stimulates excretion.

Desert animals require less water than temperate and tropical species. Some species receive enough water from food to meet requirements. Empirically, daily parenteral doses of water for rehydration are 10 to 25 ml/kg body weight (Frye, 1991a).

WATER-RELATED PROBLEMS

Water is critically important for reptiles and relates to many of the diseases seen in practice, such as gout and dysecdysis. Aquatic species are at less risk for dehydration, but water quality is critical for these animals. Routine water analyses may be important for maintaining health in aquatic reptiles (Donoghue and Langenberg, 1996). Water should be fresh for all species. Bacterial counts and culture can be included in routine water analyses. The method of providing water to reptiles will influence the humidity in the environment.

Clinical impressions suggest that inadequate humidity may contribute to dehydration, stress and dysecdysis. Likewise, excessive humidity may contribute to skin infections and hyperkeratinization.

Table 71-4. Purine content varies in foods. Low-purine and potentially acidic foods should be selected and high-purine and alkaline foods should be avoided for reptiles predisposed to gout.*

High-purine foods	**Low-purine foods**
Anchovies	Breads
Asparagus	Cereals
Brains	Cheese
Kidneys	Eggs
Liver	Fats
Mince meats	Fruits
Mushrooms	Milk
Sardines	Most vegetables
	Nuts
Potentially acidic foods	**Potentially alkaline foods**
Brazil nuts	Almonds
Breads	Beet greens
Cereals	Beets
Cheese	Chard
Corn	Chestnuts
Cranberries	Coconut
Lentils	Dairy
Meats	Dandelion
Plums	Fruits**
Prunes	Kale
Rice	Molasses
Walnuts	Mustard
	Spinach
	Turnip greens

**Except plums, prunes and cranberries.

Nitrogen

Lizards and snakes excrete mostly uric acid. Aquatic turtles tend to excrete more ammonia and urea than uric acid, whereas terrestrial tortoises excrete relatively more uric acid (Schmidt-Nielsen, 1990). Excretory patterns are clinically important because of difficulties in maintaining positive water balance and the prevalence of dehydration seen in reptiles.

Dehydration is common, especially in sick reptiles. It may result from water provided in improper form or anorexia, or may occur secondary to disease. Uricotelic species require large amounts of water to sustain normal excretion. Dehydration in these species may result in urinary stasis, hyperuricemia and gout, a disease characterized by deposition of urate crystals in soft tissues and joints. Prevention is based on maintaining adequate hydration. Reducing protein levels may restrict purines. Restriction of purines is feasible by avoiding high-purine foods such as liver (**Table 71-4**).

Many reptiles appear to have marked protein requirements. Those that are strict carnivores naturally consume diets consisting of 30 to 60% protein (metabolizable energy [ME] basis).

Table 71-5. Caloric and nutrient content of vertebrate prey.

Food items (g)	Water (%)	Energy (kcal/g)* (As fed)	Energy (kcal/g)* (DM)	Protein (% kcal)	Fat (% kcal)	NFE (% kcal)	Calcium (mg/kcal)	Phosphorus (mg/kcal)
Atlantic herring (100)	69	1.8	5.7	39	58	3	na	1.4
Atlantic smelt (100)	77	1.0	4.3	63	31	6	3.2	4.4
Chick, day old (40)	73	1.3	4.8	52	44	4	2.7	2.0

Key: NFE = nitrogen-free extract (digestible carbohydrate), DM = dry matter, tr = trace.
*To convert to kJ, multiply kcal by 4.184.

Herbivorous reptiles consume less protein, but optimal ranges remain to be defined. Feeding trials in green iguanas suggested that dietary protein levels of about 28% DM are needed for optimal growth (Donoghue, 1994, 1997).

Other Nutrients

Intake of nutrients varies with feeding habits. For large carnivorous reptiles, vertebrate prey are assumed to be "complete and balanced" packages that contain all of the essential nutrients. However, neonatal prey (e.g., pinkie [newborn] mice) that are fed to smaller carnivores and omnivores, may lack sufficient calcium and fat-soluble vitamins (Douglas et al, 1994). In adult prey, calcium, phosphorus and magnesium are provided by bone, most trace minerals and vitamins by liver and kidneys, iodine by thyroid glands and zinc by the pancreas. The protein quality is high. Calories are provided almost entirely by fat and

protein, and carbohydrate sources are limited to the intestinal content of the prey (**Table 71-5**).

Invertebrate prey also contain much fat and protein but lack a calcium-rich skeleton (**Table 71-6**). The chitinous (aminocellulose) exoskeleton of most invertebrates contains nonprotein nitrogen. The digestibility of this chitin is questionable (Donoghue and Langenberg, 1996).

Invertebrates are routinely "dusted" with powdery vitamin-mineral supplements to supply calcium and other nutrients lacking in the diet. Dusting can be problematic; it may induce nutrient toxicities if excessive and create deficiencies if too little is provided. Additionally, some reptiles will refuse foods that have been dusted because calcium salts and many vitamins are unpalatable.

Domestic fruits and vegetables available from grocery stores are lower in nutritional value (especially protein and fiber) than fruits and plants consumed in the wild. Among domestic produce, higher protein levels are found in greens (e.g., romaine lettuce, collard greens and spinach), alfalfa and mung-bean sprouts, mushrooms and bamboo shoots. Domestic produce rarely provides enough protein, calcium and fiber, or adequate levels of trace minerals and vitamins to support growth and reproduction in reptiles; therefore, produce needs supplementation (**Table 71-7**) (Donoghue and Langenberg, 1996).

Herbivorous reptiles consume fruits readily, probably because of the bright colors, sweet taste and moist texture. However, fruits contain mostly water, fructose and small amounts of fiber. Even small amounts of fruit can markedly dilute the calories, nutrients and fiber provided by greens.

Nutrient Deficiencies and Excesses

With the exception of those species consuming whole prey, many reptiles suffer from deficiencies and excesses of nutrients. Common among many species are deficiencies of calcium and vitamin D_3.

Vitamin D_3 is problematic. Limited research data, anecdotal evidence and clinical impressions suggest that, at least in some species, dermal synthesis of 1,25-dihydroxycholecalciferol may be more efficient than gastrointestinal absorption of dietary vitamin D_3. Thus, exposure to natural sunlight or ultraviolet (full spectrum) lighting may be critical for adequate vitamin D_3 synthesis in some reptile species. Interactions between vitamin D, calcium and phosphorus, and secondary interactions with vitamin A and several trace minerals, complicate nutritional requirements. For now, general recommendations include consistent but not excessive supplementation of diets (except when feeding whole vertebrate prey) with both calcium and vitamin D_3, exposure to full-spectrum lights and, whenever possible, exposure to direct sunlight.

Diet-related nutritional deficiencies in carnivores include calcium deficiency from feeding primarily unsupplemented invertebrates or muscle meat, vitamin A deficiency from feeding primarily iceberg lettuce and muscle meat and thiamin (vitamin B_1) and tocopherol (vitamin E) deficiency from feeding fish containing thiaminases and high levels of polyunsaturated fatty acids.

Common problems in herbivores include multiple deficiencies, especially calcium deficiency, from feeding unsupplemented produce and protein deficiency from feeding diets containing large amounts of fruit.

Over-supplementation may potentially lead to toxic intakes of vitamins A and D, phosphorus, selenium, iodine and other trace minerals. Some nutrient interactions may occur in reptiles. For example, excess dietary calcium may interfere with the absorption of zinc and copper and affect the thyroidal uptake of iodine.

METABOLIC BONE DISEASE

Metabolic bone disease is probably the most common nutritionally related disease seen in lizards, especially green iguanas. This disease is caused by a dietary deficiency of calcium, excess of dietary phosphorus, deficiency of vitamin D_3 or a combination of these factors. Clinical signs include soft mandibular and maxillary bones, deformed or fractured bones, muscle tremors, poor growth, spinal deviations and paralysis (Frye, 1991a). The disease is most commonly seen in young, growing lizards and adults maintained indoors. Metabolic bone disease is also common in chelonians (tortoises and turtles). Clinical signs include a soft carapace and plastron, improper shell growth and fractured limbs (Frye, 1991a). Treatment includes dietary correction and provision of natural sunlight or full-spectrum ultraviolet light. For severe cases, parenteral injections of calcium, vitamin D_3 and calcitonin may be necessary (Boyer, 1996; Donoghue and Langenberg, 1996; Rossi, 1992; Mader, 1993; Barten, 1995).

HYPOVITAMINOSIS A

Deficiency of vitamin A occurs in lizards fed unsupplemented produce and insects. It is characterized by squamous metaplasia, which causes shedding problems, stomatitis, palpebral edema, conjunctivitis and respiratory disease (Frye, 1991a). Secondary bacterial infections are also common. Treatment includes vitamin A supplementation, parenterally and orally, and dietary correction.

Hypovitaminosis A is likely the most common nutritional disease of chelonia. These animals are typically fed unsupplemented iceberg lettuce, hamburger or other foods deficient in vitamin A. Squamous metaplasia results in palpebral edema and respiratory disease. Common clinical findings include conjunctivitis, nasal discharge, wheezing and stridor (Frye, 1991a). Additionally, respiratory disease may cause water turtles to swim in a lopsided fashion due to fluid buildup in one lung. Secondary bacterial infections are common. Poor skin and shell quality may also be noted.

Treatment of hypovitaminosis A includes dietary correction and oral administration of vitamin A (200 to 300 IU/kg body weight). Secondary bacterial infections are treated with an appropriate antibiotic. Dietary vitamin A should be increased (2,000 to 10,000 IU/kg diet DM).

FAT-SOLUBLE VITAMIN TOXICITIES

Over-supplementation with fat-soluble vitamins may result in renal disease, hepatic disease and metastatic calcification.

The exact requirements of vitamins A and D_3 are currently unknown, but excessive amounts may cause problems in lizards. Clinical signs are consistent with multiple organ failure. The most common example is seen in green iguanas maintained on dog and/or cat food. Renal failure and metastatic calcification of major vessels typically occur. Treatment in most cases involves attempts to reverse organ damage through supportive care, especially fluid therapy. Additionally, calcitonin[a] may be used (2 IU/kg body weight, given intramuscularly q24h) to help reverse metastatic calcification (Frye, 1991; Barten, 1995).

Tortoises and box turtles are very sensitive to injections of vitamin A. When given parenterally, these drugs may cause sloughing of the skin, resulting in severe skin ulceration (Frye, 1991, 1991a). These preparations are best given orally. Treatment for vitamin toxicity in most cases is supportive care and removal of the vitamin source.

Although commercially prepared foods may occasionally be involved, the excessive use of vitamin supplements is more commonly the cause of vitamin toxicities.

THIAMIN DEFICIENCY

Thiamin deficiency is seen occasionally in garter snakes and water snakes fed exclusively frozen fish. Thiaminases, found in many species of fish, deplete available thiamin. Thiamin-deficient snakes typically present with neurologic disease characterized by ataxia, seizures, twisting and rolling. Treatment involves changing the diet to include fresh fish, insects and mice scented with fish, and medicating with oral or parenteral thiamin hydrochloride (25 mg/kg body weight, per os or intramuscularly) (Frye, 1991).

FEEDING PLAN

The advantages and disadvantages of feeding reptiles commercially prepared foods and homemade diets were discussed above. If an individual reptile is healthy and exhibits no signs of deficiency disease, the owner probably is feeding the reptile appropriately and there is no need to change the food.

Although some prepared foods have been available for only a limited time, the overall nutritional quality of commercially prepared foods is rapidly improving as manufacturers consider new scientific information when they prepare their formulations. As commercially prepared foods become more widely used, many of the diet-induced diseases currently observed by veterinarians will become of historical interest only, just as they have for other companion pets.

Assess and Select the Food

Foods appropriately balanced with carbohydrates, proteins, fats, vitamins, minerals and water are essential for all reptiles. Care of captive reptiles must address good nutrition at several levels; the daily satisfaction and health of the reptile as well as the long-term contributions to growth, maturation, defense against disease and reproductive health-the hallmark of good nutrition.

Three methods of providing nutrients and achieving these objectives are commonly used: 1) commercially prepared foods, 2) homemade mixed foods or 3) a combination of commercial and homemade foods, with or without supplements.

Commercially Prepared Foods

Reptiles may be fed commercially prepared foods formulated for the species or the most similar domestic animal. There is little scientific literature about the nutrient requirements of reptiles. However, several reports provide some insight into the levels of dietary nutrients required to result in a nutritionally adequate diet (Allen et al, 1989). These reports make it possible to formulate prepared foods with a high probability of nutritional adequacy for some reptilian species.

Testing protocols for nutritional adequacy have not yet been established for reptile foods, as they have been for commercially prepared canine and feline foods. As commercially prepared reptile foods become more widely used, testing protocols for nutritional adequacy will be established and required.

Commercially prepared foods offer many benefits, including nutrient balance and convenience. A moist, extruded or pelleted food will supply all the nutrients in one particle or form. Thus, the probability of producing a nutritional imbalance by feeding a commercially prepared food is much less than when reptiles are fed individual human foods prepared by uninformed owners.

If commercially prepared food is offered, examine the label for nutrient information or guarantees. The primary nutrients of concern depend on whether the reptile is carnivorous, omnivorous or herbivorous. Protein, fat, digestible (soluble) carbohydrate, fiber, vitamin and mineral levels should be appropriate for the individual reptile. Label space does not allow for detailed nutrient information. Therefore, the manufacturer should be contacted for additional nutritional information. When purchasing or recommending commercial herbivore foods, read labels with extreme care. Some may contain low levels of antibiotics and other growth promotants that have unpredictable and potentially deleterious effects on reptiles. Regardless of the type of food fed, a sample can be submitted to a commercial laboratory for analysis. Consult the laboratory in advance to determine the sample size needed, preservation techniques recommended and shipping instructions.

Compare the nutrient levels of the commercial food to those recommended in this chapter to determine if there are any discrepancies in the nutrient profile. If the food doesn't meet recommended nutrient levels, the owner should change or supplement the diet. The food should not be fed if its label contains no nutrient information and the manufacturer does not provide nutrient levels in other promotional literature or is unavailable to answer questions by phone.

Commercial forages for herbivorous reptiles include legumes, primarily alfalfa, which can be pelleted, cubed and chopped. Unfortunately, most tortoises and herbivorous lizards show limited interest in alfalfa-based meals, eating these items only when disguised with fresh produce or when no other foods are available.

Hay can be purchased from feed stores and farms. Chopped

and cubed hay is sold in pet shops and feed stores. Care should be taken to avoid prolonged storage of these products because about half the vitamin A activity from β-carotene is lost from hay within a year of cutting.

Hay-based pellets range from 12 to 28% DM crude protein and 14 to 19% DM crude fiber. Some success has been noted in the use of hay-based pellets as bedding for juvenile herbivorous reptiles. Although these products are safe if wholesome, pellets can mold quickly and the reptile may then be at risk to develop respiratory disease and digestive upset.

Some commercially prepared foods marketed specifically for iguanas are variable in content. Look for products with at least 18% DM crude protein. Pellets may be soaked in water or fruit juice before feeding. Wet pellets may mold, so they should be offered fresh daily.

Some commercially prepared foods marketed specifically for aquatic species are sold as complete diets and are made from fish and crustacean meals, plant-based ingredients and various additives. Some manufacturers fail to add essential vitamins and minerals. Processes used in extrusion and pelleting involve high temperatures that partially destroy labile vitamins. Mineral and vitamin content of fish meals vary with the species, season of harvest and processing. Examine labels and products carefully. Some foods may not be adequate to sustain growth or even maintenance of carnivorous reptiles. However, the alternative homemade diet is often less desirable.

Protein in dog and cat foods ranges from 16 to 40% of ME; many pet foods provide more than 22% of ME from protein and more than 25% of ME from fat. These protein levels are likely to be adequate for carnivorous reptiles.

Herbivores generally suffer digestive upset when dietary fat exceeds about 12%. Herbivorous reptiles are unlikely to thrive on diets containing more than 12% fat, which limits the use of commercial pet foods to the "light" varieties. Light varieties often contain higher levels of fiber, which is favorable for herbivores.

Homemade Diets

A wide variety of homemade diets have been suggested for reptiles. Although homemade diets may provide adequate nourishment, most reptile owners are unwilling to devote the time necessary to properly prepare these diets. Additionally, owners must be willing to regularly observe which food components are being consumed to prevent reptiles from developing or reverting to preferential selection of specific ingredients. Considering these factors, well-formulated commercially prepared foods are a better alternative for most captive reptiles.

Supplements

Supplements are marketed as containing primarily vitamins and minerals in various amounts. Few if any supply all vitamins and minerals known to be essential for domestic species including reptiles. The tendency is to leave out those that are unpalatable or expensive. Until more work is done about reptile nutrition, no one product should be relied upon to supply all essential nutrients to captive reptiles. Better value may be achieved by using a broad-spectrum micronutrient product designed for people or domestic animals. These products may be used for reptiles, but care must be taken to provide vitamin D_3 (not vitamin D_2) and to avoid overdosage (Donoghue and Langenberg, 1996). A general mammalian guideline that may also be useful in assessing reptile supplements is vitamins A:D:E should be present in a ratio approximating 100:10:1. A review of the nutrient content of many of the commonly used supplements for reptiles has been published (Donoghue and Langenberg, 1996). If a commercially prepared food constitutes more than 50% of total dietary intake, supplements are contraindicated.

Although calcium is often included in commercial vitamin-mineral supplements, it is rarely present in quantities sufficient to meet requirements for reptiles fed mixed salads or invertebrates. Additional calcium may be provided as limestone (38% calcium), or as calcium salts-carbonate (40% calcium), lactate (18% calcium) and gluconate (9% calcium). Calcium and phosphorus are supplied in bone meal (24% calcium, 12% phosphorus) and dicalcium phosphate (18 to 24% calcium, 18% phosphorus). Bone meal tablets vary in size. A small (aspirin size) tablet weighs 0.75 g and provides about 180 mg calcium and 90 mg phosphorus. Products vary, so read labels carefully. Powdered calcium supplements can be dusted on salads and tablet forms can be crushed and mixed with food.

Assess and Select the Feeding Method

It may not always be necessary to change the feeding method when managing reptile patients; however, a veterinarian should verify that an appropriate feeding method is being used. Items to consider include feeding route, amount fed, how the food is offered and who feeds the reptile. All of this information should be gathered when the nutritional history is obtained. If the reptile has normal body condition and weight, the amount of food previously fed (on an energy basis) was probably appropriate.

Lizards

Lizard species (*Sauria*) may be herbivorous, omnivorous or carnivorous. Lizards that are carnivorous may consume either invertebrate or vertebrate prey, or both. Gastrointestinal morphology reflects feeding behavior. Thus, herbivorous lizards have hindguts adapted for fermentation of dietary fiber, and carnivorous lizards have relatively short and simple intestinal tracts suited for hydrolysis in the small intestine.

Herbivores

The green iguana (*Iguana iguana*) is the most common herbivorous lizard seen in veterinary practice. These large, arboreal, diurnal lizards originate from Central and South America and require tropical temperatures (approximately 32°C [90°F]) and humidity (approximately 90% relative humidity). With proper care, green iguanas may live 10 to 15 years in captivity. However, mistakes in husbandry and diet often lead to an early demise.

Other herbivorous lizards occasionally seen in practice include prehensile tail skinks (*Corucia* spp.) and chuckwallas (*Sauromalus* spp.). Others, such as spiny tailed lizards (*Uromastyx* spp.) and rock iguanas (*Cyclura* spp.), use hindgut fer-

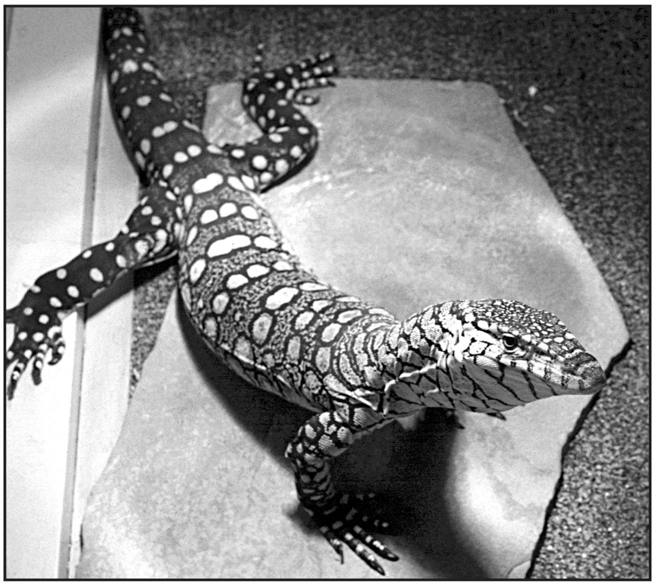

Figure 71-1. Monitor lizards are carnivorous. This large monitor (*Varanus giganteus*) awaits a large pre-killed rat to be dropped into its enclosure.

mentation and are often classified as herbivores, but also are known to consume invertebrate prey.

Diets for herbivorous lizards should include leafy greens such as romaine lettuce and collard greens, mustard greens and endive, dandelion and clover. Vegetables such as green beans, okra, carrots, yellow squash, zucchini and commercial thawed frozen mixed vegetables can make up a small fraction, perhaps 10 to 20%, of the diet.

Spinach, cabbage, peas, potatoes and beet greens contain oxalates that bind calcium and trace minerals, inhibiting their absorption. Trace mineral deficiencies may result if the diet is composed primarily of these foods and mineral intakes are marginal. Goitrogens are found in cabbage, kale, mustard and other cruciferous plants. Large intakes of these foods with marginal iodine intake may lead to hypothyroidism. Small amounts of these oxalate-containing and goitrogenic vegetables may still be fed safely as part of the diet.

Fruits can be used as "treats" or as a very small portion of the diet. Palatable choices include papaya, mango, cantaloupe, grapes and oranges.

Commercially prepared foods may constitute a significant portion of the diet (i.e., up to 50 to 60%). Treats and other nutritionally imbalanced foods should constitute no more than 10% of the diet.

If commercially prepared foods are used for 50% or more of the diet, additional supplementation is usually unnecessary. Homemade diets of vegetables and fruits should be supplemented. Several recipes have been published (Frye, 1991; Donoghue and Langerberg, 1996). Juveniles should be fed bite-sized foods, once or twice daily. Adults should be fed daily or every other day. These diurnal lizards should be offered food at a time that correlates with their need to bask and thermoregulate to allow efficient digestion of food.

Omnivores

Some of the most common omnivorous lizards presented to veterinary practitioners include bearded dragons (*Pogona* spp.), blue-tongued skinks (*Tiliqua* spp.), water dragons (*Physignathus* spp.) and plated lizards (*Gerrhosauras* spp.). In captivity, these omnivores consume prey (often invertebrates) or a meat-based, commercially prepared food mixed with fruits and vegetables.

A commercially prepared food should make up 60 to 75% of the total diet. The remaining portion may include invertebrates such as crickets, mealworms, wax worms, sweepings (insects found by gently sweeping grasses with a net; counsel clients to make sure no pesticides have been used on the grass), earthworms, snails and slugs (especially for skinks). Other prey includes small vertebrates, such as newborn and fuzzy mice, chicks and adult mice and rats. Cooked eggs may also be included as a protein source. Dog food (moist and dry), primate biscuits and trout food can be fed. Cat food is appropriate (up to 50 to 60% of the diet) for blue-tongued and pink-tongued skinks; however, these foods should be fed cautiously to other omnivorous lizards to prevent risks from over-feeding a high-fat diet.

Fresh greens and produce may make up the rest of the diet. Palatable foods include leafy vegetables, squash, carrots, green beans, alfalfa sprouts and thawed frozen mixed vegetables. Fruits should include melon, papaya and oranges.

Nutritionally adequate, commercially prepared foods are available for omnivorous lizards. However, because no long-term feeding trials have been reported, performance of lizards should be monitored to ensure that they are thriving.

In general, the more varied the overall diet, the less supplementation is necessary. If 50% or more of the diet includes dog food, monkey biscuits, cat food or complete omnivore foods, no supplementation is necessary. Otherwise, supplementation of produce and dusting of invertebrates are recommended.

Carnivores

The most common carnivorous lizards kept in captivity are monitors (*Varanus* spp.), tegus (*Tupinambis* spp.) and Gila monsters and beaded lizards (*Heloderma* spp.). These animals eat whole prey items (vertebrate [**Figure 71-1**] and invertebrate), but some also will eat cooked meat and eggs and commercial pet food. Feeding cooked meat and eggs is recommended to avoid exposure to potential pathogenic bacteria such as *Salmonella* spp.

Commercially prepared foods are available for monitors and tegus. As with any dietary regimen, reptiles should be monitored for any dietary-related disease. Supplementation is rarely necessary for adult carnivorous lizards if they are eating whole vertebrate prey items or commercially prepared food or a variety of foods. A calcium and vitamin D_3 supplement can be used twice weekly for juveniles fed a diet of newborn mice and insects.

Insectivorous lizards kept in captivity include species of geckos (*Gekkonidae* and *Eublepharidae*), old-world chameleons (*Chamaeleo* spp.), water dragons (*Physignathus* spp.), anoles

(*Anolis* spp.), small skinks (*Scincidae*), monitors (*Varanus* spp.), girdle-tailed lizards (*Cordylus* and *Pseudocordylus* spp.), lacertas (*Lacertidae*), basilisks (*Basiliscus* spp.), collared lizards (*Crotaphytus* spp.), sailfin dragons (*Hydrosaurus* spp.), ameivas (*Ameiva* spp.) and swifts (*Sceloporus* spp.). These species thrive on a wide variety of well-fed and well-supplemented insects such as crickets, mealworms, wax-moth larvae, king mealworms, cockroaches and fruit flies (for juveniles). Other insects, when available, include butterworms, grasshoppers, earthworms, flies, fly larvae and sweepings.

Insects can be fed a relatively balanced diet to "gut load" them before they are fed to lizards. A variety of whole diets can be used to feed insects including psittacine pellets, tropical fish flakes and commercial invertebrate "gut loading" foods. Also, insects can be fed vegetables that have a high precursor vitamin A content such as collard greens, kale, romaine and red-leaf lettuce, grated carrots and sweet potatoes (Stahl, 1997). Invertebrates should be dusted with a calcium supplement and a multivitamin supplement before they are fed to the reptile. (See Supplements.) Calcium supplement can be used daily for young growing reptiles and three to four times weekly for adults. Multivitamin supplements (which should contain some preformed vitamin A) should be used less frequently (i.e., once or twice weekly) (Stahl, 1997).

Prey should be of the appropriate size for the lizard. A general guide is for prey length to be less than the width of the lizard's head. Insects that are too large may bite the lizard or, if swallowed, cause it to regurgitate. Generally, only enough prey to be consumed at one feeding should be offered. Excess numbers of insects may cause stress or injury to the lizard.

Juveniles should be fed daily. Adults can be fed every second or third day.

Occasionally, larger and adult species of insectivorous lizards can be fed newborn, fuzzy or adult mice. The mice should make up no more than about 25% of the diet.

Several small lizard species, such as anoles and day geckos, readily accept fruit-flavored baby foods and yogurt. Basilisks, sailfin dragons and water dragons may accept a small amount of fruit. These soft foods provide a convenient medium for supplementation of calcium, vitamins and trace minerals.

Fresh water should always be available for lizards. Large soaking bowls should be provided for some species, such as water dragons and water monitors, Nile and Dumeril's monitors, sailfin lizards and basilisks. Misting the environment daily may help increase humidity for tropical species. Chameleons and some smaller species of lizards (e.g., anoles) usually won't drink from standing water. It is usually necessary to visually stimulate these lizards with drip systems, air bubbling systems or by misting the trees and plants in their environment to encourage drinking. These reptiles can also be placed on a clothes-drying rack or large plant, such as a *Ficus* spp., and placed under a spray of water in a shower, in order to simulate a rain shower and encourage drinking.

Some of the desert species (e.g., *Uromastyx* lizards and chuckwallas) need only small water bowls for drinking; however, they may benefit from being soaked in a warm water bath once or twice weekly. Water sources may harbor bacteria so bowls must be kept meticulously clean. Routine disinfection is recommended. Vitamin-mineral supplements should not be added to water sources because they may reduce palatability and result in increased bacterial populations.

Snakes: Serpentes

Snakes that Eat Mammalian and Avian Prey

Most of the snakes seen by private practitioners feed on mammals. Boids (pythons and boas), rat and corn snakes (*Elaphe* spp.) and gopher, bull and pine snakes (*Pituophis* spp.) are some of the more common snakes presented to veterinarians. Their diet consists of rats, mice, gerbils, rabbits and young chicks. These prey items should be fed a high-quality, complete ration to provide adequate nutrition for snakes.

Trauma associated with feeding live prey is common. Therefore, training snakes to eat stunned, dead or frozen-thawed prey is preferred. These reptiles are attracted to prey by the smell, the heat radiating from the prey item and by movement. To help encourage snakes to eat dead food, the prey item should be warm when offered. It can also be wiggled with a long pair of forceps. Eventually, even stubborn snakes become accustomed to eating dead prey.

Frozen rodents should be thawed rapidly in very hot water to minimize bacterial intestinal bloom. Caution should be used when feeding chicks or other birds to snakes because of potential exposure to salmonella. Boiling chicks before feeding may reduce the risk.

Some snakes are finicky feeders. For example, ball pythons prefer gerbils (which are found in their native habitat) or brown or black rodents, rather than white laboratory rodents.

Supplementation is unnecessary when feeding whole vertebrate prey. The only exception is with long-term feeding of newborn mice, which may be deficient in calcium. Allowing newborn mice to obtain milk from the mother for a day or two improves their calcium content. Also, dipping newborn mice in a liquid calcium supplement increases dietary calcium content. Feeding fuzzy mice also improves calcium content. Obese rodents and those that have been frozen for more than six months may have reduced vitamin content.

Snakes that are housed together should be separated for feeding to minimize injuries to each other and to help identify which snake has eaten. If two or more snakes attack the same prey, one snake may inadvertently eat or injure the other.

Feeding frequency varies, depending on the species of snake. Generally, young growing snakes should be fed every five to seven days. Mature, adult snakes may be fed weekly, biweekly or even monthly.

Snakes that Eat Reptiles, Amphibians and Fish

Some snakes feed on ectotherms, including amphibians, fish, crayfish and other reptiles. Snakes that eat these prey items include king snakes (*Lampropeltis* spp.), indigo snakes (*Drymarchon* spp.), water snakes (*Nerodia* spp.), hog-nosed snakes (*Heterodon* spp.), ring-necked snakes (*Diadophis* spp.) and garter snakes (*Thamnophis* spp.). The prey should be frozen for

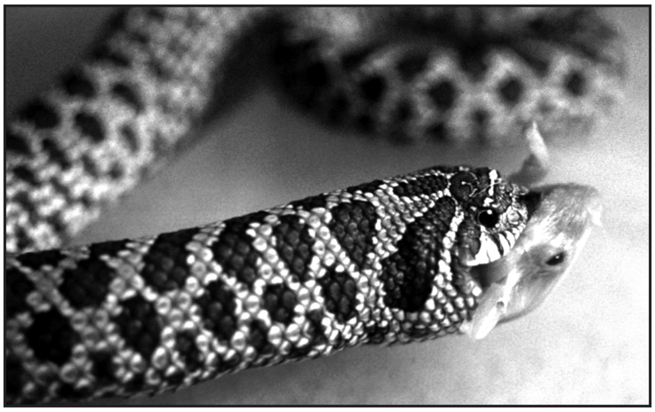

Figure 71-2. Hog-nosed snakes typically feed on amphibians, such as toads, in the wild. In captivity, they can be tricked into eating toad-scented mice. This young Western hog-nosed snake is eating a mouse backwards.

at least three days to minimize exposure to parasites; many of the prey are intermediate hosts to reptile parasites. Freezing may eliminate nematode parasites; however, it will not usually eliminate bacteria and protozoa. Regular fecal examination and deworming may be necessary to control protozoal parasites.

Ectotherm snakes should be trained to eat rodents. Initially, rodents can be scented with a more typical prey item. For example, a hog-nosed snake that typically eats toads and frogs in the wild can be encouraged to eat a rodent whose fur has been rubbed with a toad or frog to impart a familiar scent (**Figure 71-2**). Eventually, most of these snakes will accept rodents as their primary diet. Supplementation is usually unnecessary if a portion of the diet is made up of rodents.

Snakes that eat other snakes in the wild (e.g., king snakes) should be housed alone to prevent cage-mate predation.

Insectivorous Snakes

Insect-eating snakes typically seen by veterinarians include green snakes (*Opheodrys* spp.), worm snakes (*Carphophis* spp.), ring-necked snakes (*Diadophus* spp.), brown snakes (*Storeria* spp.) and other primarily fossorial snakes. Additionally, some ectotherm snakes eat insects, especially as juveniles.

A variety of insects should be offered, including crickets, mealworms, earthworms, nightcrawlers and wax-moth larvae. Insects should be fed a complete diet before they are fed to snakes. Insects should be dusted with a calcium and vitamin supplement weekly. Some of the larger snakes in this group may be weaned onto pinkie mice for added nutrition. Pinkies can be supplemented by dipping them into a liquid calcium supplement.

Many of these snakes also feed on very small amphibians, such as salamanders, tadpoles and frogs. As with feeding ectotherm snakes, cold-blooded prey items should be frozen for at least three days to minimize parasitic infections.

For all snakes, fresh water should be provided at all times. Water bowls should be cleaned and disinfected regularly. A water container that is large enough for soaking should be provided. Vitamin-mineral supplements should not be added to the water. Palatability may be reduced and bacteria in the water may feed on the supplements resulting in a bacterial bloom.

Turtles and Tortoises: Chelonia

Carnivores

The most common carnivorous turtles seen by veterinarians are water turtles, such as snapping turtles (*Chelydra* spp.), mata mata turtles (*Chelys* spp.) and alligator snapping turtles (*Macrochelys* spp.). These turtles usually eat only while in water. They can be fed in their regular aquatic environment or, better yet, in a separate water-filled tank. This practice decreases the amount of fecal material and decaying food in their aquarium, thereby reducing water quality problems.

Most aquatic turtles are fed commercial turtle or fish pellets. Trout food comes in several sized pellets. Large pellets tend to float well and are attractive to large turtles, whereas the smaller pellets tend to sink quickly but are readily accepted by juveniles and small turtles. Trout food may be difficult for reptile owners to find because it is usually only available by special order from feed stores. It is typically sold only in 50-lb bags. Veterinarians who see a large number of reptiles may want to purchase the food, separate it into smaller amounts (store it in a freezer) and make it available to clients who own turtles.

Fish (e.g., goldfish, minnows and guppies) are also fed to aquatic turtles and are available as feeder fish from pet stores. Smelt, mackerel and other oily fish should be fed in limited quantities because their high polyunsaturated fatty acid content may lead to vitamin E deficiency and steatitis. Also, fish may contain thiaminases. Feeding wild-caught fish should also be discouraged because they may be intermediate hosts for reptile parasites. Amphibians (e.g., tadpoles and frogs) can also be fed but they too are safest if captive-born. Crayfish are not recommended because they may harbor the bacterium *Beneckia chitonvora*, which has been implicated in shell diseases of turtles (Boyer and Boyer, 1992).

Other food items include earthworms, snails, slugs, beetles, grasshoppers, moths, crickets, mealworms, giant mealworms, wax worms and other insects. Wild-caught prey should be free of insecticides and pesticides.

Carnivorous turtles may occasionally consume leafy vegetables or fruits, which can be fed as treats. Vitamin-mineral supplementation is not necessary if turtles eat a variety of commercial foods. Cuttlebone may be added as a calcium supplement for juveniles.

Omnivorous Aquatic Turtles

The most common omnivorous water turtles seen by veterinarians are red-eared sliders (*Trachemys* spp.), painted turtles (*Chrysemys* spp.), Reeves turtles (*Chinemys* spp.), diamondback terrapins (*Malaclemys* spp.), map turtles (*Graptemys* spp.) and river cooters (*Pseudemys* spp.). Many omnivorous water turtles are primarily carnivores as juveniles and become more herbivorous as they age. The carnivorous portion of the diet is the same as described for carnivorous water turtles and should make up between 75 and 100% of the diet for juveniles and about 50% of the diet for adults. A wide variety of vegetables should be

offered to round out the diet.

Generally, vegetables that float are preferable because turtles can nibble on them throughout the day. Favorites include greens such as romaine lettuce, collard greens, endive, Swiss chard and kale. Fruits tend to disintegrate in water. Supplementation of the diet is usually unnecessary if the diet is varied and includes commercial foods.

Box Turtles

Some of the most popular box turtles include the eastern box turtle (*Terrapene carolina carolina*), the ornate box turtle (*Terrapene ornata ornata*), the three-toed box turtle (*Terrapene carolina triunguis*) and Asian box turtles (*Cuora* spp.).

Box turtles are primarily omnivorous, although some species such as Asiatic box turtles are more carnivorous. Box turtles tend to eat more animal protein as juveniles and become more omnivorous as they mature. The carnivorous portion of the diet is similar to that described for water turtles and should include a wide variety of invertebrates such as earthworms, slugs, mealworms and wax worms.

Commercial box turtle foods, low-fat dog food, trout food, primate biscuits and small amounts of cat food add variety and nutritional balance to the diet. Fruits and vegetables will be more readily accepted as box turtles mature, but should be offered at all ages (**Figure 71-3**). Box turtles seem most interested in eating red, orange and yellow foods. They tend to favor strawberries, tomatoes, raspberries and blueberries. These fruits can be used to entice turtles to eat. Red food dye can be used to convince stubborn animals to try different and more balanced foods.

Water for box turtles should always be available in a shallow, heavy bowl or dish to allow the turtle to enter the water without spilling the contents. Additionally, box turtles should be soaked in a warm water bath once or twice weekly for approximately 30 minutes. Vitamin and mineral supplements should not be placed in water sources because they may reduce palatability and may increase bacterial growth.

Herbivorous Tortoises

The most common tortoises seen by veterinarians are California desert tortoises (*Gopherus agassizii*), leopard tortoises (*Geochelone pardalis*), South American red-footed tortoises (*Geochelone carbonaria*), yellow-footed tortoises (*Geochelone denticulata*), Greek tortoises (*Testudo graeca*), hingeback tortoises (*Kinexys* spp.) and gopher tortoises (*Gopherus polyphemus*). Most tortoises are strictly herbivorous, although a few accept meat-based foods. All use hindgut fermentation.

The basic diet for most tortoises includes a staple of leafy vegetables, such as collard greens, romaine lettuce, parsley, leaf lettuce, dandelion greens, turnip greens and Swiss chard. Dandelion and clover are excellent forages. These should make up 60 to 70% of the diet. Avoid feeding excessive quantities of produce containing oxalates (e.g., spinach) and goitrogens (e.g., kale). Commercially prepared foods for tortoises and iguanas work well for the other 30 to 40% of the diet because they supply protein, vitamins and minerals not present in vegetables.

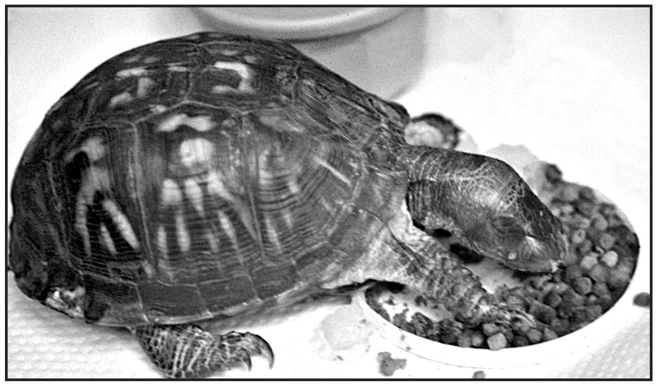

Figure 71-3. Box turtles are omnivorous. This Eastern box turtle is eating a commercial turtle ration with added chopped fruit.

Timothy hay, alfalfa hay and pellets and grass clippings may be offered to increase the fiber content of the diet. The remainder of the diet may include small amounts of fruits and vegetables.

For juvenile tortoises, foods should be finely chopped into small, manageable pieces to increase consumption. To minimize ingestion of cage and enclosure substrate, food should be offered on flat trays or plates that juveniles can climb onto. Tortoises are often unable to eat from bowls or raised feeders.

Produce should be supplemented with calcium, vitamins and trace minerals. Usually, diets are supplemented twice weekly for hatchlings and once every seven to 10 days for adults. Supplementation may be unnecessary if 50% or more of the tortoise's diet is comprised of commercial food.

Many tortoises will not drink from water bowls, so all tortoises should be soaked in a tub or large bowl of warm water (up to the plastron) for 15 to 20 minutes to encourage drinking and excretion. Generally, tropical species should be soaked twice weekly, whereas desert species may need to be soaked only once a week. Hatchlings should be soaked daily.

CASE 71-1

Swollen Eyes and Respiratory Difficulty in a Box Turtle

Scott Stahl, DVM, Dipl. ABVP (Avian)
Stahl Exotic Animal Veterinary Services
Vienna, Virginia, USA

Susan Donoghue, VMD
Nutrition Support Services
Pembroke, Virginia, USA

Patient Assessment

An adult, female Eastern box turtle (*Terrepene carolina carolina*) weighing 357 g was presented for examination. The turtle had a carapace length of 125 mm, and a plastron length of 121 mm. The turtle had been caught and maintained in captivity for one year. It was kept indoors during the winter in a 20-gallon aquarium with one other female Eastern box turtle. In the late spring, it was placed in an outdoor enclosure. The outside environment contained a small wooded area, weeds, grass and leaves. Open areas in the enclosure allowed exposure to sunlight. One male and two other female box turtles also lived in this outdoor enclosure. The turtle was observed laying a clutch of eggs one month earlier.

The owner presented the turtle because its eyes were swollen and sometimes sealed shut. Congestion was noted and mucus bubbled from the turtle's nares. The turtle was anorectic and lethargic.

Physical examination revealed bilaterally swollen eyelids with conjunctivitis and purulent discharge. Visual inspection of the corneas was difficult due to swelling. Mucus was present in both nares, and congestion and mucus were noted in the oral cavity. Increased upper respiratory noises were heard. Skin and shell quality were normal. Body weight was fair.

A culture was taken of the mucus in the nares. A diagnosis of hypovitaminosis A and secondary bacterial conjunctivitis and rhinitis was made based on the historical information and physical examination findings.

Assess the Food and Feeding Method

The turtle's diet for the previous year consisted of a variety of fruits, such as apples, bananas, strawberries, and earthworms and insects found in the outdoor enclosure. The owner had not used any supplements for several months, but previously had used a multivitamin supplement.

Questions

1. What nutrient problems should be suspected based on the dietary history?
2. What should the initial treatment be for this turtle?
3. What long-term changes should be made in the diet?

Answers and Discussion

1. The current diet was probably deficient in vitamin A and other vitamins and minerals, such as calcium. Earthworms are generally a nutritious dietary item, but the fruits offered provided only trace amounts of calcium and inadequate supplementation was provided. Additionally, not feeding a complete food, such as commercial box turtle, trout or dog food as a part of the diet contributed to the problem.
2. The patient was soaked in a warm water bath for 20 minutes then placed in an incubator at 29°C (85°F) and fluid therapy was initiated (20 ml/kg body weight of lactated Ringer's solution given epicoelomically). Vitamin A (200 to 300 IU/kg body weight) was given orally. The turtle was started on enrofloxacin[a] (5 mg/kg body weight, q48h) administered into the musculature of the front legs. One or two gentamicin ophthalmic drops were placed in each eye twice daily.[b]
3. The patient's diet was changed to include foods with higher vitamin A content. A variety of vegetables and fruits, and a commercial box turtle food were provided.

Progress Notes

The following day, the box turtle was soaked in a warm water bath for 15 minutes. Afterward, purulent material was gently removed from the periocular tissues with an eye rinse.[c] Gentamicin ophthalmic drops were placed in both eyes. The patient was then tube fed an enteral diet[d] placed directly into the stomach with a curved metal feeding tube. The following day, the enrofloxacin, gentamicin drops and the warm water bath were repeated.

The turtle was sent home with a two-week course of parenteral enrofloxacin and gentamicin drops. The owner was instructed to apply a vitamin A eye preparation[e] to the eyes daily for 14 days and soak the turtle daily for 15 to 20 minutes. Changes in the diet were recommended and the owner was encouraged to offer food immediately following the soaks.

At a follow-up visit two weeks later, the owner said the turtle had begun to eat well and was much more active. Upon physical examination, the eyes were open and markedly less swollen (**Figure 1**) and no nasal discharge was present. Culture results of the nasal discharge taken earlier revealed *Pseudomonas aeruginosa*. This organism was sensitive to enrofloxacin and gentamicin. The oral dose of vitamin A was repeated, and enrofloxacin, gentamicin and vitamin A drops were continued for another seven days.

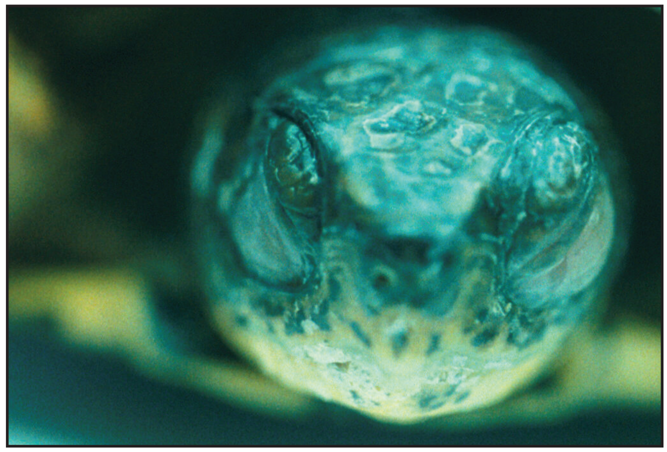

Figure 1. An Eastern box turtle that presented initially for bilaterally swollen eyelids and conjunctivitis with purulent discharge.

CASE 71-2

Lethargy and Bone Swelling in a Green Iguana

Scott Stahl, DVM, Dipl. ABVP (Avian)
Stahl Exotic Animal Veterinary Services
Vienna, Virginia, USA

Susan Donoghue, VMD
Nutrition Support Services
Pembroke, Virginia, USA

Patient Assessment

An 18-month-old green iguana (*Iguana iguana*) was purchased from a local pet store as a farm-raised juvenile and had been in the owner's possession for one year. The iguana was examined for anorexia of 10 days' duration, a swollen mouth and lethargy.

The iguana was housed in a 20-gallon aquarium with indoor/outdoor carpeting, a branch, plastic plant, water bowl and food bowl. A large "hot rock" provided heat. No artificial lighting was provided, but the cage was placed near a window. The iguana was housed alone; the owner had no other reptiles. The iguana had no history of illness and had never been examined by a veterinarian.

The iguana was generally depressed. Its color was a dull yellow-green. At 253 g and 8 inches (snout to vent length) the animal appeared stunted. Under optimal conditions, it should have been three or four times heavier and markedly longer (i.e., 12 to 14 inches). The mandibular bones were severely swollen, the right side significantly more so than the left. Yellow-brown dried material was present along the exposed mandibular mucous membranes. The right forearm, left tibia and right and left femurs were enlarged. The muscle mass over the rear limbs and tailbase was poor. Results of abdominal palpation were normal. The patient exhibited muscle tremors and fasciculations when handled. It was unable to lift its body off the ground to ambulate but would try to slide along the ground.

Radiographs were taken to assess the skeletal system. The right radius and ulna were fractured, but the fractures appeared old (i.e., callous formation). Poor cortical bone density was evident on all long bones and the mandibular and maxillary bones.

A diagnosis of metabolic bone disease was made based on the clinical history, physical examination and radiographic findings.

Assess the Food and Feeding Method

The patient had been raised on a diet of red-tipped and iceberg lettuce, peas, corn, carrots, apples and strawberries. It was fed daily and was offered two or three of these items at a time. The food was always chopped into small pieces and sometimes dusted with a "reptile vitamin." The owner did not know the name of the supplement, only that it came in a yellow container. The supplement hadn't been used for months. Fresh water was always available.

Questions

1. What nutrient problems should be suspected based on the dietary history?
2. What is the initial treatment for metabolic bone disease?
3. What should be the long-term feeding plan?
4. What other husbandry recommendations should be made?

Answers and Discussion

1. The iguana was fed a diet low in calcium and high in phosphorus, with poor and inconsistent calcium and vitamin supplementation. The iguana was not exposed to natural sunlight or ultraviolet light, probably leading to vitamin D_3 deficiency. Sunlight through a glass window does not provide ultraviolet exposure. Other nutrient deficiencies are likely, too.
2. Initially the patient was placed in an incubator at approximately 31°C (88°F). Warm lactated Ringer's solution was given intracoelomically (20 ml/kg body weight). Eight hours later, vitamin D (1,000 IU vitamin D/kg body weight, intramuscularly) and a calcium-containing solution[a] (0.5 ml/kg body weight, subcutaneously) were given. The iguana was kept overnight in the incubator. The following day, fluid therapy was repeated and an enteral nutritional product[b] was administered orally (50% of metabolic requirement, e.g., 5.5 kcal [23 kJ] or 5.5 ml of the liquid enteral product) using a 14-Fr. red rubber urinary catheter. The iguana was started on an oral calcium supplement (1 mg/kg body weight).[c]
3. The iguana's diet was changed to include a wider variety of calcium-rich vegetables. Supplementation included calcium carbonate sprinkled onto the greens, and once weekly sprinkling of a vitamin D_3-containing product onto the greens. Recommendations included placing a full-spectrum fluorescent bulb within 12 to 18 inches of the patient.
4. Iguanas are diurnal basking lizards and must be provided with radiant heat. A temperature gradient should be provided in their environment. The upper end of the temperature range should be 31 to 35°C (88 to 95°F). A "hot rock" does not provide adequate heat for an iguana. A clamp lamp with an incandescent light bulb was placed at one end of the aquarium to keep the hot end of the cage between 31 and 33.5°C (88 and 92°F). In addition, a hide box was provided to help minimize stress and branches were removed to prevent falls until the patient's bones strengthened.

Progress Notes

The iguana's owner was instructed to slowly feed the enteral nutritional product with a syringe (5 to 10 kcal [21 to 42 kJ] daily in small divided doses). The patient was also soaked daily in a warm water bath. The iguana was given the oral calcium supplement (1 ml/kg body weight, b.i.d.) for 30 days.

The iguana returned in one week for a follow-up examination. The owner reported that the iguana was readily accepting the enteral nutritional product and was more alert and active. Upon physical examination, the mandible seemed firmer and the patient was much more responsive. Calcitonin[d] was administered intramuscularly (50 IU/kg body weight). The patient's diet was switched from the enteral product to moistened commercial iguana food. Small meatball-shaped pellets were fed (four to five pieces were fed one or two times daily, depending on the iguana's appetite). Additionally, two tablespoons of chopped dark green leafy vegetables (e.g., collard greens, kale, romaine lettuce) were offered daily. Oral calcium was continued.

The iguana returned weekly for calcitonin injections and a second injection of vitamin D. Three weeks later, a follow-up examination revealed stronger, firmer mandibular and maxillary bones and reduced swelling and increased strength in the long bones. The iguana was able to lift its body off the ground to ambulate. It was eating commercial food vigorously and also eating some of the greens. The owner reported that the iguana was spending time basking and had become more active. The oral calcium supplement was reduced to once daily dosing.

A recheck one month later revealed that the iguana was able to move normally (**Figure 1**). The mandibular and maxillary bones were firm and the patient's appetite was dramatically improved. Rechecks were recommended at three-month intervals over the next year to prevent relapses.

CASE 71-3

Anorexia and Lethargy in a Green Iguana

Connie J. Orcutt, DVM, Dipl. ABVP (Avian)
Angell Memorial Animal Hospital
Boston, Massachusetts, USA

Patient Assessment

A two-year-old female green iguana weighing 1.6 kg was presented for anorexia and lethargy of six days' duration. The owner obtained the iguana 18 months ago. The iguana was housed in a 75-gallon aquarium with another iguana. The aquarium was heated with a heating pad under the tank and a 220-watt infrared heat lamp. Ultraviolet-B light was provided by an artificial light source; however, the owner couldn't specify how long the source was provided daily.

When examined, the iguana was lethargic, but moved when stimulated. The overall skin coloration was dark and dull. A firm mass was palpated in the caudodorsal coelomic cavity; deep palpation elicited a response from the patient. The patient's long bones were palpably normal. The mandible was firm and non-compressible.

Abnormal results of a complete blood count and serum biochemistry profile included a heterophilic leukocytosis, hyperproteinemia, marked hyperphosphatemia, hyperuricemia and marked increases in creatine kinase levels and aspartate aminotransferase activity. Radiographs demonstrated bilaterally symmetric soft tissue opacities in the caudodorsal coelomic cavity; these opacities were thought to be the patient's kidneys. A sonogram revealed enlarged hyperechoic kidneys bilaterally.

Assess the Food and Feeding Method

The iguana's diet consisted of a variety of vegetables including greens, broccoli and dandelions as well as an unspecified commercial iguana food, which made up approximately 50% of the total diet. Fruit was given occasionally. The owner had been supplementing the diet with a vitamin-mineral supplement twice daily for several months.

Questions

1. What nutritional problems are suggested by the diet? Could any of these explain the iguana's clinical signs?
2. What is the pathophysiology of the biochemical abnormalities? What is the significance of the abnormalities found by imaging?
3. How can this condition be treated?

Answers and Discussion

1. The owner has been providing large amounts of vitamin D_3 in the form of the vitamin-mineral supplement and the commercially prepared iguana food. Vitamin D_3 is essential for calcium uptake from the intestinal tract; however, it can be toxic when given in large amounts. Either hypervitaminosis D or hypocalcemia could be responsible for the lethargy and anorexia exhibited by the patient.
2. Hyperproteinemia may be due to dehydration. Hyperuricemia and hyperphosphatemia indicate some degree of renal failure. The increase in aspartate aminotransferase activity and elevated creatine kinase value indicate either muscle degeneration and/or hepatic damage. Renomegaly and pain elicited when the kidneys were palpated are signs consistent with nephrosis. The increased opacity in the region of the kidneys seen radiographically and by ultrasound is consistent with mineralization of the renal parenchyma. The combination of these findings is suggestive of renal failure secondary to hypervitaminosis D.

3. Excessive supplementation with vitamin D_3 allows large amounts of calcium to be absorbed from the intestinal tract. The resulting soft tissue mineralization, however, can be widespread and severe. Endstage renal failure is generally unresponsive to treatment; however, diuresis may provide short-term palliative treatment.

Progress Notes

The iguana was diuresed with a mixture of 0.9% saline, 2.5% dextrose and lactated Ringer's solution administered intracoelomically for two days. Unfortunately, the patient died on Day 3. Results of a necropsy examination revealed moderate tubular nephrosis and severe degeneration with mineralization and necrosis of the heart and skeletal muscles. The final diagnosis was vitamin D toxicosis. Vitamin D_3 and calcium metabolism are still not well elucidated in iguanas and vitamin D_3 requirements have not been established. It is unclear how well vitamin D_3 is absorbed in these animals. The risk of over-supplementation can be avoided by providing exposure to adequate amounts of ultraviolet-B light, thus allowing the body to form its own vitamin D_3 instead of giving oral supplementation.

Chapter 72

Feeding Passerine and Psittacine Birds

George V. Kollias
Heidi Wearne Kollias

"Of all forms of life, birds are the most beautiful, most musical, most admired, most watched and most defended. Without them much of our world would seem ominously lifeless and silent."
Roger Tory Peterson

INTRODUCTION

One avian medicine reference states that 75% of the medical problems seen in companion and aviary birds have at least a partial nutritional basis (MacWhirter, 1994). Dietary-induced deficiencies and excesses may lead to immune dysfunction, increased susceptibility to infectious diseases and metabolic and biochemical derangements that manifest clinically as nutritional secondary hyperparathyroidism, thyroid hyperplasia (dysplasia), hemochromatosis and a variety of other problems.

Dietary-induced diseases frequently occur in companion and aviary psittacine and passerine birds for several reasons. First, until recently, specific nutritional requirements for these birds were unknown. Thus, investigators and veterinary practitioners tended to extrapolate the well-known nutrient needs of poultry to other avian species. Although these nutrient needs generally apply, specific nutritional differences of domestic chickens and other avian species have been reported. For example, riboflavin deficiency in broiler chicks manifests itself clinically as "curled-toe paralysis," which is not observed in cockatiel chicks. Cockatiels lack pigmentation (achromatosis) in their primary feathers as a result of riboflavin deficiency (Grau and Roudybush, 1985). Although differences of this type exist experimentally, many prepared foods overcome these differences by supplying levels of nutrients well in excess of the minimum requirement for chickens.

Second, and more important, many people perceive that all-seed diets (particularly diets composed of only one seed type, e.g., millet or sunflower) and diets composed of or are heavily supplemented with, fruits, vegetables and other human foods are complete foods for birds. In reality, most commercially available seeds are deficient in certain limiting nutrients (e.g., specific amino acids, vitamins and trace and macrominerals such as calcium and sodium). Also, seeds are not the primary or natural diet of most species of companion birds. For example, one study revealed that when given the opportunity, the endangered Puerto Rican parrot (*Amazona vittata*) consumed seven species of fruits, seeds and leaves (new foliage), the fruiting structures of 44 species of trees (in addition to bark) and seven

species of canopy vines (Synder, 1987). Thus, seeds compose only a small part of their total diet in the wild.

Additionally, evidence suggests that increased protein may be needed during certain points in the reproductive cycle. In the wild, insects supply these increased needs. It is difficult for bird owners to meet these special needs feeding only seed mixtures.

But, perhaps the most common cause of dietary-induced diseases in companion birds is the practice of adding fruits and vegetables sold for human consumption to commercially prepared foods or supplemented seed mixtures. The most readily available fruits and vegetables contain primarily water, carbohydrates and fiber. They are severely deficient in protein, vitamins and minerals (Nutrient Content of Foods, USDA), when compared to the nutrient recommendations for psittacine and passerine birds (Nutrition Expert Panel Report, 1996). Thus, fruits and vegetables primarily dilute key nutrients present in nutritionally balanced commercially prepared foods. Birds often preferentially eat fruits and vegetables due to their high water content instead of dry extruded or pelleted foods and seed mixtures. In fact, birds often select food items based on water content, texture, color or taste, rather than nutrient content (Ullrey et al, 1991), resulting in very imbalanced nutrient intakes.

This common feeding practice leads directly to the third reason captive birds develop nutritional deficiencies, which is the tendency of individual birds to select specific food items from a variety of offerings. Because malnourished birds often tend to overeat the food items presented to them, it is unclear whether this is a cause or an effect of malnutrition. It does lead to the popular misconception that birds are able to preferentially balance their diets. As a result, individual birds may become habituated or fixated on a specific food item (e.g., sunflower, safflower or millet seeds or grapes or oranges). Yet these specific items are usually deficient in several essential nutrients.

This chapter summarizes assessment criteria and feeding plans for healthy birds commonly kept as pets.

PATIENT ASSESSMENT

Signalment

Veterinary practitioners and their health care teams should become familiar with the most common psittacine and passerine species. Psittacine birds are members of the order Psittaciformes, (parrots and parakeets). Passerine birds belong to the order Passeriformes, which includes finches, sparrows, buntings, mynahs, canaries and serins.

Estimation of age and sex is important in nutritional assessment; like dogs and cats, birds have different requirements with varying age and function. Immature psittacine and passerine species characteristically have dull-colored feathers. Beak color varies with age in some species. If adults are dark-billed, immature birds of the same species may have light-colored bills. If adults have pale beaks, those of juveniles are generally dark or have dark markings at the base of the beak. Immature passerine birds are particularly difficult to identify until they go through their first or second molt.

Iris color may help in estimating the age in some species. Young psittacine birds have brown or dark irides. The iris color of macaws fades to gray within one year, appears white from one to three years and then turns yellow in mature birds. The iris color of Amazon parrots may change to red-orange as birds mature. African grey parrots' irides lighten from brown through gray to white. The irides of both genders of immature Moloccan cockatoos (and most all-white cockatoos) are brown; mature males have red irides and mature females have dark brown irides.

History

Because the clinical manifestations of malnutrition in birds are quite variable, the history and physical examination are very important (**Table 72-1**). Before a bird is presented at the veterinary hospital, the client should be instructed to:

1. Bring the bird in its own cage.
2. Not clean the cage.
3. Empty the water dish.
4. Remove all grit (if used) from the cage.
5. Cover the cage and wrap it with a blanket in cold weather.
6. Remove all cage furniture if the bird is weak or injured.
7. Bring any medications and vitamin-mineral supplements the bird has been offered.
8. Bring a sample of the foods offered daily (e.g., seed mixtures, pelleted or extruded food) and a list of fruits, vegetables and other foods regularly fed.

The history should include general questions such as: 1) the origin of the bird, 2) length of ownership, 3) housing arrangements, 4) type of heat and humidity provided, 5) light sources used (e.g., ultraviolet, full spectrum, fluorescent, natural, etc.), 6) exposure to other birds, 7) foods and supplements normally fed, for how long and in what quantities, 8) the owner's assessment of the presenting condition (including changes in food and water consumption, droppings, environment and behavior) and 9) information relative to previous treatment by the owner or another veterinarian.

The history for a newly acquired bird (owned for less than 10 months of age) will often include exposure to infectious diseases (viral, mycoplasmal, bacterial and mycotic) as a result of contact with other birds in a pet shop, aviary or quarantine facility. These problems are among the most difficult to accurately diagnose and treat. Other problems commonly associated with a newly acquired bird include acute malnutrition, trauma, parasitism (hematogenous, gastrointestinal and respiratory), intoxications and secondary immune suppression associated with one or a combination of the above.

Birds owned for more than 10 months can be considered to be from an "uncontaminated" environment unless other birds frequently immigrate and emigrate from the household or collection. Individual birds not exposed to other birds for this period may have chronic malnutrition of dietary origin.

Physical Examination

General Examination

Observation of the patient in its cage or aviary environment is important. The condition of the cage may indicate the type of human-animal bond (e.g., concern, or lack thereof). First

Table 72-1. Clinical manifestations of malnutrition in birds.*

System	Physical or clinical manifestation
Pansystemic or generalized	Behavioral changes
	Epithelial hyperplasia or metaplasia (skin, respiratory, gastrointestinal)
	Gout
	Hypocalcemia
	Immune suppression (lack of infectious disease resistance)
	Low body weight
	Polyphagia/obesity
	Polyuria/polydipsia
	Poor growth
	Subcutaneous edema (vitamin E/selenium deficiency)
Integumentary	
Skin	Dryness
	Exfoliative dermatitis
	Pododermatitis
	Poor wound healing
	Pruritus
	Uropygial gland hypertrophy and duct obstruction
Beak	Excessive or abnormal beak growth, dryness, epithelial exfoliation
Feathers	Abnormal markings in feathers ("stress lines")
	Brittle frayed feathers
	Color or pigment changes (depigmentation, hyperpigmentation, melanosis)
	Curling of feathers
	Feather picking
	Lack of development of contour feathers
	Molting abnormalities
	Retained feather sheaths
Gastrointestinal	Generalized epithelial alterations
Oropharynx	Mucosal ulceration
	Salivary gland abscessation
	White (caseous appearing) plaques involving the oral mucosa
Crop	Lithiasis
	Regurgitation
	Secondary crop stasis or impaction
Esophagus, proventriculus, ventriculus	Altered motility, mucosal erosion, regurgitation
	Koilin abnormalities (erosion, dysgenesis)
Small and large bowel	Diarrhea
	Enteritis (e.g., clostridial infections secondary to high sugar diets)
	Malabsorption
Liver	Hepatopathies (e.g., fatty liver syndrome)
Pancreas	Pancreatic atrophy
Respiratory	Generalized epithelial alterations
	Partial or complete upper or lower airway obstruction causing dyspnea (rhinal cavity, sinuses, syrinx)
Nares	Serous nasal discharge
Eyes	Serous ocular discharge
	Lacrimal duct obstruction (epiphora) secondary to epithelial debris accumulation
	Palpebrae (eyelid) paresis or paralysis
Central and peripheral nervous and neuromuscular	Abnormal gait, "jerky leg movements" (pyridoxine deficiency)
	Behavioral changes (e.g., aggression, cannibalism, self mutilation)
	Cervical paralysis (folic acid deficiency)
	Muscular weakness/paresis (vitamin E deficiency, hyponatremia)
	Seizures (salt toxicity, hypothiaminosis, hypocalcemia, vitamin E deficiency)
	Syncope (hypoglycemia, hypocalcemia)
Musculoskeletal	Hock (tibiotarsal/tarsometatarsal) joint enlargement
	Limb deformities (valgus/varus deformities involving long bones)
	Pathologic fractures (metabolic bone disease)
	Slipped tendon (deficiency of manganese, biotin, pantothenic and/or folic acid in some species)
Urogenital	Egg binding (endocrine or neuromuscular in origin)
	Endocrinopathy affecting fertility/reproductive performance
	Epithelial hyperplasia/metaplasia (renal and/or ureteral obstruction)
	Gout
Cardiovascular	Anemia
	Coagulopathy (vitamin K deficiency, hepatopathy)
	Hemorrhagic diathesis (vitamin E deficiency)
Endocrine	Goiter (thyroid dysplasia), iodine deficiency

*Adapted from MacWhirter P. Malnutrition. In: Ritchie BW, Harrison GJ, Harrison LR, eds. Avian Medicine: Principles and Applications. Lake Worth, FL: Wingers Publishing, 1994; 842-861. Kollias GV. Diets, feeding practices, and nutritional problems in psittacine birds. Veterinary Medicine 1995; 90: 29-39.

observe the bird at a distance (nonthreatening). A healthy bird should appear alert and attentive. Tame birds generally appear relaxed and calm. Some birds vocalize and are very active during examination (macaws, Amazon parrots, African grey parrots and conures). Abnormalities include fluffing of the feathers, head tucking, rhythmic movement of the tail, frequent blinking, lethargy and falling asleep on the examination table.

Trunk and limb asymmetry and skeletal deformities are obvious if the veterinarian is familiar with normal conformation. Drooping wing(s) may indicate paresis or injury. Restlessness, shifting of body weight or favoring one leg may suggest discomfort or dysfunction from pain or injury. Dysequilibrium may be associated with spinal malformation, toxin ingestion, head injury or metabolic derangement affecting the central nervous system that may be associated with malnutrition, especially inadequate intake of calcium or B-complex vitamins. Only minimal restraint should be used during the physical examination.

Oral Examination

The oral cavity should have a neutral odor. Causes of a foul-smelling oral cavity include bacterial pharyngitis, sinusitis or digestive disorders that may be exacerbated by diet or malnutrition. Normal oral epithelium is shiny and has uniform color. Some psittacine and passerine birds (cockatoos, Amazon parrots and macaws) have darkly pigmented oral epithelium, whereas others have a pink oral mucosa.

White caseous lesions on or below the mucosa may suggest inflammatory changes secondary to squamous metaplasia associated with hypovitaminosis A. These types of lesions may also be observed with poxvirus infection, candidiasis, trichomoniasis and coliform abscesses. Sick birds often accumulate mucus in the mouth, under the premaxilla and tongue. Birds that recover from hypovitaminosis A and viral infections may have scar formation around the choanae, or the normal papillae on the choanal boarders may be blunted or absent.

Tongue characteristics vary with the species. Psittacine birds normally have a smooth-surfaced, symmetric, thick and fleshy tongue with a thick layer of epithelium near the tip. The color varies from pink to black depending on the species. Passerine birds have a rigid tongue with a whitish or light gray tip. Unilateral swelling of the tongue may indicate abscess formation.

Beak and Cere Examination

The beak is normally smooth and uniformly colored with a deep sheen. Abnormal, rapid beak growth may be associated with malnutrition, specific viral disease (psittacine beak and feather virus), obesity or hepatopathy. Budgerigars with rapid beak growth often have reddish-black discoloration on the anterior margin of the premaxilla. Twisted beaks (mostly seen in fledglings) are often associated with malnutrition, systemic disease, feeding trauma or genetic-based malformation. Psittacine birds require branches or hardwood to chew on for beak conditioning. Cuttlebones and mineral blocks are inadequate for this purpose. In fact, cuttlebones should *not* be recommended for beak conditioning or as a nutritional supplement. A flaky or rough-looking beak may be associated with malnutrition, lack of proper chewing or systemic disease. The beak should also be examined for fractures, dislocations and erosive lesions that may result from bacterial, fungal and viral infections (e.g., psittacine beak and feather disease).

The cere, a soft cutaneous appendage containing the nares, should normally be firm and smooth, and lack flakes and debris. The nares should be evenly placed in relationship to the cere and be bilaterally symmetric in size and shape. Change in diameter may indicate past or present respiratory infections or neoplasia. Nasal discharge is abnormal and may be indicated by staining of the feathers above the cere.

Eye and Ear Examination

The eyes are best examined with the aid of transillumination externally and from inside the oral cavity. Birds have the ability to voluntarily control pupil size, thus pupillary constriction in response to light is not an accurate indication of vision. A menace response should be present bilaterally.

Symmetry, position and mobility of the globes should be noted. If conjunctivitis is present, culture and sensitivity testing should be done along with a detailed nutritional history. The cornea should be smooth and shiny. Any irregularities should be investigated by staining with fluorescein dye. The anterior chamber of the eye should be examined with indirect or direct ophthalmoscopy. The iris should be flat and thin and have a freely moving pupillary border. Clarity of the lens should be determined when the pupil is dilated.

A normal fundic examination should reveal an evenly reflective, avascular retina. The pecten, a heavily pigmented pleated vascular structure, extends from the optic disk into the vitreous.

The ears normally are free of exudate and debris. Epithelial debris often accumulates in the external auditory meatus of birds as a sign of malnutrition.

Skin and Feather Examination

Injuries and other problems involving the wings are common in birds. Examination should include complete palpation of both wings. Twisted, brittle and deformed wing feathers may be associated with nutritional, genetic, traumatic or a combination of causes. Abnormal feathering is associated with a variety of problems and diseases; malnutrition is the most common cause.

Large areas of feather loss may result from self-mutilation secondary to dermatitis, suggesting possible nutritional and/or systemic disease. The wing web (propatagium) should be evaluated for signs of dermatitis and trauma. The feathers often have to be displaced away from the featherless tracts (apterylae) to examine the skin over the head, dorsum, wings, upper legs and abdomen. Dry exfoliating skin may indicate nutritional problems or a very dry environment.

Primary dermatologic problems in birds are rare; most problems are secondary to trauma or systemic diseases, including malnutrition. Skin overlying cervical and abdominal regions can be assessed for elasticity in an attempt to crudely determine hydration and nutritional status in young birds and to a lesser

extent in older birds. The skin of the feet and legs should be shiny and have a uniform scaled pattern. Malnutrition can cause smooth, worn and ulcerated palmar surfaces of the feet. Pododermatitis, with or without ulcer formation, is often associated with improper perches and is exacerbated by malnutrition (e.g., hypovitaminosis A).

Overgrowth of the claws often accompanies beak lesions and is associated with metabolic and nutritional disorders, especially in lories, finches, budgerigars, canaries and Amazon parrots. Some species, such as Frill canaries, normally have long claws.

Contour feathers should adhere tightly together, appear homogeneous and have a bright sheen. The eclectus parrot, however, characteristically has loose, hair-like feathers. The wing and tail feathers should be transilluminated to examine for mites, color abnormalities, structural damage and vane abnormalities (e.g., holes).

Feather lice and mite infestations are common in newly imported birds. Feather picking and mutilation occur commonly in psittacine birds but only occasionally in passerine species. Frequent causes include boredom, stress (change in owner/bird routine), systemic diseases and improper diet.

Feathers of psittacine birds overlying the rump, thigh and crest areas should be examined for signs of viral beak and feather disease. Powder down (a powdery white substance) is present on the feathers of white cockatoo species, African grey parrots and cockatiels. Powder down is a normal finding.

Soiled feathers around the vent may indicate disease of the urogenital or gastrointestinal system. Protrusion of the cloacal mucosa may be associated with mucosal hyperplasia, cloacal papillomas, uterine prolapse (associated with egg binding), irritation due to masturbation, straining due to low intestinal obstruction or inflammation.

Regional Palpation
After examination of the skin and feathers, the intermandibular space should be palpated for swelling (e.g., abscess formation) that may be secondary to hypovitaminosis A in psittacine birds. The crop should normally be partially filled with food. A fluid-filled crop is an abnormal finding, except in recently fed chicks. Normally the ventral borders of the liver are barely evident. Caudally, the ventriculus is palpable between the right and left acetabulum.

The keel or pectoral musculature, a reservoir for large quantities of glycogen, should be palpated as an indicator of overall body condition. No body condition scoring system has been developed for birds. Besides palpation, body weight (mass) is the best criterion.

Cardiopulmonary Examination
Cardiopulmonary examination includes auscultation of the sinuses, trachea and thoracic and abdominal air sacs using a pediatric stethoscope. Normally, only the gentle rush of air should be heard. Audible sounds on inspiration and expiration indicate respiratory disease. Abnormal sounds (e.g., clicking, rattling, wheezing, squeaking and honking) may be associated with hepatopathies, respiratory parasites (air sac mites in passerine birds), malnutrition-induced air sac and tracheal epithelial debris and endocrine disease (e.g., thyroid dysplasia).

Birds normally respire with their mouths closed. Open mouthed breathing may result from: 1) anxiety (stress), 2) hyperthermia, 3) compensation for a plugged nostril, 4) anemia, 5) lung, tracheal and air sac disease, 6) abdominal masses and ascites that compress air sacs and 7) excessive handling and excitement. A bird's respiratory rate should return to normal one to two minutes after handling; if not, cardiopulmonary dysfunction may be present. Auscultation is of value to assess rate and rhythm, but murmurs are rarely heard.

Laboratory and Other Clinical Information
Laboratory data can help in the assessment of avian patients. However, veterinary diagnostic laboratories and practices generally do not offer the expertise necessary to provide reproducible laboratory results unless there is an individual on the staff who has taken a special interest in avian clinical laboratory medicine. A detailed description of avian laboratory evaluations is beyond the scope of this chapter; however, a few clinical biochemistry tests with nutritional implications deserve special comment.

Nitrogen excretion in birds involves the conversion of purines to uric acid via the enzyme xanthine oxidase. Renal tubular water resorption is highly variable in birds (60 to 99%). Avian kidneys are often in a number of primary (e.g., renal gout) and secondary diseases (e.g., bacterial enteritis, acute chlamydiosis) because of their relatively large size (approximately 1% of body weight) and the associated renal portal system. There is no single best test to assess renal function. Single plasma uric acid levels are a relatively insensitive indicator of renal tubular damage. Consequently, plasma creatine values, blood gas analysis, urinalyses in polyuric birds and/or serial plasma uric acid determinations must be used to diagnose and predict the outcome of avian renal disease.

Normal avian serum glucose levels are much higher than those of mammals with equivalent body surface area. Glucose values range from 550 to 600 mg/dl in hummingbirds to 140 to 180 mg/dl in ostriches. Stress associated with handling can rapidly elevate serum glucose levels.

FEEDING PLAN

Assess and Select the Food
The patient history should minimally include a list of foods offered daily. In addition, clients should be encouraged to provide a sample of any commercially prepared foods they feed.

If the food offered is commercially prepared, examine the label for nutrient information or guarantees. The primary nutrients of concern are protein and calcium. Many foods commonly fed to companion birds are composed primarily of carbohydrates and fat. The label of an acceptable commercially prepared food should list a protein guarantee of at least 12%. From the list of ingredients on the label determine if a source of calcium is included in the food. Seeds commonly contain more phosphorus than calcium. Thus, an added calcium source

**To convert to kJ, multiply kcal by 4.184.

such as calcium carbonate, dicalcium phosphate, bone meal, ground limestone or ground oyster shells helps balance the calcium-phosphorus ratio of bird foods. Regardless of the type of food fed, a sample can be submitted to a commercial laboratory for analysis. Consult the laboratory in advance to determine sample size needed, preservation techniques recommended and shipping instructions.

Compare the nutrient levels of the food to those recommended in **Table 72-2** to determine if there are any discrepancies in the nutrient profile. Complete nutrient levels of foods can sometimes be found on the label, in sales materials or from the manufacturer. The food is acceptable if its nutrient levels meet or exceed those levels in **Table 72-2**. If not, recommend that the owner select a food that meets these recommended levels.

The food should not be used for long-term feeding if its label contains no nutrient information or is just a list of ingredients such as seeds or dried fruit. The following discussion describes common strategies used to feed birds. In some instances, it can be very difficult to determine whether an individual bird receives levels of nutrients recommended in **Table 72-2**. (See Food Selection below.)

Foods appropriately balanced with carbohydrates, proteins, fats, vitamins, minerals and water are essential for all birds. Stewardship of confined birds must address good nutrition at several levels: the daily satisfaction and health of the bird as well as the long-term contributions to growth, maturation, defense against disease and reproductive health-the hallmark of good nutrition.

Three methods of providing nutrients and achieving these objectives are commonly used: 1) commercially prepared foods, 2) seeds and seed mixtures and 3) homemade mixed foods.

Table 72-3. Special nutritional needs of emberizids (order Passiformes, family Emberizidae).*

Genus and species	Common name	Special nutritional needs**
Emberzia hortulana	Ortolan bunting	Same as *E. tahapisi*
Emberzia tahapisi	Cinnamon-breasted rock bunting	Canary seed mix, mealworms, ant eggs, weed seeds, milk-soaked bread needed in breeding season
Lophospingus pusillus	Black-crested finch or pygmy cardinal	Live foods (e.g., insects, mealworms) needed during breeding season
Paroaria capitata	Yellow-billed cardinal	Must offer a variety of foods to prevent this species from only eating seeds; diet should consist of live food, fruits (berries, apples, oranges, greens [chickweed]), small mealworms, ant eggs and canary seed mix
Paroaria dominicana	Red-crowned Dominican or Pope cardinal	Live food recommended in addition to canary seed mix as for *S. albigularis*
Passerina lelancheri	Orange-bellied, orange-breasted or rainbow bunting	Canary seed mix, insects, canary color foods or pine and spruce twigs to maintain brilliant coloration
Rhodospingus cruentus	Crimson or rhodospingus finch	Same as *S. albigularis*
Sicalis flaveola	Saffron or Brazilian saffron finch	Need an abundance of insects and some greens in breeding season, in addition to that listed for *E. tahapisi*
Sicalis luteola	Yellow grassquit or little saffron finch	In addition to canary seed mix, insects and greens are required
Sporophila albigularis	White-throated seedeater	Canary seed mix, greens, small mealworms and fruits (apples and bananas are essential)
Sporophilia lineola	Lined seedeater	Same as *L. pusillus*
Tiaris canora	Cuban grassquit or Cuban finch	Same as *S. luteola*
Tiaris olivacea	Yellow-faced grassquit or olive finch	Honeycomb regularly; canary seed mix, ant eggs, hard-boiled egg, insects, mealworms, leaf lice, little spiders, greens (chickweed, etc.), tropical seed varieties
Volatina jacarina	Blue-black grassquit or jacarina finch	Same as *S. albigularis*

**In addition to commercial foods, these dietary "supplements" or additions are thought to be necessary to stimulate courtship and reproductive behavior or to prevent self-mutilation or feather picking by providing environmental/behavioral enrichment.

Table 72-4. Special nutritional needs of fringillids (order Passeriformes, family Fringillidae).*

Genus and species	Common name	Special nutritional needs**
Carduelis (chloris) chloris	Greenfinch	Canary seed mix, rape seed, small sunflower seed, some hemp, linseed, teasel and greens
Carduelis carduelis	European goldfinch	In addition to the basic finch diet, thistle seeds, other seeds, insects and other invertebrates
Fringilla coelebs	Chaffinch	Need live insects, supplemental commercial softbill diet, sprouted seeds (rape, turnip, radish) and canary seed mixture in breeding season
Serinus alario	Black-headed canary or alario finch	Varied seed mixture needed to induce breeding
Serinus canaria	Wild canary, island canary	Same as *S. mozambicus*
Serinus leucopygia	White-rumped, Layard's seedeater or gray singing finch	Same as *S. mozambicus*
Serinus mozambicus	Yellow-eyed or green singing finch, yellow fronted canary	Canary seed mix, insect diet, greens
Serinus serinus	European serin	Additional small seeds (e.g., lettuce, spray millet, etc.)

**In addition to commercial foods, these dietary "supplements" or additions are thought to be necessary to stimulate courtship and reproductive behavior or to prevent self-mutilation or feather picking by providing environmental/behavioral enrichment.

Commercially Prepared Foods

The benefits of using commercially prepared, nutritionally complete foods become obvious when the feeding of birds kept as companions is compared to the feeding of other companion animals. Prepared foods supply more than 90% of the nutrients for companion dogs and cats in North America and can contribute markedly to the health of these animals. The gradual transition from diets composed primarily of human food, including table scraps, to commercially prepared complete and balanced foods for dogs and cats has taken approximately 50 years. The same transition will undoubtedly occur for pet birds in a much shorter time as the number and quality of products available increase.

The major benefits of commercially prepared foods are nutrient balance and convenience. Manufacturers commonly formulate commercial foods using sound scientific principles following established nutrient recommendations (**Table 72-2**) (Nutrition Expert Panel Report, 1996). Although adherence to these recommendations and ingredient quality may vary among manufacturers, an extruded or pelleted diet supplies all the nutrients in one particle. Such formulations help prevent alteration of nutrient balance by uninformed owners who feed imbalanced seeds or human foods, or by birds that consume different quantities of imbalanced foods that are fed separately.

A potential disadvantage to feeding commercial foods is that testing protocols for nutritional adequacy have not yet been established for avian foods, as they have been for commercial canine and feline foods. Still, the probability of producing a nutritional imbalance by feeding a commercial avian food is much less than when seeds or human foods prepared by uninformed owners are fed to birds. As the use of commercial avian foods becomes more widespread, such protocols will undoubtedly be established.

Seeds and Seed Mixtures

Seeds are a popular, convenient, inexpensive method of providing nutrients to companion birds. But they are not necessarily the best or even the most natural food for pet birds. A recent renaissance in the pet bird food industry has taken into account the long forgotten holistic views of habitats and natural history of many avian species. Interesting facts have come to light. Food selection in birds is predominantly a learned behavior. Nestling birds accept the appropriate foods brought to them by their parents and once fledged observe where and how to obtain these foods for themselves. In a pet industry where captive breeding and isolation of companion birds are the norm, individual birds have little or no experience with their natural environment or natural food sources and may not have the opportunity to observe feeding behaviors of other birds. Although hundreds of years of domestication in some species have altered feeding behaviors, the associated physiology of nutrient assimilation and use have not changed markedly. The types of seeds present in most commercial mixes are not native to areas where most pet bird species originate. Although seeds may have been used opportunistically in the wild, they would not have been available in large quantities. Considering all these facts, seeds are no more of a "natural" food than any other method of providing nutrients for companion birds.

Other disadvantages of all seed diets are that uninformed owners can alter the diet easily or birds can consume certain seed types, avoiding others, resulting in an imbalanced nutrient intake. With these disadvantages in mind, seeds are much less desirable than commercially prepared foods for feeding birds.

As mentioned, seeds are a common element in many pet bird diets. A well-balanced seed mixture can supply essential nutrients such as fats, carbohydrates and some minerals. However, seeds are rarely, if ever, an appropriate sole nutritional source because they provide inadequate levels of protein, vitamins and minerals. There are numerous commercially available seed mixtures that vary greatly in type and quality. Individual seed types are also sold in most stores, thus formulating seed mixtures is a common practice. The availability of individual seed types promotes nutrient imbalance when uninformed owners create a mixture based primarily on the price and physical appearance of the seeds. Thus, creation or use of homemade seed mixtures should be discouraged.

Commercial mixtures for a particular group of birds may vary greatly in seed types and proportions from one company to another, indicating the lack of scientific sophistication involved in preparing seed mixture diets. Seed mixtures may contain protein and vitamin-mineral supplements in pellet or crumble form. This is the manufacturer's attempt to overcome the nutrient imbalances inherent in a seeds-only diet. The assumption is that birds will consume all of the seeds and supplement pellets, and thus have a nutritionally balanced diet. Unfortunately, this assumption is not always true. If seed mixtures containing supplements are used to feed confined birds, the owner should be advised to leave the food in front of the bird until the entire mixture has been eaten before giving the bird more of the mixture. This practice will ensure that the bird consumes the entire diet, not a nutritionally imbalanced, isolated segment. Because individual birds may not accept some components of a supplemented seed mixture, consuming them irregularly or not at all, an imbalanced nutrient intake is much more likely to occur when a supplemented seed mixture is the sole dietary form fed.

Bird owners feed a variety of live foods as supplements to seeds and seed mixtures. When research showed that even strict seed-eaters opportunistically eat insects as a protein source at certain periods in their reproductive cycle and to improve their condition for migration, insect foods became commercially available. Insect supplements are particularly appropriate for Pekin robins, Indian white eyes, shamas, waxbills and cardinals. Live food must be supplied for other species, most notably chaffinch, avadavats and all Phloceids.

White worms (*Enchytraes* larvae) are available commercially and can be kept for long periods much like earthworms in a cool, damp moss and leaf litter substrate. These worms are especially useful to provide when parent birds are brooding and feeding their young. Ant pupae, which bird fanciers have relied on heavily for their avian diets, are now available commercially in large outlets and by mail order. Water shrimp (*Daphnia* spp.) are relished by some species and greatly enhance red pigments in plumage. Aphids that feed on members of the rose family

Table 72-5. Special nutritional needs of waxbills and allies (order Passeriformes, family Estrildidae).*

Genus and species	Common name	Special nutritional needs**
Amandava amandava	Strawberry finch or red avadavat	Some live food is essential year round
Amandava formosa	Green avadavat	Some live food is essential year round
Amandava subflava	Golden-breasted or zebra waxbill	Some live food is essential year round
Chloebia gouldiae	Gouldian finch	During molting, these birds must be supplied with protein-rich foods, vitamins and minerals, soaked and recently sprouted seeds. Avoid white millet in this species
Estrilda astrild	Common or St. Helene waxbill	Insects and soaked seeds are essential
Estrilda caerulescens	Red-tailed lavender, lavender waxbill	Ant eggs, fine cut mealworms, white worms, greens (lettuce, endive, chicory, chickweed)
Estrilda melpoda	Orange-cheeked waxbill	Require small insects for maintenance and breeding
Estrilda rhodopyga	Crimson or rosy-rumped waxbill	Require insects all year, especially during breeding season
Granatina (U.) granatina	Violet-eared waxbill	In addition to small seeds (grass seeds, spray millet) live food is essential all year for behavioral enrichment
Lagonosticta senegala	Red-bellied firefinch	When chicks are hatched, extra amounts of live food, greens and egg foods are essential for feeding chicks
Longchura caniceps	Gray-headed munia or pearl-headed silverbill	Same as *L. ferruginosa*
Longchura castaneothorax	Chestnut-breasted finch or munia	Same as *L. ferruginosa*
Longchura ferruginosa	Black-headed chestnut or chestnut bellied munia or black-headed nun	Insects, weed seeds, basic passerine seed mix, greens, canary-chick rearing food and bread soaked in milk during breeding season
Longchura malabarica	Indian silverbill or white-throated munia	Same as *L. ferruginosa*
Longchura malacca	Black-headed munia or pearl-headed silverbill	Same as *L. ferruginosa*
Longchura punctulata	Scaly-breasted munia, spice bird or spice finch	Same as *L. ferruginosa*
Longchura striata var. domestica	Bengalese	Same as *L. ferruginosa*
Neochimia modesta	Cherry or plum-headed finch	Ripe and half-ripe seeds, berries, greens, and a variety of live foods are necessary
Neochimia ruficauda	Star finch	During the breeding season, provide a rich variety of insects, seeds, greens and commercial egg and rearing foods
Padda oryzivora	Java sparrow or rice bird	Basic passerine seed mix and greens for breeding
Poephilia acuticauda	Long-tailed finch	Same as *N. modesta*
Poephilia cincta	Black-throated or parson finch	In addition to small ripe and half-ripe seeds, insects, greens, soaked white bread, soaked and germinated seeds and cuttlefish bone are essential
Poephilia personata	Masked finch	Same as *P. cincta*
Pytillia melba	Melba finch or crimson-faced waxbill, green winged pytilia	Need a rich variety of insects and small seeds to prevent hatchling rejection
Taeniopygiaa guttata	Zebra finch	Same as *N. modesta*
Taeniopytia bichenovii	Bicheno's or double-barred finch	Same as *N. modesta*
Uraeginthus angolensis	Blue breasted cordon bleu, Angolan cordon bleu or blue-breasted waxbill	Same as *U. bengalus*
Uraeginthus bengalus	Red-cheeked cordon bleu	Live food important, especially for breeding (aphids, ant eggs, and spiders)

New York, NY: Blanford Press, 1987; 15-23.
**In addition to commercial foods, these dietary "supplements" or additions are thought to be necessary to stimulate courtship and reproductive behavior or to prevent self-mutilation or feather picking by providing environmental/behavioral enrichment.

concentrate the same pigments and may be more appropriate for small passerine birds. Moth larvae, commonly known as waxworms, and beetle larvae, called mealworms, supply extra protein and fat, especially at the onset of breeding season. Care should be taken to restrict the intake of these insects or the bird will rapidly gain weight and become obese.

Most true insect-eating birds remove the heads of larvae before the larvae are ingested. Clients should be instructed to remove the head capsules before feeding such larvae, if it is observed that the bird does not perform this function. This

practice removes a largely indigestible chitinous mass from the gastrointestinal tract and eliminates the possibility that a live larva could burrow through the crop wall or cause gastrointestinal obstruction.

Homemade Mixed-Food Diets

A wide variety of homemade mixed-food diets have been suggested as alternatives for birds that will not accept commercially prepared foods or seed mixtures even with added fruits and vegetables (Kollias, 1995; Burgmann, 1993; Lint and Lint, 1988; Vriends, 1984; Woolham, 1987). These diets can result in excellent feathering and appropriate body mass for the species, with no discernible signs of nutritional deficiency, if prepared carefully from scientifically developed recipes. These diets often contain varying amounts of ingredients such as seeds, nuts, cooked eggs, low fat yogurt or cheese, vegetables, fruits, grains, bread, pasta, multigrain cereals, legumes, seed mixes, pelleted or extruded psittacine diets, vitamin supplements and calcium supplements. When converting birds to a new homemade diet, have the client offer a mixture containing all the ingredients at one time. This practice usually prevents preferential selection of certain ingredients. Although larger parrots have difficulty eating small seeds such as milo or oat groats, a seed mixture containing 30% hulled safflower, 30% milo, 30% oat groats and 10% peanuts works well for smaller birds.

Although homemade mixed-food diets may provide adequate nourishment, most companion bird owners are unwilling to devote the time necessary to adequately prepare these diets. Additionally, owners must be willing to regularly observe which food components are being consumed to prevent birds from developing or reverting to preferential selection of specific ingredients.

Water

Although feeding a well-balanced food is essential, it is easy to overlook the single most important dietary component: water. As with all animals, water is absolutely essential for birds. Water acts as a food carrier and aids in digestion. Some foods are high in water content whereas others require the addition of free water for efficient digestion and absorption. Some avian species are more physiologically adept at extracting water from their foods. Budgerigars in the wild, for example, are capable of absorbing sufficient water from seeds and green foods to allow them to go without additional sources of water for many days. This observation, however, is not an experiment to be undertaken by pet owners. Birds should never go for more than a few hours without access to fresh clean water. Studies have shown that canaries will die within 48 hours if water is withheld.

Water comprises more than 50% of a bird's body weight (in young birds, the percentage may be even higher). Blood and lymph are largely composed of water. Furthermore, because birds have no sweat glands, water intake plays an important role in thermoregulation. Breeding females may require increased amounts of water for egg production and for heat regulation while incubating eggs.

Water should be provided in containers that are easily accessible but not located in a place that can collect feces, feathers, food particles, etc. For this reason, water bowls should be attached to the wall of enclosures, near or above food bowls. They should not be so large as to invite bathing.

Food Selection

The advantages and disadvantages of feeding birds commercially prepared foods, seeds and seed mixtures and homemade mixed foods are discussed above. If an individual bird is healthy and exhibits no signs of deficiency disease, the owner probably is feeding the bird appropriately and there is no need to change the food. In general, however, fewer deficiency diseases will result from feeding a complete, nutritionally balanced food that meets the nutrient levels listed in **Table 72-2**.

Although some prepared foods have been available for only a limited time, the overall nutritional quality of commercial foods is rapidly improving as manufacturers use new scientific information to create their formulations. As commercially prepared foods become more widely used, many of the diet-induced diseases currently observed by avian veterinarians will become of historical interest only, just as they have for other companion pets.

Owners should be encouraged to experiment with different prepared foods if their bird does not accept a particular product. Often a bird will readily accept an alternative form, shape or formulation of a complete food. When changing the diet of a bird from seeds or fresh human foods to a commercially prepared complete food, the previous foods should be eliminated or substantially restricted to encourage consumption of the complete avian food.

Tables 72-3 through **72-7** list foods that meet the special nutritional or behavioral needs of passerine birds. In addition to commercial foods, these dietary "supplements" or additions are thought to be necessary to stimulate courtship and reproductive behavior or to prevent self-mutilation or feather picking by providing environmental/behavioral enrichment. **Table 72-8** lists homemade mixed-food diets for psittacine birds.

Assess and Determine the Feeding Method

It may not always be necessary to change the feeding method when managing an avian patient, but a thorough assessment includes verification that an appropriate feeding method is being used. Items to consider include feeding route, amount fed, how the food is offered and who feeds the bird. All of this information should have been gathered when the history of the bird was obtained. If the bird has normal body condition, the amount of food it was fed previously (energy basis) was probably appropriate.

Because of the convenience, most owners offer food free choice with additional food added to the bowl as needed. When a seed mixture or homemade diet is offered free choice, it is unknown how much and what components the bird actually consumes. Therefore, the owner may not realize that the bird has not eaten for 24 to 48 hours.

Owners who feed prepackaged seeds, seed mixtures or treats for birds often assume that the product is nutritionally complete and the bird will eat all parts of the product. Both of these

Table 72-6. Special nutritional needs of weavers, wydahs and queleas (order Passiformes, family Ploceidae).*

Genus and species	Common name	Special nutritional needs**
Euplectus afra	Napoleon weaver, yellow-crowned or golden bishop	Live food is essential, as are small seeds, fruits and greens (See *Ploceus* spp.)
Euplectus ardens	Red-collared willow bird or wydah	Same as *P. cucullatus, E. afra*
Euplectus hordeacea	Blackwinged bishop, crimson crowned bishop	Same as *P. cucullatus, E. afra*
Euplectus orix	Grenadier weaver or red bishop	Same as *P. cucullatus, E. afra*
Euplectus progne	Long-tailed willow bird, giant wydah	Same as *P. cucullatus, E. afra*
Ploceus cucullatus	Rufous-necked, black-headed, village weaver or vitelline masked weaver	Live food is essential, in addition to millet, white grass, weed seeds and grains (oats and wheat) for breeding
Ploceus intermedius	Masked weaver	Same as *P. cucullatus*
Ploceus phillippinus	Baya weaver	Same as *P. cucullatus*
Ploceus vitellinus	Half-masked weaver, Zesser-masked weaver	Same as *P. cucullatus*

**In addition to commercial foods, these dietary "supplements" or additions are thought to be necessary to stimulate courtship and reproductive behavior or to prevent self-mutilation or feather picking by providing environmental/behavioral enrichment.

Table 72-7. Special nutritional needs of babblers and starlings (order Passeriforme, family Timaliidae, family Sturnidae).*

Genus and species	Common name	Special nutritional needs**
Gracula religiosa	Hill mynah	Must be offered a commercial or formulated low-iron food to prevent hemochromatosis; during breeding requires insects and fruit low in or devoid of iron
Leitothrix lutea	Red-billed leiothrix or Pekin robin	Dead, dried or live food are essential for breeding

*Adapted from Kollias GV. Diets, feeding practices, and nutritional problems in psittacine birds. Veterinary Medicine 1995; 90: 29-39. Burgmann PM. Feeding Your Pet Bird. New York, NY: Barron's Educational Series, 1993. Lint KC, Lint AM. Feeding Cage Birds-A Manual of Diets for Aviculture. New York, NY: Blanford Press, 1988; 133-175.
**In addition to commercial foods, these dietary "supplements" or additions are thought to be necessary to stimulate courtship and reproductive behavior or to prevent self-mutilation or feather picking by providing environmental/behavioral enrichment.

assumptions are often incorrect. To correct or avoid these problems, bird owners should offer a nutritionally complete prepared food at regular intervals as a part of the total diet.

Feeding Intervals

An ideal strategy is to ensure that food is offered to companion birds for one to two hours, two or three times daily. The food should be removed during the interim periods, although this is not standard practice for most owners or care providers. Offering food at specific times during the day creates a bond between the owner and bird. This feeding regimen also increases the probability that an owner will examine the contents of the food and water bowls to determine exactly what and how much was consumed and whether the bowls require cleaning.

Changing Foods

Unless commercially prepared nutritionally complete foods are fed, birds fed free choice may develop a habituation to a single type of food (monophagism). This fixation may result in single or multiple nutrient deficiencies. After a deficiency occurs, the owner is faced with changing the food. This can be a formidable challenge depending on the age and species of the bird. Changing foods is generally easier with younger birds and with smaller parrots such as cockatiels and conures. Cockatoos, macaws and African grey parrots are more resistant to change. Most passerine birds switch to new foods easily.

Food changes should not be attempted if the bird is sick or stressed (e.g., recent acquisition, change in environment, exposure to temperature extremes, molting etc.). Conversion to a new balanced food may take weeks to months depending on the degree and length of habituation. Ninety percent of healthy cockatiels can be converted to a new food within seven days.

A variety of strategies can be used to convert birds to a new food. If one of these approaches is unsuccessful, an alternate one should be tried.

1. Gradually add the new food to the current diet, increasing the amount of the new food over days to weeks. Texture and color are important; adding a food that the bird really likes may make the conversion much easier.
2. Unless the new food is extruded or pelleted, warming or cooling it may make a difference in acceptance. The food should be no hotter than 40.6°C (105°F). Alternatively, food can be cooled to refrigerator temperatures (2 to 4°C [35 to 40°F]).
3. Try offering the bird a soft food such as baby cereal, fruits or vegetables, cooked oatmeal or cream of wheat. Birds like the texture of these foods. Then gradually add a prepared diet to these mixtures.
4. If a bird is hand-trained or hand-reared, feeding outside the cage is often helpful. Alternatively, place the new food item

Table 72-8. Homemade mixed-food diets for psittacine birds.*

Diet 1	20-30% seeds and nuts 20-30% dark green, yellow and orange vegetables 10-15% fruit (avoid excess apples and bananas, which have little nutritional value and may contain excessive phosphorus) 20-30% pelleted or extruded psittacine food, which is added to the mixture after thawing and immediately before feeding Much of this diet can be made in advance and frozen in small portions
Diet 2	30% small- or large-parrot seed mix 20% cooked brown rice, dark multigrain bread, pasta and multigrain cereals 15% frozen or fresh vegetables, such as peas, carrots and squash 15% legumes, such as cooked kidney and pinto beans 20% pelleted or extruded psittacine food, which is added to the mixture after thawing and immediately before feeding Much of this diet can be made in advance and frozen in small portions
Diet 3	45% grains, breads and cereal group (whole wheat bread, cooked brown rice, seed mixture) 45% fresh vegetables (broccoli, endive, carrots, pumpkin, winter squash, collard greens, sweet potato) and fruits (limit quantities of papaya, cantaloupe and apricots to 5% of total fruit) 5% from the protein and fat group, including hard-cooked or scrambled eggs and peanuts or other mature legumes (e.g., navy or kidney beans) 5% dairy group (for calcium and protein) Use low-fat non-lactose dairy products, such as low-fat yogurt, cottage cheese and hard cheese; other sources of calcium (although not as good as food sources) may include cuttlebone, oyster shell and mineral blocks; larger psittacine birds may ignore these items or destroy rather than consume them
Diet 4	24% cooked long grain rice 25% cooked kidney beans 24% frozen whole kernel corn 24% pelleted or extruded psittacine diet (total soft diet = 96.63%) Approximately 2% powdered vitamin supplement 1-4% calcium supplement (total supplements = 3.37%) This diet is formulated based on wet weight. Small portions can be frozen (excluding the pelleted or extruded diet) and used as needed. Pay particular attention to food hygiene because these foods decompose fairly rapidly.

*Some species of psittacine birds, such as lorries, have specific dietary requirements for fruit or nectar that differ from that of more common species of New World parrots. When fruit or nectar is used, percentages in the diet should be based on relative proportions by volume, not on a dry or wet weight basis. Avoid including avocado because it is toxic to small psittacine birds. (Adapted from Ullrey DE, Allen MR, Baer DJ. Formulated diets versus seed mixtures for Psittacines. Journal of Nutrition 1991; 121: S193-S205. Kollias GV. Diets, feeding practices, and nutritional problems in psittacine birds. Veterinary Medicine 1995; 90: 29-39.)

in the cage at strategic locations (e.g., by a mirror or favorite toy or attach the food item to the cage bars).

5. Have the owner eat what you want the bird to eat. Some birds mimic their owners by eating foods they see their owners eat.
6. Begin feeding a new food every other day. For larger birds, remove the seeds on that day. If a smaller bird has not eaten the new food by the late afternoon, offer seeds to prevent hypoglycemia overnight. Alternate-day feedings will also prevent excessive weight loss. Increase feedings to four, then five, then seven days a week.
7. Remove all seeds before retiring for the night. In the morning, offer a commercially prepared complete food with new food items instead of the seed. Do not add seed until noon. This strategy presents no danger to the bird because the previous seeds are available later in the day.

The bird's physical condition and body weight should be monitored during the conversion period to prevent starvation. Keep in mind that most birds eating all seeds or "junk food" (e.g., potato chips, peanuts, candy) may be overweight or even obese. If a bird loses excessive body condition during the conversion period, as determined by weighing, it may refuse to eat the previously fed food. Gavage or tube feeding for one to three days will be required to stimulate the bird to eat.

All of these strategies have been successful in enticing companion psittacine birds to eat a more balanced food. Occasionally, however, individual birds cannot be converted. These birds may require specialized water and food supplements to help overcome serious vitamin and mineral deficiencies. In some cases when conversion is unsuccessful, the bird may need to be hospitalized away from the owner. At the hospital, a rigorous dietary protocol can be implemented that may be successful after the behavioral influences of the owner are eliminated.

In multiple-bird households, owners will have an easier time converting birds to a new food if at least one bird has been converted and the other birds can observe it eating the new food. Some companies may provide an "instructor" bird to assist in food conversion if all other methods are unsuccessful.

Client education is crucial to the success of food conversion, especially with companion birds. Owners should be advised to be persistent and patient during this process.

CASE 72-1

Feather Loss in a Captive Sulfur Crested Cockatoo

Cheryl L. Dikeman, PhD
Department of Nutrition
Henry Doorly Zoo
Omaha, Nebraska, USA

Patient Assessment

An eight-year-old, male sulfur crested cockatoo was examined for feather loss. The case was brought to the nutrition department after thorough veterinary examination revealed nothing unusual upon fecal testing, radiography and results of biochemistry and hematologic panels. Initial examination by the nutritionist revealed the bird was bright, alert, responsive and vocalizing. The keepers noticed the feather plucking behavior for approximately three weeks. Nothing had changed in the bird's enclosure for the past five weeks. Before that, the bird was moved from a public viewing aviary exhibit to an off exhibit holding area while repairs to the area were being completed. The bird was used in educational programs, and its training and use in educational programs had continued without interruption. Based on the previous examination by the veterinarians and initial screening for the presence of infection and parasites, no additional abnormalities were noted other than the excessive feather picking.

Assess the Food and Feeding Method

The bird's diet consisted of approximately 60% extruded commercial parrot maintenance diet, 20% parrot seed mixture and 20% mixed fruit and (or) vegetables daily (**Table 1**). Water was offered free choice.

Table 1. Guaranteed analysis of the bird's total diet.*

Crude protein (min.)	17.0%
Crude fat (min.)	9.2%
Crude fiber (max.)	10.0%
Zinc	91.0 mg/kg

*(100% dry matter basis)

Questions

1. What nutrients may be problematic and contribute to the etiology of feather plucking?
2. What additional laboratory testing may be beneficial in this case?
3. What additional questions may be useful to ask the keepers about this bird's behavior over the past several weeks?
4. What are the short-term goals to assist in the management of this bird?
5. What are the long-term goals to assist in the management of this bird?

Answers and Discussion

1. Although generalized malnutrition can be a medical cause associated with chronic feather plucking in psittacine birds, malnutrition is rare. Regardless, the diet should be carefully examined and analyzed for key nutrients. One key nutrient for psittacine birds is zinc. Zinc toxicity may be a contributing dietary cause of feather plucking and, therefore, should not be discounted.
2. Although radiographs did not reveal abnormalities or potential ingestion of zinc containing items (pennies, toys, etc.) serum/plasma concentrations of zinc should be determined to rule out potential zinc toxicities. In addition, hormonal abnormalities should be considered.
3. Additional questions should primarily focus on the bird's behavior and environment since its move off exhibit.
   a. What was the social interaction when it was in the aviary; was the bird housed singly or with other birds?
   b. Did it have more human interaction while in the exhibit?
   c. Has the social structure within the area changed (keeper turnover, change in keeper schedules, etc.). Due to the bonding birds have with particular "flock" members, alterations in schedules may disrupt the hierarchy of the "flock" structure and stability.
4. Likely this bird is responding to the environmental changes over the past several weeks. Short-term goals included altering the stimuli in the temporary off exhibit holding area daily. In addition, the seed mixture of the diet was increased to 50%. The complete diet accounted for 30%, and a variety of fruit and vegetables 20% of the diet. The additional seeds were included to supply a source of additional environmental stimuli. The keepers worked to develop a schedule that included only two individuals feeding, and caring for the bird until it was moved back.
5. The long-term goal was to evaluate the bird weekly while off display, then reevaluate it weekly once back on display. The bird's diet would be changed back to the original diet if excessive plucking stopped.

Progress Notes

When the bird was re-checked after one week, it was still plucking; however, the keepers believed the bird's condition had improved. The bird's routine was more consistent. During the following week, the bird was returned to the exhibit aviary that included several other birds and mixed species. By the third week, the keepers did not see any of the excessive plucking behavior observed in

the off exhibit area. The bird's diet was changed back to the original formulation.

CASE 72-2

Obesity in Caged Cockatiel

Cheryl L. Dikeman, PhD
Department of Nutrition
Henry Doorly Zoo
Omaha, Nebraska, USA

Patient Assessment

A nine-year-old male cockatiel was examined upon arrival to a foster home from an owner relinquishment. The bird was re-homed after a single home for eight years. The relinquishing owners had reported the cockatiel had been purchased from a local breeder in the area, when the bird was approximately 16 weeks of age. The bird had been housed in the same cage while the owners had the bird. The cage was located in a small bedroom that served as an in-home office that had access to one window for UV light. The owners indicated they interacted with the bird at least once daily. No recent changes had been made to the bird's diet or daily husbandry. Physical examination revealed a healthy and alert bird. Its initial weight was 128 grams. Based on current weight and physical keel palpation, the bird was considered overweight. No additional abnormalities were noted.

Assess the Food and Feeding Method

The owners indicated the bird was fed commercial seed mixtures formulated for cockatiels and purchased from local pet supply stores and (or) grocery stores. The bird reportedly did not readily accept or consume offered fruits, vegetables or complete formulated pelleted diets; therefore, they had not been offered consistently within the previous four years. The most recent fortified commercial seed mixture's ingredient list and guaranteed analysis is included below (**Table 1**). Fresh water and the seed mixtures were changed/offered daily free choice. The bird was not offered additional supplements.

Table 1. Current seed mixture ingredient list.

Canary Grass Seed, White Millet, Striped Sunflower, Safflower, Oat Groats, Red Millet, Wheat, Toasted Corn Flakes, Buckwheat, Corn Gluten Meal, Ground Corn, Ground Wheat, Dehulled Soybean Meal, Flax Seed, Calcium Carbonate, Wheat Middlings, Dicalcium Phosphate, Salt, Soy Oil, Sun-cured Alfalfa Meal, Brewers Dried Yeast, Wheat Germ Meal, Vitamin A Supplement, Choline Chloride, L-Lysine, Ferrous Sulfate, Vitamin B12 Supplement, Manganous Oxide, Vitamin E Supplement, Zinc Oxide, DL-Methionine, Orange Oil, Niacin, Riboflavin Supplement, Menadione Sodium Bisulfite Complex (source of vitamin K activity), Ethoxyquin (a preservative), Cholecalciferol (source of vitamin D3), Copper Sulfate, Calcium Pantothenate, Pyridoxine Hydrochloride, Thiamine Mononitrate, Folic Acid, Calcium Iodate, Biotin, Dried *Bacillus coagulans* Fermentation Product, Dried *Bacillus licheniformis* Fermentation Product, Dried *Bacillus subtilis* Fermentation Product, Cobalt Carbonate, Sodium Selenite, Beta-Carotene, Artificial Color.

Guaranteed analysis (100% dry matter basis)	
Crude protein (min.)	17%
Crude fat (min.)	10.2%
Crude fiber (max.)	15.9%

Questions

1. What would be the benefit to including the ingredient list and guaranteed analysis in the assessment of the commercially formulated seed mixture?
2. What should be considered specifically regarding seed mixes when addressing the guaranteed analysis on the label?
3. What are the short-term goals to assist in the management of this bird?
4. What are the long-term goals to assist in the management of this bird?

Answers and Discussion

1. Commercial seed mixes vary in the quality, quantity and types of ingredients used. In this case, it was valuable to determine the variety of seeds included and which types of seeds the bird was potentially selecting more than others. Typically, granivores, such as cockatiels, select more palatable seeds that typically contain higher concentrations of fat, such as sunflower seeds. Assessing the guaranteed analysis on a dry matter basis, gave the practitioner an idea of overall macronutrient profiles. In this case, the seed mix contained a moderately high fat content of 10.2%, which would be contributing to the bird's weight status.
2. Guaranteed analyses are conducted on the whole diet. In the case of seed mixtures, seeds are analyzed in their entirety. Granivorous birds dehull the seeds before consumption, thereby altering the nutrient profile. In some cases, dehulled seeds may contain twice the analyzed fat content as their hulled counterparts. This should be considered when seed mixes are fed.
3. Short-term goals included not only altering the diet for this bird, but also increasing its level of activity. Birds housed in indoor aviary enclosures, have approximately 15% higher energy requirements, compared with those in indoor cage environments. Therefore, this bird was housed in an indoor aviary that offered three times more room than its original cage. Its food and water dishes were placed on opposite sides of the enclosure to encourage movement. In addition, a lower fat seed mixture was selected along with a commercial extruded diet.
4. The nutritional goal was to transition the bird to an extruded diet. The nutrition plan also included monitoring and recording body weight weekly initially for eight weeks and reassess at that time. The bird's estimated ideal body weight was 110 grams.

Progress Notes

When the bird was weighed seven days later, it had lost 2 grams (1.6% body weight). At this time, it was consuming the new lower fat seed mixture readily. The extruded diet was added at a rate of 10% extruded to 90% seed mixture. At Week 2, the bird weighed 122 grams. The diet was then altered to 20% extruded diet to 80% seed mix. At Week 3, it weighed 121 grams and the diet was changed to 25% extruded to 75% seed mix. By Week 8, the bird weighed 115 grams and was consuming a diet of 50% extruded diet and 50% seed mixture free choice. Due to the 8% body weight loss over eight weeks, this plan was continued and monitored closely. From Week 12 to 16 the bird had maintained an ideal body weight range of 108 to 112 grams. At this time, the bird was consuming a diet of 50% extruded diet and 50% seed mixture. The decision was made to maintain the bird on this diet.

Appendix 7. Vitamins A, D and E: Conversions from international units to equivalent activity.*

Vitamins	Units	Substances	
Vitamin A	1 IU	0.300 µg of crystalline retinol (vitamin A alcohol)	0.550 µg of vitamin A palmitate
Vitamin A	1 RE*	1 µg of crystalline retinol	6 µg of β-carotene 12 µg of other provitamin A carotenoids
Provitamin A	1 IU	0.6 µg β-carotene	1.2 µg of other provitamin A carotenoids
Vitamin D	1 IU	0.025 µg of crystalline vitamin D_3	
Vitamin E	1 IU	1 mg of synthetic racemic α-tocopherol acetate	= dl-α-tocopherol acetate = all racemic α-tocopherol acetate

1 mg of synthetic racemic α-tocopherol = 1 mg of synthetic racemic α-tocopherol = 1.1 IU of vitamin E
1 mg of naturally occurring α-tocopherol = d-α-tocopherol = RRR-tocopherol = 1.49 IU of vitamin E
1 mg of naturally occurring α-tocopherol acetate = d-α-tocopherol acetate = 1.36 IU of vitamin E

*On pet food labels and tables with daily nutrient allowances for pets, the vitamins A, D and E are expressed in international units (IU). These units reflect the activity of these vitamins, not their amounts. United States Pharmacopeia Units (USP) are equivalent to IU. In human foods, retinol equivalent (RE) is often used for vitamin A activity.

Appendix 8. Metabolic weight ($BW^{0.75}$) of dogs and cats.*

Appendix 13. Litter sizes and birth weights of selected canine breeds.*

Breeds**	Average litter sizes	Birth weights (g)
Airedale terrier	9	300
Appenzell mountain dog	10	465
Australian silky terrier	3	-
Bernese mountain dog	5	445
Borzoi	9	450
Boxer	8	440
Cavalier King Charles spaniel	4	230
Chihuahua	2-3	140
Chow chow	6	460
Dachshund	4	215
Dalmatian	5-6	-
Doberman pinscher	7	410
English bulldog	7	295
English cocker spaniel	6	230
English springer spaniel	11	375
Fox terrier	3	260
French bulldog	5	215

Appendix 13 (continued). Litter sizes and birth weights of selected canine breeds.*

Breeds**	Average litter sizes	Birth weights (g)
German shepherd dog	6	445
German shorthaired pointer	7-8	415
Great Pyrenees	≥5	705
Hovawart	11	435
Irish terrier	6	270
Labrador retriever	5	450
Maltese	3	155
Miniature dachshund	3	210
Miniature pinscher	3	-
Miniature poodle	2-3	165
Miniature schnauzer	4	155
Newfoundland	7	595
Norwich terrier	5	225
Papillon	3	120
Pekingese	2-3	-
Pomeranian	2	-
Pug	3	-
Rottweiler	7	-
Saint Bernard	7	640
Scottish terrier	5	240
Shetland sheepdog	4-5	260
Shih Tzu	2-3	-
Sloughi	3	670
Standard schnauzer	6	285
Yorkshire terrier	5	95

*Because of the very large variation in the adult body weight of dogs and number of puppies per litter, there is no direct relationship between birth weight and the body weight of the mother. Puppies from the largest breeds weigh approximately 1% of the bitch's weight, whereas a Chihuahua puppy averages 6.4% of its mother's body weight.
**Breeds listed here are those for which data were available.

Appendix 14. Body weights in kilograms and height at withers in centimeters of selected canine breeds.

Breeds	Body weights (kg)		Height at withers (cm)

Key: ME = metabolizable energy, kcal = kilocalories, kJ = kilojoules, NFE = nitrogen-free extract, Ca = calcium, P = phosphorus, Na = sodium, K = potassium, Mg = magnesium, tr = trace, g = grams, Tbs = tablespoons (15 ml), na = not available.
*All nutrients are expressed on a percent as fed or as is basis unless otherwise designated.
**Metabolizable energy/100 g as is.
***g/serving.
†Low-sodium cereal breakfast is available with about 0.01% sodium.

Appendix 25. Nutrient content of selected mineral sources.*

Mineral sources	Moisture (%)	Ca (%)	P (%)	Na (%)	K (%)	Mg (%)	Cl (%)	Ca/P ratio	Weight (g/tsp)
Bone meal	10	≥28	≥13	0.5	na	0.7	0.0	2.1	4
Calcium carbonate	0	36-39	na	na	na	na	na	na	5
Tums tablets contain 0.50 g calcium carbonate per tablet = 200 mg calcium									
Tums Extra tablets contain 0.75 g calcium carbonate per tablet = 300 mg calcium									
Tums Ultra tablets contain 1.0 g calcium carbonate per tablet = 400 mg calcium									
Dicalcium phosphate, powder	20.9	23	18	na	na	na	na	1.3	4
Salt (NaCl)	0	0	0	39.3	0	0	60.7	0	4
Lite salt (50% NaCl/50% KCl)	0	0	0	17.3	29.4	0	53.3	0	5
Salt substitute (potassium chloride)	0	0	0	0	52.4	0	47.6	0	5

Key: Ca = calcium, P = phosphorus, Na = sodium, K = potassium, Mg = magnesium, Cl = chloride, g = grams, tsp = teaspoons, na = not available.
*All nutrients are expressed on a percent as fed or as is basis.

Appendix 26. Purine content of selected foods.

Foods highest in purines (250-825 mg/100 g as fed)

Anchovies (363 mg/100 g)
Kidney (beef: 200 mg/100 g)
Game meats
Gravies
Herring
Liver (calf/beef: 233 mg/100 g)
Mackerel
Meat extracts (160-400 mg/100 g)
Sardines (295 mg/100 g)
Scallops
Sweat breads (825 mg/100 g)

Foods high in purines (50-150 mg/100 g as fed)

Asparagus
Whole grain breads and cereals
Cauliflower
Eel
Fish
Legumes: beans, lentils, peas
Meat: beef, lamb, pork, veal
Meat soups and broths
Mushrooms
Oatmeal
Poultry: chicken, duck, turkey
Shellfish: crab, lobster, oysters
Spinach
Wheat germ and bran

Foods low in purines (0-50 mg/100 g as fed)

Breads and cereals, except whole grain
Cheese
Eggs
Fats
Fish (roe)
Fruits
Milk
Nuts
Sugars, syrups, sweets
Vegetables, except those listed above
Vegetable and cream soups

Appendix 27. Gluten-containing and gluten-free foods.

Gluten-containing grains	Gluten-free grains and products
Barley (hordeins)	Corn, corn flour, cornmeal, cornstarch
Buckwheat	Gluten-free wheat starch
Oats (avenins)	Beans and bean flour
Rye (secalin, prolamins)	Potatoes and potato flour
Wheat (gliadin)	Rice and rice flour
	Soybeans and soy flour
